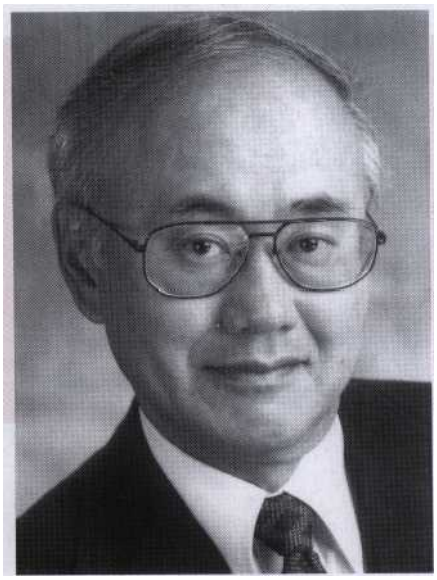
ABOUT THE AUTHORS



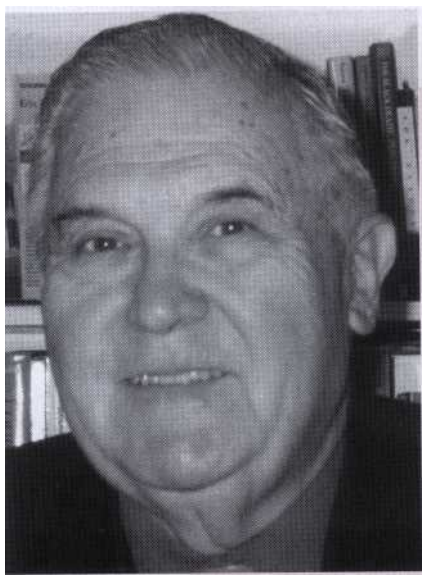
Michael G. Newman BA, DDS, FACD

Dr. Michael G. Newman graduated from the UCLA College of Letters and Sciences with a degree in Psychology. He completed his dental training at the UCLA School of Dentistry in 1972. He is a Diplomate of the American Board of Periodontology and an Adjunct Professor of Periodontics at the UCLA School of Dentistry. Dr. Newman is a Fellow and past President of the American Academy of Periodontology. In 1975, he won the Balint Orban Memorial Prize from the American Academy of Periodontology. He has been in the private practice of periodontics for more than 25 years.

Dr. Newman received a Certificate in Periodontics and Oral Medicine at the Harvard School of Dental Medicine and a Certificate in Oral Microbiology at the Forsyth Dental Center under the mentorship of Dr. Sigmund Socransky. Since that time, he has published more than 250 abstracts, journal articles, and book chapters and has co-edited seven textbooks. Dr. Newman has served as an ad hoc reviewer for NIDCR, a consultant to the Council on Scientific Affairs of the American Dental Association, and a reviewer for numerous scientific and professional journals and governmental research organizations.

Dr. Newman has lectured throughout the world on microbiology, antimicrobials, evidence-based methodology, risk factors, and diagnostic strategies for periodontal disease. Dr. Newman has a strong interest in applied science and transfer of new technology for practical use. He has served as a consultant to many major dental and pharmaceutical companies throughout the world.

Dr. Newman is the Editor-in-Chief of the *Journal of Evidence-Based Dental Practice* and the Associate Editor of the *International Journal of Oral and Maxillofacial Implants.*



Henry H. Takei, DDS, MS, FACD

Dr. Henry H. Takei graduated from the Marquette University School of Dentistry in 1965. He completed his Periodontics Certificate and Master of Science Degree in 1967 at Marquette University and the Veterans Administration Hospital in Wisconsin.

Dr. Takei is a Clinical Professor of Periodontics at the UCLA School of Dentistry, Consultant in Periodontics at the Veterans Administration Hospital in Los Angeles, and maintains a private practice limited to periodontics and implant surgery.

Dr. Takei has published numerous articles on periodontal surgery and has contributed chapters to five textbooks. He has received many teaching awards from both universities and dental organizations nationally and internationally.

Fermin A. Carranza, Dr Odont, FACD

Dr. Fermin A. Carranza graduated from the University of Buenos Aires School of Dentistry in Argentina in 1948 and completed his postdoctoral training in Periodontics at Tufts University School of Dental Medicine in 1952 under the mentorship of Dr. Irving Glickman.

Dr. Carranza is Professor Emeritus of Periodontology at the UCLA School of Dentistry. He was Head of the Department of Periodontics at the University of Buenos Aires from 1966 to 1974 and at UCLA from 1974 until his retirement in 1994.

Dr. Carranza has published more than 218 scientific papers and abstracts on basic and applied aspects of periodontics and eight books, including the last four editions of *Clinical Periodontology*. He has received numerous awards and recognition for his work, including the IADR Science Award in Periodontal Disease and the Gies Award of the American Academy of Periodontology.

Dr. Carranza has lectured throughout the world on clinical periodontology, pathology, and therapy.

Associate Professor, Department of Preventive Sciences, University of Minnesota School of Dentistry, Minneapolis, Minnesota

Kenneth T. Miyasaki, DDS, PhD
Associate Professor, Department of Oral Biology, University of California-Los Angeles School of Dentistry, Los Angeles, California

Richard J. Nagy, DDS
Lecturer, Department of Periodontics, University of California-Los Angeles School of Dentistry; Staff Periodontist, Greater Los Angeles Veterans Administration Healthcare System, Los Angeles, California

Ian Needleman, BDS, MSc, PhD, MRD, RCS (Eng)
Department of Periodontology, Eastman Dental Institute for Oral Health Care Sciences, University of London, London, England

Mirdza E. Neiders, DDS
Professor, Department of Oral Diagnostic Sciences, State University of New York at Buffalo School of Dental Medicine, Buffalo, New York

Linda C. Niessen, DMD, MPH, MPP
Clinical Professor, Department of Public Health Sciences, Baylor College of Dentistry, Texas A&M Health Sciences Center, Dallas, Texas; Vice President of Clinical Education, Dentsply International, York, Pennsylvania

Russell). Nisengard, DDS, PhD
Distinguished Teaching Professor and Associate Dean for Advanced Education and Research, Departments of Periodontics and Endodontics, State University of New York at Buffalo School of Dental Medicine, Buffalo, New York

Karen F. Novak, DDS, MS, PhD
Associate Professor, Department of Periodontics, Center for Oral Health Research, University of Kentucky, Lexington, Kentucky

M. John Novak, BDS, LDS, MS, PhD
Professor, Department of Periodontics; Associate Director, Center for Oral Health Research, University of Kentucky, Lexington, Kentucky

Joan Otomo-Corgel, DDS, MPH
Chair of Research, Department of Periodontics, Greater Los Angeles Veterans Administration Healthcare System, Los Angeles, California; Adjunct Assistant Professor in Residence, Department of Periodontics, University of California-Los Angeles School of Dentistry, Los Angeles, California

Kwang-Bum Park, DDS, MS, PhD
Visiting Assistant Researcher in Periodontics, University of California-Los Angeles, Los Angeles, California; Director, Perio-Line Institute of Clinical Periodontics and Implantology, Taegu, Korea; Lecturer in Oral Anatomy and Histology, Kyung-Pook National University, Taegu, Korea

Anna Pattison, RDH, MS
Associate Professor, Department of Dental Hygiene, School of Dentistry, University of Southern California, Los Angeles, California

Gordon Pattison, DDS
Lecturer in Periodontics, University of California-Los Angeles School of Dentistry, Los Angeles, California

Dorothy A. Perry, RDH, PhD
Vice Chair, Department of Preventive and Restorative Dental Sciences; Chair, Division of Dental Hygiene, University of California-San Francisco School of Dentistry, San Francisco, California

Gregor Petersilka, Dr. med. dent
Assistant Professor, Clinic of Periodontology, Westfalian Wilhelm University, Munster, Germany

Bruce L. Pihistrom, DDS, MS
Erwin Schaffer Periodontal Research Professor, Department of Preventive Sciences and Periodontology, University of Minnesota School of Dentistry, Minneapolis, Minnesota

John W. Rapley, DDS, MS
Director, Graduate Periodontics and Chairman, Department of Periodontics, University of Missouri-Kansas City School of Dentistry, Kansas City, Missouri

Terry D. Rees, DDS, MSD
Chairman and Professor, Department of Periodontics, Baylor College of Dentistry, Texas A&M Health Sciences Center, Dallas, Texas

Eleni Roumanas, DDS
Clinical Associate Professor, Department of Advanced Prosthodontics, Biomaterials, and Hospital Dentistry, University of California-Los Angeles School of Dentistry, Los Angeles, California

Mariano Sanz, MD, DDS, PhD
Professor, Facultad de Odontologia, Universidad Complutense de Madrid, Madrid, Spain

Robert G. Schallhorn, DDS, MS
Clinical Professor, Department of Surgical Dentistry, University of Colorado School of Dentistry, Denver, Colorado; Research Professor, Department of Periodontics, Baltimore College of Dental Surgery Dental School, University of Maryland at Baltimore, Baltimore, Maryland

Max O. Schmid
Former Associate Professor of Periodontics, University of California-Los Angeles School of Dentistry, Los Angeles, California; Private practice, Aarau, Switzerland

Dennis A. Shanelec, DDS
Director, Microsurgery Training Institute, Santa Barbara, California

Gerald Shklar, DDS, MS
Charles A. Brackett Professor of Oral Pathology, Harvard University School of Dental Medicine, Boston, Massachusetts

Thomas N. Sims, DDS
Senior Lecturer, Department of Periodontics, University of California-Los Angeles School of Dentistry, Los Angeles, California

Frank M. Spear, DDS, MSD
Affiliate Professor, Graduate Prosthodontics, University of Washington School of Dentistry, Seattle, Washington; President Elect, American Academy of Esthetic Dentistry

Leonard S. Tibbetts, DDS, MSD
Visiting Assistant Professor, Graduate Periodontics, University of Washington School of Dentistry, Seattle, Washington

Preface

The originator of this book and author of its first four editions, published in 1953, 1958, 1964, and 1972, was Dr. Irving Glickman, Professor and Chairman of the Department of Periodontology at Tufts University School of Dental Medicine, in Boston, Massachusetts.

Dr. Glickman was a prominent researcher, superb teacher, gifted speaker, and brilliant writer whose concepts shaped periodontal thinking for many years. His style of writing and many of his original illustrations, ideas, and philosophy of dental practice can still be found in many areas of this book.

After Dr. Glickman's death in 1972 at 58 years of age, the responsibility for continuing this book was passed to Dr. Fermin A. Carranza, once a student and collaborator of Dr. Glickman. At the time Dr. Carranza was Professor and Chairman of Periodontics at the School of Dentistry, University of California-Los Angeles School of Dentistry (UCLA). The following four editions were published in 1979, 1984, 1990, and 1996 under the guidance of Dr. Carranza, who is now Professor Emeritus at UCLA.

For this present edition, the task of maintaining the book's tradition of almost half a century has changed hands once again. Dr. Michael G. Newman and Dr. Henry H. Takei have joined Dr. Carranza to take major responsibility for this ninth edition.

In the 49 years that have elapsed since the first edition of this book, periodontology has made tremendous progress. The analysis of periodontal tissues and the mechanisms and causes of their involvement in various pathologic processes has gone beyond histology and physiology into cellular and molecular research. Therapeutic goals and techniques, based on the improved biologic foundation and multiple technologic advances, have surpassed the goal of attaining periodontal health and adequate function. Today, reconstruction of lost structures, replacement of teeth by implants, and achievement of esthetic results are integral parts of clinical periodontology.

All this development and growth has resulted in revisions of, additions to, and modifications in the book's content and organization throughout this latest edition. This multifaceted complex task has required the incorporation of numerous experts in the various fields that our discipline has entered.

This edition has also benefited by a number of technologic editorial advances that not only makes the book more attractive but also helps reading and understanding text and figures. The addition of a CD-ROM containing questions that may help teachers and students and an increased number of illustrations for each chapter will greatly enhance the usefulness of the book. The CD-ROM is a wonderful resource of illustrations, case studies, complex surgical procedures, implants, histopathology, and clinical photographs. The CD-ROM's slide show feature can be used to create your personal collection of images or to develop a presentation for your students or colleagues.

This book continues, however, to be primarily a textbook for practitioners of general dentistry and students preparing to become general practitioners. It contains abundant information of interest to periodontists, residents, and graduate students. It is our belief that the periodontal care of the public is primarily the concern of the general dentist, who cannot disregard his or her responsibility to examine, treat, or refer all periodontal problems. The high incidence of periodontal problems and the close relationship between periodontal and restorative dental therapies makes this an incontrovertible point. A well-trained group of periodontists who specialize in the diagnosis and treatment of severe or unusual problems should serve to supplement the general dental care available to our population.

It is our hope that this new edition will continue to be as useful to dentists, periodontists, and students as the previous editions and that it will contribute to the continuous progress of our profession.

Michael G. Newman
Henry H. Takei
Fermin A. Carranza

Acknowledgments

any scientists and clinicians have shared their knowledge and expertise for the previous editions of this book, but their names no longer appear as contributors to the present one. We would like to express our deep gratitude to the following colleagues for their many valuable concepts and ideas that are still part of this book: *Drs. Donald F. Adams, Juan J. Carraro, Edmund Cataldo, Louis A. Cohn, John H. Flocken, Vojislav Lekovic, Vanessa Marinho, Francis McCarthy, Philip McCarthy, F. Reynaldo Saglie, Donald A. Seligman, William K. Solberg, Vladimir W. Spolsky, Angela Ubios,* and *Alfred Weinstock.*

For this edition, we again have been fortunate to obtain the valuable help of a group of **scientists with remarkable expertise and knowledge** in different clinical and research areas of periodontics.

We wish to gratefully acknowledge the valuable help of the following colleagues who contributed previously unpublished information or illustrations: *E. A. Albano, Beatriz Aldape, Carl Allen, D. C. Anderson, E. I. Ball, B. O. Barletta, Burton Becker, William Becker, Sol Bernick, Charles N. Bertolami, Gerald Bowers, A. Brendel, Raul G. Caffesse, Anand P. Chaudhry, Osvaldo Costa, Louis Cuccia, Douglas Damm, B. Ehmke, L. Roy Eversole, Terry Fiori, Stuart L. Fischman, J. Frontan, R. M. Frank, Steven I. Gold, M. Goodson, Robert J. Gorlin, A. Haffajee, T. J. Han, Fredrico Herrero, Stanley C. Holt, Joseph Hsiou, Steven Kwan, Linda Lee, J. Lindhe, Max Listgarten, Frank Lucatorto, Agusti Marfany, Philip Melnick, Robert Merin, David E Mitchell, R. G. Oliver, Silvia Oreamuno, Joan Otomo-Corgel, Charles A. Palioca, Benjamin Patur, R. Earl Robinson, Ronald Rott, Joseph Schwartz, N. J. Selliseth, K. Selvig, Gerald Shklar, T. N. Sims, S. Socransky, John Sottosanti, Carlo Tinti, Sam Toll, Simon Wood, Spencer Wool re,* and *Kim D. Zussman.*

We are grateful to the following UCLA postdoctoral periodontal residents who were very helpful in reviewing the literature and gathering illustrative material: *Drs. Claudia Lemus, Mark Redd, A fshen Salamati,* and *Nelson Yen;* and to *Dr. Rodrigo Lagos* for all his devoted effort on behalf of the book.

We are grateful to the following companies that have shared information, illustrations, or both with us: *T. B. Hartzell, Hu-Friedy, Nobel Biocare, Procter & Gamble,* and 31 *Implants.*

We are indebted to *Imagineering* for their excellent artwork and their untiring efforts to follow our ideas.

Our thanks to W.B. Saunders and particularly to *Penny Rudolph, Ellen Forest, Kimberly Alvis,* and *Jaime Pendill.* Their expertise and detailed attention to every word and every concept contributed greatly to improving the quality of the book.

We also wish to express our gratitude to our mentors who guided our first steps in our profession and helped us develop our ideas in the field.

Dr. Newman: *Sigmund S. Socransky, Bernard Chaiken, Ed Loftus, Paul Goldhaber, Stephen Stone and J. D. Murray, E A. Carranza,* and *Henry Takei* for directing and nurturing me. Special thanks to *E. Barrie Kenney* for his support in providing me the opportunity to manage this large, complex, and time-consuming project.

Dr. Takei: *Donald Van Scotter, Delbert P. Nachazel,* and *John Pfeiffer.* Special thanks also to *Rose Kitayama* for her administrative help.

Dr. Carranza: *Irving Glickman, Fermin Carranza, Sr.,* and *Romulo L. Cabrini. My* gratitude also to my coeditors who will continue the tradition of this book.

Last but not least, we wish to acknowledge the constant support of our parents, colleagues, and friends. Special gratitude goes to our wives and children: *Susan, Andrea,* and *Natalie; June, Scott,* and *Akemi;* and *Rita, Fermin, Patricia,* and *Laura,* who have always been so tolerant, encouraging, and understanding.

Table of Contents

INTRODUCTION **The Historical Background of Periodontology, 1**
Gerald Shklar and Fermin A. Carranza

PART 1: The Normal Periodontium, 15

Ed.: Michael G. Newman

CHAPTER 1 **The Gingiva, 16**
Maria E. Itoiz and Fermin A. Carranza

CHAPTER 2 **The Tooth-Supporting Structures, 36**
Fermin A. Carranza and George W. Bernard

CHAPTER 3 **Aging and the Periodontium, 58**
Ian Needleman

PART 2: Classification and Epidemiology of Periodontal Diseases, 63

Ed.: Michael G. Newman

CHAPTER 4 **Classification of Diseases and Conditions Affecting the Periodontium, 64**
M.john Novak

CHAPTER 5 **Epidemiology of Gingival and Periodontal Diseases, 74**
James D. Beck and Samuel J. Arbes, Jr.

PART 3: Etiology of Periodontal Diseases, 95

Ed.: Susan Kinder Haake

CHAPTER 6 **Periodontal Microbiology, 96**
Susan Kinder Haake, Michael G. Newman, Russell J. Nisengard, and Mariano Sanz

CHAPTER 7 **Immunity and Inflammation: Basic Concepts, 113**
Kenneth T. Miyasaki, Russell J. Nisengard, and Susan Kinder Haake

CHAPTER 8 **Microbial Interactions with the Host in Periodontal Diseases, 132**
Susan Kinder Haake, Russell J. Nisengard, Michael G. Newman, and Kenneth T. Miyasaki

CHAPTER 9 **Molecular Biology of the Host-Microbe Interaction in Periodontal Diseases: Selected Topics, 153**
Susan Kinder Haake and George T.-J. Huang

CHAPTER 10 **Genetic Factors Associated with Periodontal Disease, 168**
Bryan S. Michalowicz and Bruce L. Pihlstrom

CHAPTER 11 **The Role of Dental Calculus and Other Predisposing Factors, 182**
James E. Hinrichs

CHAPTER 12 **Influence of Systemic Disease and Disorders on the Periodontium, 204**
Perry R. Klokkevold, Brian L. Mealey, and Fermin A. Carranza

CHAPTER 13 **Periodontal Medicine, 229**
Brian L. Mealey and Perry R. Klokkevold

CHAPTER 14 **Smoking and Periodontal Disease, 245**
M. John Novak and Karen E Novak

PART 4: Periodontal Pathology, 253

Ed.: Michael G. Newman and Fermin A. Carranza

- **SECTION I: Gingival Disease, 254**

CHAPTER 15 **Defense Mechanisms of the Gingiva, 254**
Jaime Bulkacz and Fermin A. Carranza

CHAPTER 16 **Gingival Inflammation, 263**
Fermin A. Carranza, John W. Rapley, and Susan Kinder Haake

CHAPTER 17 **Clinical Features of Gingivitis, 269**
Fermin A. Carranza and John W. Rapley

CHAPTER 18 **Gingival Enlargement, 279**
Fermin A. Carranza and Eva L. Hogan

CHAPTER 19 **Acute Gingival Infections, 297**
Fermin A. Carranza, and Perry R. Klokkevold

CHAPTER 20 **Gingival Disease in Childhood, 308**
Fermin A. Carranza

CHAPTER 21 **Desquamative Gingivitis, 314**
Al fredo Aguirre, Mirdza F. Neiders, and Russell J. Nisengard

- **SECTION II: Periodontal Disease, 336**

CHAPTER 22 **The Periodontal Pocket, 336**
Fermin A. Carranza and Paulo M.Camargo

CHAPTER 23 **Bone Loss and Patterns of Bone Destruction, 354**
Fermin A. Carranza

CHAPTER 24 **Periodontal Response to External Forces, 371**
Fermin A. Carranza and Paulo M. Camargo

CHAPTER 25 **Masticatory System Disorders, 384**
Michael J. McDevitt

CHAPTER 26 **Chronic Periodontitis, 398**
Richard J. Nagy and M. John Novak

CHAPTER 27 **Necrotizing Ulcerative Periodontitis, Refractory Periodontitis, and Periodontitis as a Manifestation of Systemic Diseases, 403**
Richard J. Nagy, Fermin A. Carranza, and Michael G. Newman

CHAPTER 28 **Aggressive Periodontitis, 409**
Richard J. Nagy and Karen F. Novak

CHAPTER 29 **AIDS and the Periodontium, 415**
Terry D. Rees

PART 5: Treatment of Periodontal Disease, 431

Ed.: Michael G. Newman

m SECTION 1: Diagnosis, Prognosis, and Treatment Plan, 432

Eds.: Michael G. Newman and Henry H. Takei

CHAPTER 30 **Clinical Diagnosis, 432**
Fermin A. Carranza

CHAPTER 31 **Radiographic Aids in the Diagnosis of Periodontal Disease, 454**
Fermin A. Carranza and Henry H. Takei

CHAPTER 32 **Risk Assessment, 469**
Karen F. Novak and M. John Novak

CHAPTER 33 **Determination of Prognosis, 475**
Stephen F. Goodman and Karen F. Novak

CHAPTER 34 **Advanced Diagnostic Techniques, 487**
Mariano Sanz and Michael G. Newman

CHAPTER 35 **The Treatment Plan, 503**
Fermin A. Carranza and Henry H. Takei

CHAPTER 36 **Rationale for Periodontal Treatment, 507**
Fermin A. Carranza

CHAPTER 37 **Periodontal Therapy in the Female Patient (Puberty, Menses, Pregnancy, and Menopause), 513**
Joan Otomo-Corgel

CHAPTER 38 **Periodontal Treatment of Medically Compromised Patients, 527**
Brian L. Mealey, Perry R. Klokkevold, and Joan Otomo-Corgel

CHAPTER 39 **Periodontal Treatment for Older Adults, 551**
Denise J. Fedele and Linda C. Niessen

CHAPTER 40 **Treatment of Refractory Periodontitis, Aggressive Periodontitis, Necrotizing Ulcerative Periodontitis, and Periodontitis Associated with Systemic Diseases, 558**
Richard J. Nagy and Michael G. Newman

m SECTION II: Periodontal Instrumentation, 567

Ed.: Henry H. Takei

CHAPTER 41 **The Periodontal Instrumentarium, 567**
Anna M. Pattison, Gordon L. Pattison, and Henry H. Takei

CHAPTER 42 **Manual Instrumentation, 594**
Gordon L. Pattison and Anna M. Pattison

CHAPTER 43 **Sonic and Ultrasonic Instrumentation, 607**
Gregor J. Petersilka and Thomas F. Flemmig

CHAPTER 44 **Supragingival and Subgingival Irrigation, 615**
Thomas E Flemmig

- **SECTION 111: Treatment of Periodontal Emergencies, 622**

Ed.: Henry H. Takei

CHAPTER 45 **Treatment of Acute Gingival Disease, 622**
Perry R. Klokkevold

CHAPTER 46 **Treatment of the Periodontal Abscess,** 629
Henry H. Takei

NSECTION IV: Phase, I Periodontal Therapy, 631

Ed.: Henry H. Takei

CHAPTER 47 **Scaling and Root Planing,** 631
Gordon L. Pattison and Anna M. Pattison

CHAPTER 48 **Phase I Periodontal Therapy,** 646
Dorothy A. Perry and Max O. Schmid

CHAPTER 49 **Plaque Control for the Periodontal Patient,** 651
Dorothy A. Perry

CHAPTER 50 **Chemotherapeutic Agents in the Treatment of Periodontal Diseases,** 675
David L. Jolkovsky and Sebastian G. Ciancio

CHAPTER 51 **Periodontal Management of HIV-Infected Patients,** 688
Terry D. Rees

CHAPTER 52 **Occlusal Evaluation and Therapy in the Management of Periodontal Disease,** 697
Carol A. Bibb

CHAPTER 53 **The Role of Orthodontics as an Adjunct to Periodontal Therapy,** 704
Vincent G. Kokich

E,SECTION,V:: Periodontal Surgical Phase, 719

Ed.: Henry H. Takei

CHAPTER 54 **The Surgical Phase of Therapy,** 719
Henry H. Takei and Fermin A. Carranza

CHAPTER 55 **General Principles of Periodontal Surgery,** 725
Perry R. Klokkevold, Fermin A. Carranza, and Henry H. Takei

CHAPTER 56 **Surgical Anatomy of the Periodontium and Related Structures,** 737
Fermin A. Carranza

CHAPTER 57 **Gingival Curettage,** 744
Fermin A. Carranza and Henry H. Takei

CHAPTER 58 **The Gingivectomy Technique,** 749
Fermin A. Carranza

CHAPTER 59 **Treatment of Gingival Enlargement,** 754
Paulo M. Camargo and Fermin A. Carranza

CHAPTER 60 **The Periodontal Flap,** 762
Henry H. Takei and Fermin A. Carranza

CHAPTER 61 **The Flap Technique for Pocket Therapy,** 774
Fermin A. Carranza and Henry H. Takei

CHAPTER 62 **Resective Osseous Surgery,** 786

Focal Infection
After World War II

Gingival and periodontal diseases, in their various forms, have afflicted humans since the dawn of history, and studies in paleopathology have indicated that destructive periodontal disease as evidenced by bone loss affected early humans in such diverse cultures as ancient Egypt and early pre-Columbian America." The earliest historical records dealing with medical topics reveal an awareness of periodontal disease and the need for treatment. Almost all the early writings that have been preserved have sections or chapters dealing with oral diseases, and periodontal problems comprise a significant amount of space in these writings. The relationship between calculus and periodontal disease often was considered, and underlying systemic disease often was postulated as a cause of periodontal disorders. However, methodic, carefully reasoned, therapeutic discussions did not exist until the Arabic surgical treatises of the Middle Ages; and modern treatment, with illustrated texts and sophisticated instrumentation, did not develop until the time of Pierre Fauchard in the 18th century.

EARLY CIVILIZATIONS

Oral hygiene was practiced by the Sumerians of 3000 BCE, and elaborately decorated gold toothpicks found in the excavations at Ur in Mesopotamia suggest an interest in cleanliness of the mouth. The Babylonians and Assyrians, like the earlier Sumerians, apparently suffered from periodontal problems, and a clay tablet of the period tells of treatment by gingival massage combined with various herbal medications.[36]

Periodontal disease was the most common of all diseases evidenced in the embalmed bodies of the ancient Egyptians. Thus it is not surprising that the problem received attention in medical and surgical writings of the time. The Ebers papyrus contains many references to gingival disease and offers a number of prescriptions for strengthening the teeth and gums. These remedies were made from various plants and minerals and were applied to the gums in the form of a paste with honey, vegetable gum, or residue of beer as a vehicle.20

Among the various medical papyri that have been preserved, the most sophisticated, in terms of modern medical practice, is the Edwin Smith surgical papyrus.' This remnant of a larger work presents 48 cases and discusses diagnosis, prognosis, and appropriate therapy. Mandibular fractures and dislocations are considered, but periodontal problems are not mentioned as diseases requiring surgical therapy.

The medical works of ancient India devote a significant amount of space to oral and periodontal problems. The Susruta Samhita contains numerous descriptions of

severe periodontal disease with loose teeth and purulent discharge from the gingiva.[72] In a later treatise, the *Charaka Samhita,* toothbrushing and oral hygiene are stressed:

> *The stick for brushing the teeth should be either astringent or pungent or bitter. One of its ends should be chewed in the form o f a brush. It should be used twice a day, taking care that the gums not be injured.*[15]

Ancient Chinese medical works also discussed periodontal disease. In the oldest book, written by Huang-Ti about 2500 BCE, a chapter is devoted to dental and gingival diseases. Oral diseases were divided into three types: *Fong Ya,* or inflammatory conditions; *Ya Kon,* or diseases of the soft investing tissues of the teeth; and *Chong Ya,* or dental caries.[17]

Gingival inflammations, periodontal abscesses, and gingival ulcerations are described in accurate detail. One gingival condition is described as follows:

> *The gingivae are pale or violet red, hard and lumpy, sometimes bleeding. the toothache is continuous.*

Herbal remedies *(Zn-hine-tong)* are mentioned for the treatment of these conditions. The Chinese were among the earliest people to use the "chewstick" as a toothpick and toothbrush to clean the teeth and massage the gingival tissues. Chewsticks were made of plant limbs or roots, with one end beaten into a soft fibrous condition and used for scrubbing and brushing the teeth. Chewsticks are still used by Asiatic and African peoples in underdeveloped regions.[39,47]

The importance of oral hygiene was recognized by the early Hebrews. Many pathologic conditions of the teeth and their surrounding structures are described in the Talmudic writings. Artifacts of the Phoenician civilization include a specimen of wire splinting, apparently constructed to stabilize teeth loosened by periodontal disease.[36]

GREECE

With the development of Greek culture and science came one of the golden ages of Western civilization. The Greeks attained preeminence in almost every field or discipline they attempted. Architecture, painting, sculpture, pottery, poetry, drama, philosophy, and history reached a degree of perfection rarely surpassed in succeeding ages. This was the age of Homer, Plato, and Aristotle; of Euripides, Aeschylus, and Sophocles; of Herodotus and Xenophon; of Phidias and Praxiteles. Modern science also had its birth in Greece, and medicine developed in terms of diagnostic approach and technical skill. Greek medicine continued into the succeeding Roman civilization and the early Byzantine Age.

Among the ancient Greeks, Hippocrates of Cos (460-377 BCE) was the father of modern medicine, the first to institute a systematic examination of the patient's pulse, temperature, respiration, excreta, sputum, and pulse.[13,39] He discussed the function and eruption of the teeth and the etiology of periodontal disease. He believed that inflammation of the gums could be caused by accumulations of pituita or calculus, with gingival hemorrhage occurring in cases of persistent splenic maladies. One splenic malady was described as follows:

> *The belly becomes swollen, the spleen enlarged and hard, the patient suffers from acute pain. The gums are detached from the teeth and smell bad.*[39]

ROME

Long before 735 BCE, the Etruscans were adept in the art of constructing artificial dentures, but no evidence exists that they were aware of periodontal disease or its treatment.

Among the Romans, Aulus Cornelius Celsus (25 BCE-50 CE) referred to diseases that affect the soft parts of the mouth and their treatment as follows:

> *If the gums separate from the teeth, it is beneficial to chew unripe pears and apples and keep their juices in the mouth.*

He described looseness of the teeth caused by the weakness of their roots or flaccidity of the gums and noted that it is necessary in these cases to touch the gums lightly with a red-hot iron and then smear them with honey.[14] The Romans were very interested in oral hygiene. Celsus believed that stains on the teeth should be removed and the teeth then rubbed with a dentifrice. The use of the toothbrush is mentioned in the writings of many of the Roman poets. Gingival massage was an integral part of oral hygiene.

Paul of Aegina (625-690 CE) differentiated between epulis, a fleshy excrescence of gums in the area of a tooth, and parulis, which he described as an abscess of the gums. He wrote that tartar incrustations must be removed with either scrapers or a small file and that the teeth should be carefully cleaned after the last meal of the day.[63]

THE MIDDLE AGES

The decline and eventual fall of the Roman Empire that plunged Europe into an age of darkness was accompanied by the rise of Islam and the golden age of Arabic science and medicine. The astonishing attainments of Islamic medicine provided for the rise of European medicine in the late Middle Ages and Renaissance. In the early medical schools of Salerno and Montpellier, the available texts were primarily the renowned Arabic treatises in adequate (but far from accurate) Latin translations.

Much of medieval and Renaissance stomatology and dentistry was derived directly from Arabic writings, particularly the treatises of Ibn Sina (Avicenna) and Abu'1-Qasim (Albucasis). The Arabic treatises derived much of their information from Greek medical treatises, but many refinements and novel approaches were added, particularly in surgical specialties." Many of the Greek medical classics translated into Arabic in Baghdad during the Abbassid Caliphate were eventually retranslated into Latin after the destruction and virtual disappearance of scholar-

ship in Europe during the Dark Ages. Baghdad, along with C6rdoba in Spain, enjoyed both intellectual and medical eminence; these two cities represented the greatness of the Eastern and Western Caliphates, respectively.

Hunayn ibn-Ishaq (809-73) and his associates translated into Arabic the original Greek texts of Galen, Oribasius, Paul of Aegina, Dioscorides, and the Hippocratic corpus, as well as the philosophy of Plato and Aristotle and the mathematics of Archimedes. Abu Bakr Muhammed ibn Zakariya al Razi (Rhazes) (841-926) wrote an encyclopedic work on medicine and surgery in 25 books. He was also physician-in-chief at the great Baghdad hospital and taught medicine in terms of clinical cases. Ali ibn Abbas al Majousi (Haly Abbas) (930-94) described many dermatologic conditions and recommended such surgical advances as the suturing of blood vessels before the removal of tumors. He also wrote extensively on dental subjects.

Ibn Sina (Avicenna) (980-1037), born in Persia, was possibly the greatest of the Arabic physicians. His *Canon,* a comprehensive treatise on medicine, is probably the most famous medical text of all time and was in continuous use for almost 600 years. Avicenna used an extensive materia medica for oral and periodontal diseases and rarely resorted to surgery. Headings in the *Canon* on gingival disease include "Bleeding Gums," "Fissures of the Gums," "Ulcers of the Gums," "Separation of the Gums," "Recession of the Gums," "Looseness of the Gums," and "Epulis." [5]

Abu'l-Qasim (936-1013) was the preeminent physician and surgeon of the Western Caliphate at C6rdoba. His contributions to dentistry and periodontology were among his outstanding achievements. He had a clear understanding of the major etiologic role of calculus deposits and described in detail the technique of scaling the teeth, using a sophisticated set of instruments that he developed. He also wrote in detail on the extraction of teeth, the splinting of loose teeth with gold wire, and the filing of gross occlusal abnormalities. The fame of his treatise spread through the Arab world and beyond. It was translated into Latin by Gerard of Cremona in the 12th century and greatly influenced the surgeons Guglielmo Saliceti (1201-77) and Guy de Chauliac (c. 1300-68)[59] in the 13th and 14t' centuries and Fabricius of Aquapendente (1537-1619) in the 16 t" century. Abu'l-Qasim described the way to remove calculus from teeth:'

> *Occasionally there is deposited in the inner and outer surfaces of the teeth or between the gums, large and rough ugly concretion: the teeth take on a black, yellow or green color, following which the gums are altered and the teeth become unsightly.*

To treat this disease, seat the patient in front of you, placing the head in your lap. Scale [scrape] the teeth and molars that present the concretions or the gritty deposits until nothing remains. Scrape also throughout where the teeth are black, yellow, green or otherwise colored, until they [the calculus deposits] are gone. It is possible that one scaling will suffice. If not, begin a second, third or fourth time, until your purpose is completely attained.

You should know that the scaling of teeth is done with instruments of various shapes according to the use

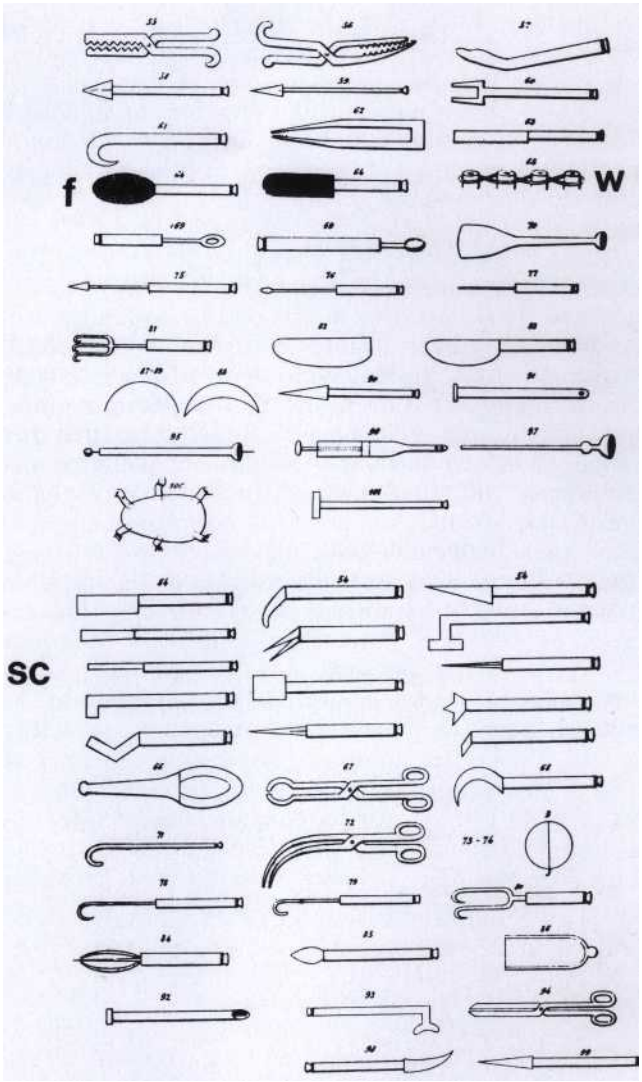

Fig. 1 Illustration of Abu'l-Qasim's periodontal instruments, showing scalers (sc), files (f), and the wiring of loose teeth (w).

that is required for them. The scalers that one uses for scaling the inner surfaces of the teeth are different than those employed for the scaling of the exterior surfaces, and those that are used to scale the interdental surfaces. Here is an assortment of scalers all of which you have at your disposition (Fig. 1).

In Japan in 984, a book by Yasuyori Tanba, entitled *I-Shin-Po,* which means "Essential Method of Medicine," was published.[26] *I-Shin-Po* consisted of 30 volumes, and in volume 5 the treatment of diseases of the mouth, teeth, throat, and nose was described. The author wrote that the teeth receive their nutrition from the bone marrow and that tooth mobility is caused by malnutrition.

RENAISSANCE

During the Renaissance, with the rebirth of classical scholarship and the development of scientific thought and medical knowledge in addition to the flowering of art, music, and literature, significant contributions were made to anatomy and surgery.

Paracelsus (1493-1541) continues to be a controversial figure of the Renaissance and Humanism. He wrote extensively on a large variety of subjects, and his collected works-14 large volumes in the fine modern edition of Sudhoff-are continuously being analyzed for an understanding of his ideas and often complex concepts, ranging from chemistry and the physical world to philosophy and the power of imagination .[61]

Paracelsus developed an interesting and unusual theory of disease among his special pathologic theories: the doctrine of calculus. He understood that pathologic calcification occurred in a variety of organs, and he considered these disease conditions to result from a metabolic disturbance whereby the body takes nourishment from food and discards the refuse as "tartarus," a material that cannot be broken down and the ultimate matter, or *materia ultima.* This tartar or ultimate material, consisting of gravel and gluelike components, was exogenous and came from barley and peas, milk, meat and fish, and drinks such as wine, beer, and fruit juice. This material in food could be eliminated by cooking and thus excreted in the feces. The tartar content of food was thought to vary in different geographic locations. Saliva served digestion in the mouth, as did other agents in the stomach. Tartar also could be precipitated by the action of salt, which dried up or coagulated mucoid matter in food. The amount of tartar formed depended on the region of the body. Paracelsus recognized the extensive formation of tartar on the teeth and related this to toothache. Toothache was thus comparable to the pain produced by calculus in other organs such as the kidneys.[61]

> *A specific digestive process already takes place in the mouth, and this process is potent enough to sustain life. Its waste products are deposited as tartar on the teeth with resulting decay of the gums, wearing down of teeth, pain due to acerbity with which tartarus is endowed. Toothache is thus comparable to the pain caused by calculus elsewhere.*[61]

Andreas Vesalius (1514-64), born in Brussels, taught at the University of Padua in the Venetian Republic, where he performed human dissections and wrote a magnificent book on anatomy with excellent illustrations throughout, which were drawn by Kalkar, a student of Titian.[75]

Bartholomaeus Eustachius (1520-74) of Rome was another outstanding anatomist and wrote a small book on dentistry, *Libellus de Dentibus ("A* Little Treatise on the Teeth"), in 30 chapters .[22]

In many ways, his anatomic studies were more detailed and comprehensive than those of his more famous contemporary, Vesalius, but his major studies remained unknown until their publication in 1722. This was the first original book on the teeth and offered many new descriptions and concepts based on research and clinical studies. In addition to the first clear description of the dental pulp and the root canal, Eustachius understood that the crowns of the teeth were composed of enamel overlying dentin, the first description of the two separate tissues of the tooth. Occlusion was described in detail in humans as well as animals. The permanent teeth were found to develop from dental follicles and not from the roots of deciduous teeth, as postulated by Vesalius. Eustachius' description of the periodontal tissues was a major advance:

> *At any rate, as I have already pointed out, the roots of all the teeth are so well attached to their respective sockets that the teeth can hardly be budged. Ligaments attached to each tooth provide added stability. Moreover, there are extremely strong fibers attached to the roots; these provide a firm connection to the socket. The manifold structure of the mouth created by the gingivae surrounds the teeth as soon as they emerge from their sockets. The structure of the gingivae themselves contributes in no small way to the strength of the teeth.*

Eustachius also described some diseases of the mouth in the last chapter of his book and offered treatment modalities as well as a rationale for treatment. His treatment of periodontitis was remarkably modern in that he advised both scaling of calculus and curettage of granulation tissue so that an actual reattachment of the gingival and periodontal tissues could take place.

> *The use of astringents to shrink the gum is of little value. But if the gums diminish and recede, and the teeth become covered with a hard, cuticle-like substance, reuniting the tooth and gum is as likely as joining the middle and index fingers unless the physician first scrapes the teeth and freshen the gums with a scalpel, and uses medicines that will encourage attachments.*

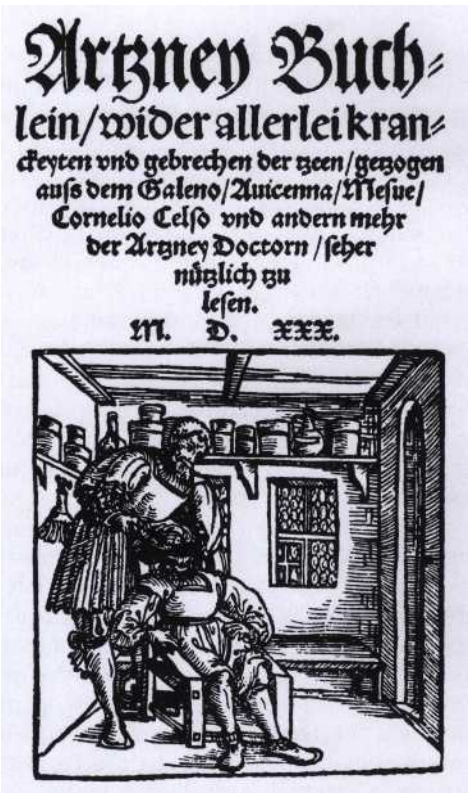

Fig. 2 Frontispiece *of Artzney Buchlein (1530).*

Ambroise Pare (1509-90), head surgeon at the Hotel Dieu in Paris, was the outstanding surgeon of the Renaissance, and his contributions to dental surgery were substantial. He developed many oral surgical procedures in detail, including gingivectomy for hyperplastic gingival tissues.[62] He also understood the etiologic significance of calculus and used a set of sealers to remove the hard deposits on the teeth. Pare wrote in French rather than in Latin, and therefore his works could be widely read and understood.

The first book written in a common language (German) and specifically devoted to dental practice, entitled *Artzney Buchlein* or *Zene Artzney*[4] (Fig. 2), was published in Leipzig in 1530; 15 separate editions were published between that time and 1576. The author of this book remains unknown despite considerable historic research attempting to discover his identity." The book was essentially a compendium of previous writings on oral and dental diseases and their management. Three chapters are devoted specifically to periodontal problems. In Chapter 7, "Concerning Yellow and Black Teeth," the author describes tartar as "a white, yellow, and black slime that settles on the lower part of the teeth and over the gums."

The author also suggests scraping black **teeth and the use of toothpastes or powders to** rub against the teeth. Recipes for several pastes and powders are offered.

Chapter 9, "Of Loose Teeth," describes periodontitis:

> *[Periodontitis] happens either through negligence or weakness or disease o f the gums, or through the separation of those substances that hold the teeth in their places, which happens when humors from the head drop down upon the gums or roots o f the teeth and loosen them by their noxious action.*

Thus a crude concept is presented of systemic and local factors in the etiology of periodontal disease. The presence of local infective agents, or "worms," also is mentioned. A variety of ointments, often astringent in nature, are suggested, and the binding of loose teeth to sound ones with silk or gold thread is recommended. Cauterizing the gingiva with a hot iron is mentioned, but "this burning is dangerous and needs an expensive skilled master." In Chapter 11, "Ulceration, Bad Smell, and Decay of the Gums," the management of necrotizing gingivitis with medicines containing vinegar and alum is discussed.

The Italian physician, mathematician, and philosopher Girolamo Cardano (1501-76) appears to have been the first to differentiate types of periodontal disease. In a publication dated 1562, he mentions one type of disease that occurs with advancing age and leads to progressive loosening and loss of teeth, as well as a second, very aggressive type that occurs in younger patients.[38] It was not until late in the 20[1]" century that this classification was rediscovered and became widely accepted.

Anton van Leeuwenhoek (1632-1723) of Delft, Holland, contributed more to the development of modern biologic science than any classically trained scholar of his age. A layman with an inquisitive mind and a hobby of grinding lenses, he developed the microscope and used it to discover microorganisms, cellular structure,

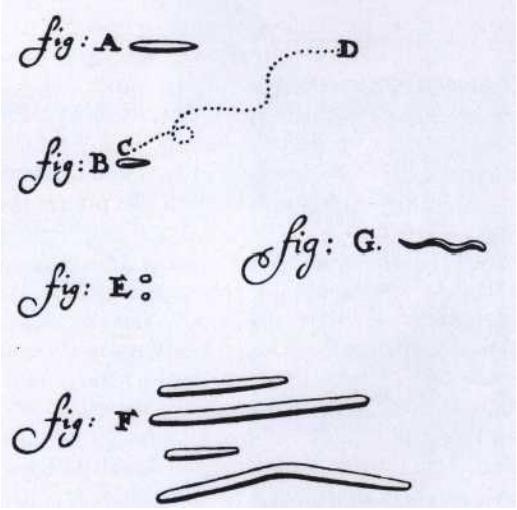

Fig. 3 Leeuwenhoek's drawing of oral spirochetes, bacilli, and other microorganisms.

blood cells, sperm, and various other **microscopic structures, including the tubular structure of dentin."** He was a strong opponent of the spontaneous generation concept, which was finally put to rest by Pasteur two centuries later. Leeuwenhoek described his findings in letters written originally in Dutch to the Royal Society of London, which translated them into English and published them in its *Philosophical Transactions.*

Using material from his gingival tissues, Leeuwenhoek first described oral bacterial flora, and his drawings offered a reasonably good presentation of oral spirochetes and bacilli (Fig. 3).

> *I didn't clean my teeth (on purpose) for three days and then took the material that had lodged in small amounts on the gums above my front teeth. . . . I found a few living animalcules.*

He also described a great amount of bacteria in a man who had never cleaned his mouth."

18*T"* CENTURY

Modern dentistry essentially developed in 18th-century Europe, particularly France and England. Pierre Fauchard, born in Brittany in 1678, is rightly regarded as the father of the profession as we know it. Although he was self-educated in dentistry, he was able to develop a systematic approach to dental practice based on contemporary knowledge. Fauchard significantly improved the instruments and technical skills required for dental treatment, and his book, *The Surgeon Dentist,* published in 1728 (Fig. 4), gave respectability to the profession and developed a wide appreciation for the technical and surgical skills of the dental practitioner.[23] Fauchard became the leading dentist in Paris and died in 1761 after a long life of service and achievement.

Fauchard's book not only transformed dental practice but also served to educate the succeeding generation

Fig. 4 Frontispiece of Fauchard's *The Surgeon Dentist (1746).*

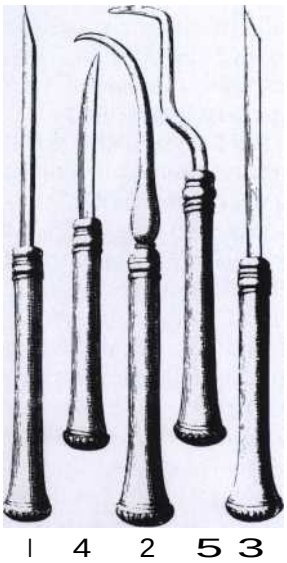

Fig. 5 The five types of instruments used by Fauchard for detaching tartar from the teeth: 1, chisel; 2, parrot beak; 3, graver; 4, convex blade; and 5, Z-shaped hook.

of dentists, some of whom emigrated to America and practiced in the early years of the Republic. Some of George Washington's dentures were made with springs similar to those in the design illustrated by Fauchard. All aspects of dental practice are presented in his book (i.e., restorative dentistry, prosthodontics, oral surgery, periodontics, and orthodontics). Preventive dentistry is described in Chapter 4 ("The Regimen and Care Required for the Preservation of the Teeth") and in Chapter 5 ("How to Keep the Teeth White and Strengthen the Gums"). Fauchard wrote that confections and sweets destroy the teeth by sticking to their surfaces and producing an acid. He described in detail his periodontal instruments (Fig. 5) and the scaling technique to "detach hard matter or tartar from the teeth."

John Hunter (1728-93), the most distinguished anatomist, surgeon, and pathologist of 18th-century England, wrote an excellent treatise on dentistry entitled *The Natural History of the Human Teeth* .42 He offered remarkably clear illustrations of the anatomy of the teeth and their supporting structures. He also described the features of periodontal diseases and enunciated the concept of active and passive eruption of teeth.

A contemporary of Hunter, Thomas Berdmore (1740-85), was considered the outstanding dentist in England and was known as "Dentist to His Majesty" (i.e., King George III). He published the *Treatise in the Disorders and Deformities of the Teeth and Gums* in 1770, with several chapters devoted to periodontal problems.' In Chapter 7, "Of Tartar of the Teeth, and the Recess of the Gums, and Toothache Occasioned by Tartarous Concretions Long Neglected," Berdmore offered detailed descriptions of instrumentation for tartar removal but stressed prevention. He also used surgery when necessary to remove hyperplastic gingival tissue once the tartar was removed:

> *For without this [surgery], the gums will not closely embrace a tooth which has been made smaller at the collar by the removal of its tartar.*

The first qualified American dentists were trained in England or France.80 Robert Woffendale (1742-1828) was trained in London by Berdmore. Woffendale wrote one of the early dental books in America. In an advertisement in the *New York Weekly Journal* of 1766, he "begs Leave to inform the Public that he performs all Operations upon the Teeth, Gums, Sockets and Palate." Similar advertisements were placed by many contemporary dentists. John Baker (c. 1732-96) was one of George Washington's dentists and had a very successful career. He imparted his dental knowledge to Paul Revere, Isaac Greenwood, and Josiah Flagg. In an advertisement in the *New York Weekly Journal* of 1768, Baker tells the public that he

> *. . . cures the scurvy in the gums, be it ever so bad; first cleans and scales the teeth from that corrosive tartarous gritty substance, which hinders the gums from growing, infects the breath and is one o f the principle causes of scurvy, and, i f not timely prevented, eats away the gums so that many people's teeth fall out fresh. . . . His dentifrice with proper directions for preserving the teeth and gums is to be had at his lodgings.*

19TH CENTURY

Leonard Koecker (1785-1850) was a German-born dentist who practiced in Baltimore. In a paper in 1821 in the *Philadelphia Journal of Medicine and Physical Sciences,* he described inflammatory changes in the gingiva and the presence of calculus on teeth, leading to their looseness and exfoliation.49 He mentioned the careful removal of tartar and the need for oral hygiene by the patient, which he recommended to be performed in the morning and af-

ter every meal, using an astringent powder and a toothbrush, placing "the bristles . . . into the spaces of the teeth." He also discouraged splinting because it loosened firm teeth, and he recommended that treatment of caries be postponed until after the gum treatment is completed and that placement of artificial teeth be avoided. Koecker was an early advocate of the odontogenic focal infection theory and recommended the extraction of all severely involved teeth and roots, including all unopposed molars, to prevent systemic infections .[49]

Levi Spear Parmly (1790-1859) was a New Orleans dentist who is considered the father of oral hygiene and the inventor of dental floss.[24] In a book published in 1819, he states that dental caries can be controlled by brushing and by using

> . . . *a waxen silken thread . . . which is to be passed through the interstices o f the teeth, between their necks and the arches of the gum, to dislodge that irritating matter which no brush can remove and which is the real source o f distress.*

The term *pyorrhea alveolaris* was used for the first time by Alphonse Toirac (1791-1863) in 1823, although some scholars dispute this." It was introduced in the U.S. by F. H. Rehwinkel, a German physician who emigrated to the U.S. and attended the Baltimore College of Dental Surgery."'

In the mid-19[1]" century, John W. Riggs (1811-85) (Fig. 6) was the leading authority on periodontal disease and its treatment in the U.S., to the point that periodontitis, or alveolar pyorrhea, was known as "Riggs' disease." He was born in Seymour, Conn., on October 25, 1811, and graduated from the Baltimore College of Dental Surgery in 1854. He practiced in Hartford, Conn., where he died on November 11, 1885. Riggs seems to have been the first individual to limit his practice to periodontics and therefore can be considered the first specialist in this field. Riggs was an associate of Horace Wells in Hartford, and he performed the first surgical operation under anesthesia, extracting a tooth of Dr. Wells' under nitrous oxide in 1844.

Riggs described his treatment of periodontal disease to an audience at the Connecticut Valley Dental Society at Northampton, Mass., in June 1867.[52] His publications, however, are very few. In a paper published in 1876 in the *Pennsylvania Journal ofDental Science,*[67] Riggs strongly advocated cleanliness of the mouth because he believed that "the teeth themselves, with their accumulated accretions and roughened surfaces . . . are the exciting cause of the disease." He strongly opposed surgery, which at the time consisted of resection of the gums.

Riggs and his disciples had great influence in the dental profession. They were the proponents of the so-called conservative approach to periodontal therapy, developing the concept of oral prophylaxis and prevention. Among his followers were L. Taylor, D. D. Smith, R. B. Adair, and W. J. Younger."[8] Many papers by followers and contemporaries of Riggs described clinical features and treatment of periodontal disease, the latter based mostly on hygienic measures.[52,66] Younger (1838-1920) considered periodontal disease a local infection and in 1893, he

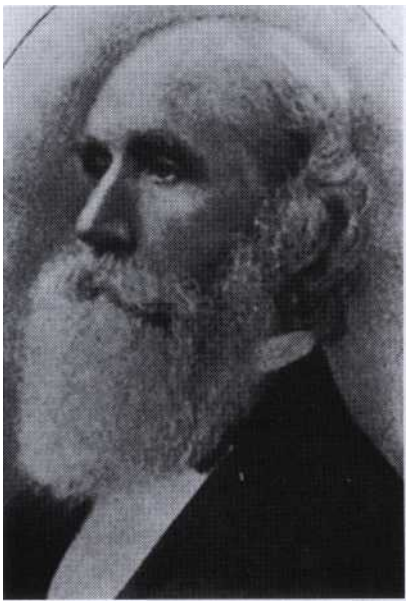

Fig. 6 John W. Riggs (1811 -85). (From Hoffman-Axthelm W: History of Dentistry. Chicago, Quintessence, 1981.)

was the first to discuss the possibility of "reattachment." In 1902, Younger reported a case in which he grafted gingival tissue "from behind the third molar" to an extensive area of recession in an upper cuspid of the same patient. He first treated the root of the cuspid with lactic acid and then fixed the gum graft with "fine cambric needles," and he claims the operation to have been a success."

Several major developments in medical science occurred in the second half of the 19[1]" century, starting the era that can be called *modern medicine,* which of course includes dentistry.[12]

The first was the *discovery of anesthesia* by Horace Wells (1813-48) of Hartford, Conn. in 1845 and by William Morton (1819-1968) of Boston in 1846, who discovered the general anesthetic effects of nitrous oxide and ether, respectively. Four decades later, Sigmund Freud (1856-1939) experimented on the psychic effects of cocaine and noted its numbing effects on the tongue. He provided his friend Carl Koller (1857-1944), a Vienna ophthalmologist, with this drug, and he produced anesthesia of the eye with drops of cocaine. Further developments led to the discovery in 1905 of procaine (Novocaine) by the Munich chemists Alfred Einhorn and Richard Willstadter. Later, with the addition of adrenaline, discovered separately in the U.S. by Jokichi Takamine and Thomas Bell Aldrich, local anesthesia was born.[41]

The second scientific breakthrough was made by the French chemist Louis Pasteur (1822-95),[18,72] who finally proved that spontaneous generation of organisms does not exist and who established through his studies of the diseases of silk worms that one organism (a protozoa) can cause disease in another (the silk worm), thus establishing the *germ theory of disease.* Subsequently, the German physician Robert Koch (1843-1910), in a series of

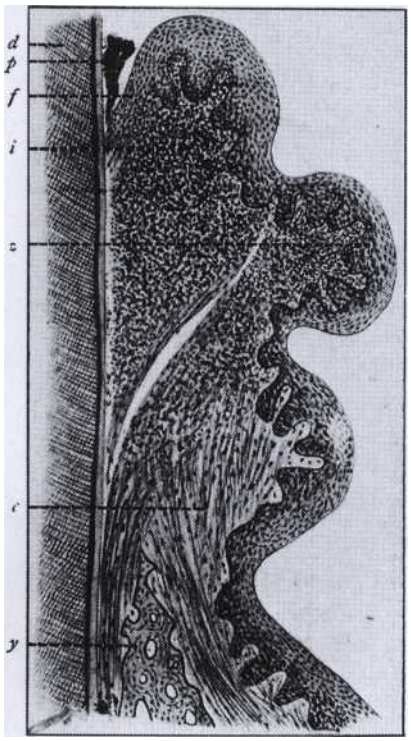

Fig. 7 Microscopic features of periodontal disease as presented by Znamensky.

brilliant investigations, discovered the microorganism that causes the cattle disease anthrax and the bacterial etiology of tuberculosis.'°

The concepts of Pasteur were initially transferred to the clinical and surgical practice by Joseph Lister (1827-1912) of England, and thus the era of antisepsis (and later, asepsis) in surgery was born. Pasteur, Koch, and their collaborators and followers (Elie Metchnikoff, Emile Roux, Paul Ehrlich, Emit von Behring, Shibasaburo Kitasato, and many others) discovered the bacterial etiology of numerous diseases (e.g., pneumonia, cholera, puerperal fever, diphtheria, meningitis, plague, dysentery, syphilis) and gave birth to two sciences that became basic to periodontics: bacteriology and immunology.

A third scientific finding that changed the practice of dentistry in general and periodontics in particular was the *discovery of radiographs* by the German physicist Wilhelm Rontgen (1845-1923).[26] Rontgen's discovery was made in 1895 at the University of Wurzburg and was purely a basic science finding, but it was immediately taken up by physicians and dentists and proved to be a crucial development in periodontics and many other areas of medicine and dentistry.

Also in the late 19th century, studies by Rudolph Virchow (1821-1902), Julius Cohnhein (1839-84), Elie Metchnikoff (1845-1916), and others had started to shed light on the microscopic changes occurring in inflammation.' This resulted in an understanding of the pathogenesis of periodontal disease based on histopathologic studies. N. N. Znamensky in Moscow understood the complex interaction of local and systemic factors in the etiology of periodontal disease (Fig. 7), and his observations and concepts were summarized in 1902 in a classic paper" in which he describes the presence in inflamed gingivae of a cellular infiltrate that extends deeper as the disease progresses, causing bone resorption associated to multinucleated cells (osteoclasts) and Howship's lacunae. Znamensky treated pyorrhea with removal of calculus and deep curettage of the pockets, using cocaine anesthesia.

The first individual to identify bacteria as the cause of periodontal disease appears to have been the German dentist Adolph Witzel (1847-1906),[3'84] who taught at the University of Jena, but the first true oral microbiologist was Willoughby D. Miller (1853-1907). Miller was born in Alexandria, Ohio and received training in basic sciences at the University of Michigan. He emigrated to Germany but later returned to the U.S. to receive his dental training at the Pennsylvania Dental College. Back in Berlin, he worked in Robert Koch's microbiology laboratory and embarked on a research career that introduced modern bacteriology principles to dentistry. His greatest accomplishments were in caries research, where he developed the chemicoparasitic theory of caries. In his classic book *The Microorganisms of the Human Mouth,* published in 1890, he described the features of periodontal disease and considered the role of predisposing factors, irritational factors, and bacteria in the etiology of pyorrhea alveolaris. He believed that the disease was not caused by a specific bacterium but by a complex array of various bacteria normally present in the oral cavity. This constitutes what was later known as the *nonspecific plaque hypothesis* that went unchallenged for seven decades.'[1,54]

However, Miller did not recognize bacterial plaque. This was left to J. Leon Williams (1852-1932), an American dentist who practiced in London and who in 1897 described a gelatinous accumulation of bacteria adherent to the enamel surface in relation to caries;[83] and to G. V. Black (1836-1915), who in 1899 coined the term *gelatinous microbic plaque.*

Salomon Robicsek (1845-1928), born in Hungary, obtained his medical degree and practiced dentistry in Vienna. He developed a surgical technique consisting of a scalloped continuous gingivectomy excision, exposing the marginal bone for subsequent curettage and remodeling.[71] The first description (1901) of a possible role of trauma from occlusion and bruxism in periodontal disease is generally attributed to the Austrian dentist Moritz Karolyi (1865-1945),[46] who also recommended its correction by grinding occlusal surfaces and preparation of bite plates.

Acute Necrotizing Ulcerative Gingivitis

Acute necrotizing ulcerative gingivitis (ANUG) had been recognized in the 4th century BCE by Xenophon, who mentioned that Greek soldiers were affected with "sore mouth and foul-smelling breath." In 1778, Hunter had described the clinical features of this disease and differentiated it from scurvy and chronic periodontitis. ANUG occurred in epidemic form in the French army in the 19th century, and in 1886 the German pathologist Hersch discussed some of the features associated

Fig. 8 Bernhard Gottlieb (1885-1950). (From Gold SI. Periodontics. The past. Part II. J Clin Periodontol 1985; 12:171.)

Fig. 9 Balint J. Orban (1899-1960). (From J Periodontol 1960; 31:266.)

with the disease, such as enlarged lymph nodes, fever, malaise, and increased salivation.

Hyacinthe Jean Vincent (1862-1950),[31.76] a French physician working at the Pasteur Institute in Paris, and Hugo Carl Plaut (1858-1928),[65] in Germany, described the spirillum and fusiform bacilli associated with what later became known as *Vincent's angina,* and in 1904 Vincent described these organisms in acute ulceronecrotic gingivitis.77

20TH CENTURY

In the first third of the 20th century, periodontics flourished in central Europe, with two major centers of excellence: Vienna and Berlin.

Vienna

The Vienna school developed the basic histopathologic concepts on which modern periodontics was built. The major representative from this group was Bernhard Gottlieb (1885-1950) (Fig. 8), who published extensive microscopic studies of periodontal disease in human autopsy specimens. His major contributions appeared in the German literature in the 1920s and described the attachment of the gingival epithelium to the tooth,[12] the histopathology of inflammatory and degenerative periodontal disease[21,33,34] the biology of the cementum, active and passive tooth eruption, and traumatic occlusion. Gottlieb also carried out histologic studies on animal periodontal tissues in the laboratory of Julius Tandler. Reviews of Gottlieb's studies appeared in English in 1921 in *The Dental Cosmos* and in 1927 in the *journal of the American Dental Association.* A book published in 1938 by Gottlieb and Orban, *Biology and Pathology of the Tooth and Its Supporting Mechanism*,35 presented a complete review in English of the concepts developed by Gottlieb and his co-workers in Vienna.

A younger contemporary of Gottlieb's in Vienna was Balint J. Orban (1899-1960) (Fig. 9), who carried out extensive histologic studies on periodontal tissues that serve as the basis for much of current therapy. Other members of the Viennese school were Rudolph Kronfeld (1901-40), Joseph P. Weinmann (1889-1960), and Harry Sicher (1889-1974). All these scientists emigrated to the United States in the 1930s and contributed greatly to the progress of American dentistry.

Berlin

The Berlin group consisted mostly of clinical scientists who developed and refined the surgical approach to periodontal therapy. Prominent in this group were Oskar Weski and Robert Neumann.

Weski (1879-1952) (Fig. 10) carried out pioneering studies correlating radiographic and histopathologic changes in periodontal disease.81 He also conceptualized the periodontium as formed by cementum, gingiva, periodontal ligament, and bone and gave it the name *paradentium,* which was later changed (owing to etymologic reasons) to *parodontium,* a term still used in Europe. The contributions of Alfred Kantorowicz (1880-1962) and Karl Haupl (1893-1960), among others, to the histopathology of the periodontal tissues also deserve mention.

Neumann (1882-1958) (Fig. 11), in a book published in 1912[56] (with new editions in 1915, 1920, and 1924) described the principles of periodontal flap surgery, including osseous recontouring as it is currently known[28] (Fig. 12). Other clinicians who described flap surgery at the beginning of the century were Leonard Widman of Sweden (1871-1956)[82] and A. Cieszynski of Poland. A bitter controversy developed between Widman, Cieszynski, and Neumann in the 1920s over the priority in the description of the periodontal flap.58

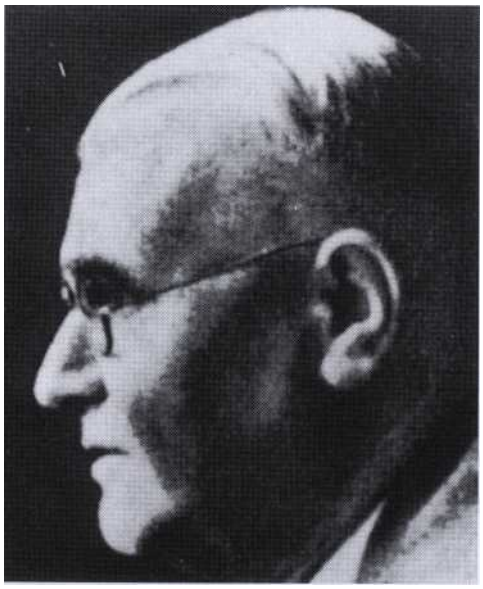

Fig. 10 Oskar Weski (1879-1952). (From Hoffman-Axthelm W: History of Dentistry. Chicago, Quintessence, 1981.)

Fig. 11 Robert Neumann (1882-1958). (Courtesy Dr. Steven I. Gold, New York, N.Y.)

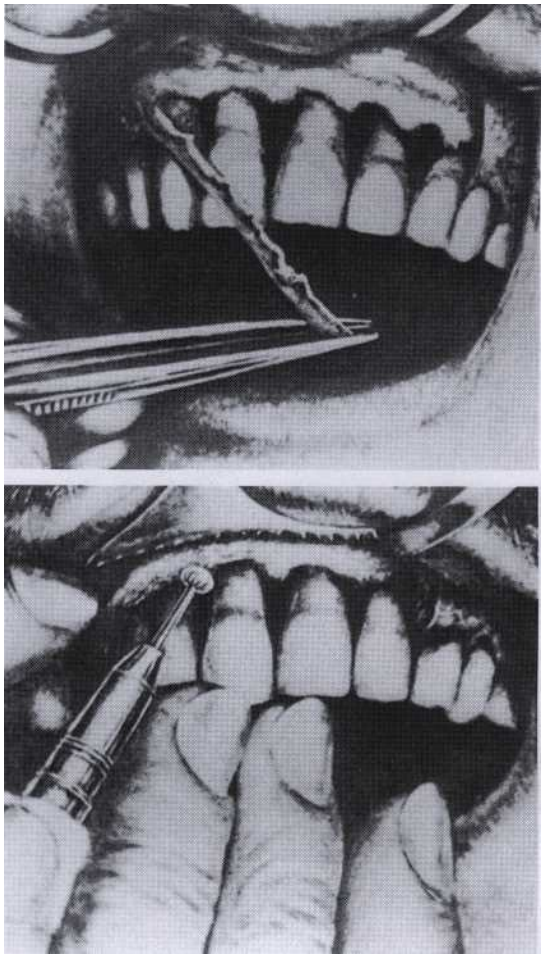

Fig. 12 Surgical procedure advocated by Robert Neumann in the early part of the 20th century. Top, After raising a mucoperiosteal flap, its edge is trimmed with scissors, leaving a scalloped outline. Bottom, Osseous recontouring with burs. (From Gold SI: Robert Neumann-a pioneer in periodontal flap surgery. J Periodontol 1982; 53:456.)

The United States and Other Countries

In the U.S., periodontal surgery developed in the first decades of the century. Early in the century, surgical techniques were developed for the coverage of denuded roots (W. J. Younger, 1902[3]; A. W. Harlan, 1906[63]7; and P. Rosenthal, 1912[6]8). However, these techniques did not attain wide usage. Before World War 1, important contributions to periodontal surgery were made by A. Zentler,[86] J. Zemsky,[8s] G. V. Black,[8] O. Kirkland,[48] A. W. Ward,[78] A. B. Crane and H. Kaplan," and others. In 1923, Ward introduced the surgical pack under the trade name Wondr-Pak.[79]

The nonsurgical approach was championed by Isadore Hirschfeld (1882-1965) of New York, who wrote classic papers on oral hygiene,[40] local factors, and other topics. In 1913 the first school for dental hygienists was created by Alfred Fones (1869-1938) in Bridgeport, Conn.

In other countries, H. K. Box (Canada); M. Roy and R. Vincent (France); R. Jaccard and A. J. Held (Switzerland); F. A. Carranza, Sr., and R. Erausquin (Argentina); W. W. James, A. Counsell, and E. W. Fish (Great Britain); and A. Leng (Chile) are well known for their important contributions. Probably the most comprehensive book on periodontics published in the first half of the 20th century was El *Paradencio, Su Patologia y Tratamiento,* by the Uruguayan F. M. Pucci, which appeared in 1939.

Focal Infection

The concept of systemic diseases originating in dental and oral infections had been mentioned in the Assyrian clay tablets (7th century BCE), by Hippocrates (460-370 BCE), in the Babylonian Talmud (3`d century CE), and by Girolamo Cardano and the German Walter Hermann Ryff in the 16th century.[41,60] In the 19[1]" century, Benjamin Rush (famous physician and one of the signers of the American Declaration of Independence) in 1818 and Leonard Koecker in 1828 recognized the role of oral sepsis in rheumatic and other diseases. Later in the century, W. D. Miller also mentioned oral infections as the cause of many diseases.[54]

In a paper published in 1900[43] and a decade later, in a lecture at McGill University in Montrea1,[43] Sir William Hunter (1861-1937), a British physician, indicted dentistry as being the cause of oral sepsis, which in turn caused rheumatic and other chronic diseases. This idea was taken up by Billings, Rosenow, and many others,[73] who advocated extractions of all teeth with periodontal or periapical infections to prevent systemic diseases. This led to wholesale extractions of teeth (and removal of tonsils).

The focal infection theory fell into disrepute when it was found that extractions failed to eliminate or reduce the systemic diseases to which the infected teeth were supposed to be linked.[21,60] However, the concept has been revisited in the 1990s, this time with a more solid research foundation (see Chapter 13).

After World War II

The U.S. and Scandinavia took a leading role in basic and clinical periodontal research from the 1950s on, with major advances in the fields of experimental pathology, microbiology, and immunology.

Animal models of periodontal disease were developed, and the role of local and systemic factors was studied by many investigators. Irving Glickman (1914-72) (Fig. 13) was a leading researcher of this period. Among other scientists who contributed to the knowledge of the experimental pathology of the periodontal tissues were Herman Becks (1897-1962), Paul Boyle (1901-80), Henry Goldman (1911-91), Balint Orban (1899-1960), Sigurd Ramfjord (1911-91), Isaac Schour (1900-64), Joseph Weinmann (1889-1960), and Helmut Zander (1912-91). In the clinical area, many authors expanded this knowledge, including Frank Beube (1904-95), Samuel Charles Miller (1902-57), Timothy O'Leary (1921-91), John Prichard (1907-90), Saul Schluger (1908-90), and Sidney Sorrin (1900-78).

The leading figure of the Scandinavian group was Jens Waerhaug (1907-80) (Fig. 14) of Oslo, whose dissertation, *The Gingival Pocket,* published in 1952, opened a new era in the understanding of the biology of the periodontium, challenging the ideas of the Vienna school on gingival attachment, and establishing the primary role of bacterial plaque in the etiology of periodontal diseases[051] Prominent members of the Scandinavian school include Harald Loe, Jan Lindhe, Sture Nyman, and Jan Egelberg.

At present, the role of microorganisms and the immunologic response are the center of attention of many research groups. Investigators such as Robert Genco, Roy Page, Sigmund Socransky, Max Listgarten, Walter Loesche, Jorgen Slots, and many others are carrying the torch into the future. This book documents their contributions.

Several workshops and international conferences have summarized the existing knowledge on the biologic and clinical aspects of periodontology. Worthy of mention are those conducted in 1951, 1966, 1977, 1989, and 1996 that were co-sponsored and published by the American Academy of Periodontology.

The American Academy of Periodontology, founded in 1914 by two female periodontists, Grace Rogers Spalding (1881-1953) and Gillette Hayden (1880-1929),

has become the leader in organized periodontics. Its monthly scientific publication, *The Journal of Periodontology,* presents all the advances in this discipline. Other scientific periodontal journals include *Journal of Periodontal Research, Journal of Clinical Periodontology, Periodontology* 2000, and *International Journal of Periodontics and Restorative Dentistry*. In other languages, *Journal de Parodontologie* (France), *Periodoncia* (Spain), and *Journal of the Japanese Association of Periodontology* (japan) deserve mention.

Periodontal education in the U.S. also has grown in the second half of the 20th century, and most dental schools have separate and independent units for teaching and research in this discipline. Periodontics was recognized as a specialty of dentistry by the American Dental Association in 1947. The first university-based programs for the training of specialists in periodontics were begun in several universities (Columbia, Michigan, Tufts) in the late 1940s; these 1-year programs expanded to 2-year programs about 10 years later. Currently, more than 50 periodontal graduate programs are based in universities and hospitals; all of these are 3-year programs.

The Normal Periodontium

Michael G. Newman

The periodontium consists of the investing and supporting tissues of the tooth (gingiva, periodontal ligament, cementum, and alveolar bone). It has been divided into two parts: the gingiva, whose main function is protection of the underlying tissues, and the attachment apparatus, composed of the periodontal ligament, cementum, and alveolar bone.[1,2] The cementum is considered a part of the periodontium because, with the bone, it serves as the support for the fibers of the periodontal ligament.

The periodontium is subject to morphologic and functional variations as well as changes associated with age. This section deals with the normal features of the tissues of the periodontium, knowledge of which is necessary for an understanding of periodontal diseases.

The soft and hard tissues surrounding dental implants have many similar features and some important differences with the periodontal tissues. They are dealt with in Chapter 67.

CHAPTER

The Gingiva

Maria E. Itoiz and Fermin A. Carranza

CHAPTER OUTLINE

CLINICAL FEATURES
- **Marginal Gingiva**
- **Gingival Sulcus**
- **Attached Gingiva**
- **Interdental Gingiva**

MICROSCOPIC FEATURES
- **Gingival Epithelium**
- **Gingival Connective Tissue**

CORRELATION OF CLINICAL AND MICROSCOPIC FEATURES
- **Color**
- **Size**
- **Contour**
- **Shape**
- **Consistency**
- **Surface Texture**
- **Position**

THE oral mucosa consists of three zones: the gingiva and the covering of the hard palate, termed the masticatory mucosa; the dorsum of the tongue, covered by specialized mucosa; and the oral mucous membrane lining the remainder of the oral cavity. The gingiva is the part of the oral mucosa that covers the alveolar processes of the jaws and surrounds the necks of the teeth.

CLINICAL FEATURES

The gingiva is divided anatomically into marginal, attached, and interdental areas.

Marginal Gingiva

The marginal, or unattached, gingiva is the terminal edge or border of the gingiva surrounding the teeth in collarlike fashion (Figs. 1-1 and 1-2). In about 50% of cases, it is demarcated from the adjacent, attached gingiva by a shallow linear depression, the free gingival groove.[1] Usually about 1 mm wide, it forms the soft tissue wall of the gingival sulcus. It may be separated from the tooth surface with a periodontal probe.

Gingival Sulcus

The gingival sulcus is the shallow crevice or space around the tooth bounded by the surface of the tooth on one side and the epithelium lining the free margin of the gingiva on the other. It is V shaped and barely permits the entrance of a periodontal probe. The clinical determination of the depth of the gingival sulcus is an important diagnostic parameter. Under absolutely normal or ideal conditions, the depth of the gingival sulcus is or is about 0.[43] These strict conditions of normalcy can be produced experimentally only in germfree animals or after intense, prolonged plaque control .[8,23]

In clinically healthy gingiva in humans, a sulcus of some depth can be found. The depth of this sulcus, as determined in histologic sections, has been reported as 1.8 mm, with variations from 0 to 6 mm[81]; other studies have reported 1.5 mm[125] and 0.69 mm, respectively.[40] The clinical maneuver used to determine the depth of

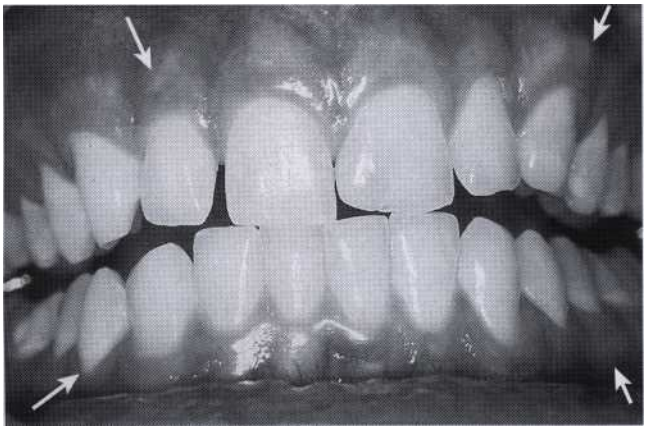

Fig. 1-1 Normal gingiva in a young adult. Note the demarcation (mucogingival line) (arrows) between the attached gingiva and the darker alveolar mucosa.

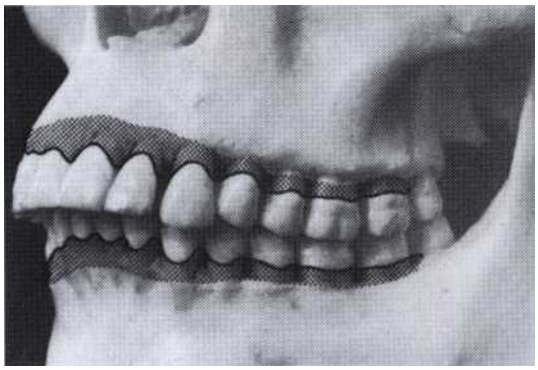

Fig. 1-3 Mean width of attached gingiva in human permanent dentition.

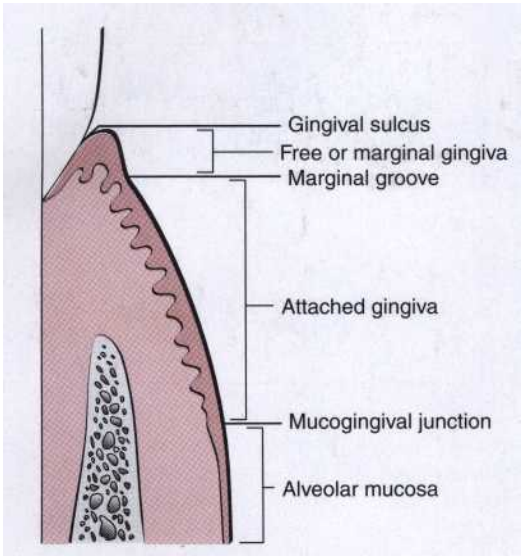

Fig. 1-2 Diagram showing anatomic landmarks of the gingiva.

the sulcus is the introduction of a metallic instrument-the periodontal probe-and the estimation of the distance it penetrates. The histologic depth of a sulcus need not be exactly equal to the depth of penetration of the probe. The so-called probing depth of a clinically normal gingival sulcus in humans is 2 to 3 mm (see Chapter 30).

Attached Gingiva

The attached gingiva is continuous with the marginal gingiva. It is firm, resilient, and tightly bound to the underlying periosteum of alveolar bone. The facial aspect of the attached gingiva extends to the relatively loose and movable alveolar mucosa, from which it is demarcated by the *mucogingival junction* (see Fig. 1-2).

The *width o f the attached gingiva is* another important clinical parameter. It is the distance between the mucogingival junction and the projection on the external surface of the bottom of the gingival sulcus or the periodontal pocket. It should not be confused with the width of the keratinized gingiva because the latter also includes the marginal gingiva (see Fig. 1-2).

The width of the attached gingiva on the facial aspect differs in different areas of the mouth." It is generally greatest in the incisor region (3.5 to 4.5 mm in the maxilla and 3.3 to 3.9 mm in the mandible) and less in the posterior segments, with the least width in the first premolar area (1.9 mm in the maxilla and 1.8 mm in the mandible)3 (Fig. 1-3).

Because the mucogingival junction remains stationary throughout adult life,' changes in the width of the attached gingiva are caused by modifications in the position of its coronal end. The width of the attached gingiva increases with age' and in supraerupted teeth.2 On the lingual aspect of the mandible, the attached gingiva terminates at the junction with the lingual alveolar mucosa, which is continuous with the mucous membrane lining the floor of the mouth. The palatal surface of the attached gingiva in the maxilla blends imperceptibly with the equally firm, **resilient palatal mucosa.**

Interdental Gingiva

The interdental gingiva occupies the gingival embrasure, which is the interproximal space beneath the area of tooth contact. The interdental gingiva can be pyramidal or have a "col" shape. In the former, the tip of one papilla is located immediately beneath the contact point; the latter presents a valleylike depression that connects a facial and lingual papilla and conforms to the shape of the interproximal contact29 (Figs. 1-4 and 1-5).

The shape of the gingiva in a given interdental space depends on the contact point between the two adjoining teeth and the presence or absence of some degree of recession. (Fig. 1-6 depicts the variations in normal interdental gingiva.)

Fig. 1-4 Site of extraction showing the facial and palatal interdental papillae and the intervening col (arrow).

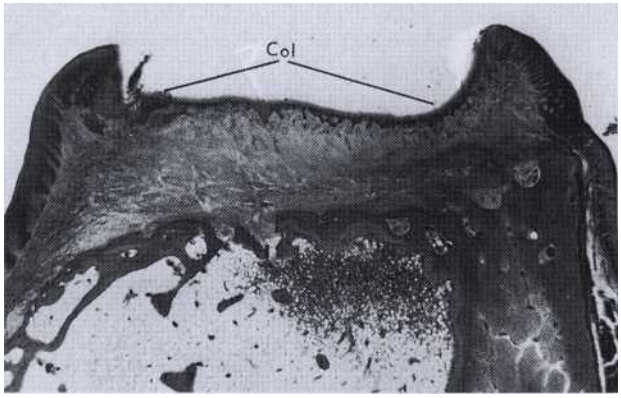

Fig. 1-5 Faciolingual section (monkey) showing col between the facial and lingual interdental papillae. The col is covered with nonkeratinized stratified squamous epithelium.

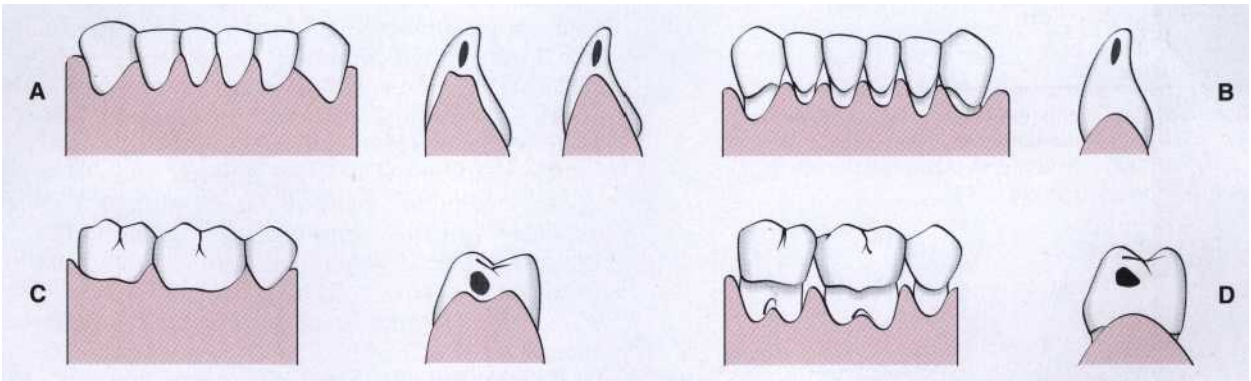

Fig. 1-6 Diagram comparing anatomic variations of the interdental col in the normal gingiva (left side) and after gingival recession (right side). A, B, Mandibular anterior segment, facial and buccolingual views, respectively. C, D, Mandibular posterior region, facial and buccolingual views, respectively. Tooth contact points are shown in B and D.

Fig. 1-7 Interdental papillae with central portion formed by attached gingiva. The shape of the papillae (P) varies according to the dimension of the gingival embrasure. (Courtesy Dr. Osvaldo Costa.)

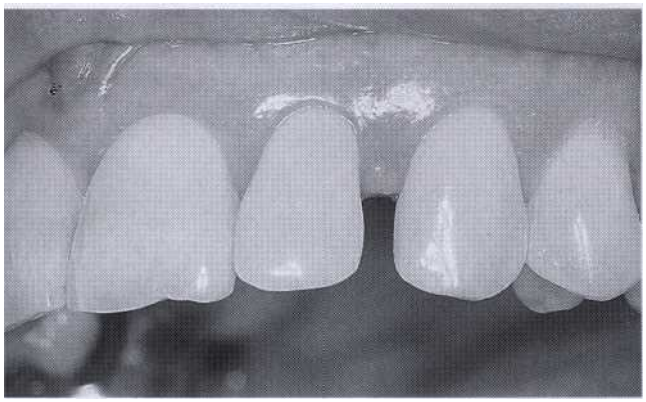

Fig. 1-8 Absence of interdental papillae and col where proximal tooth contact is missing. (Courtesy Dr. Osvaldo Costa.)

The facial and lingual surfaces are tapered toward the interproximal contact area, and the mesial and distal surfaces are slightly concave. The lateral borders and tips of the interdental papillae are formed by a continuation of the marginal gingiva from the adjacent teeth. The intervening portion consists of attached gingiva (Fig. 1-7).

If a diastema is present, the gingiva is firmly bound over the interdental bone and forms a smooth, rounded surface without interdental papillae (Fig. 1-8).

MICROSCOPIC FEATURES

The gingiva consists of a central core of connective tissue covered by stratified squamous epithelium. These two tissues will be considered separately.*

Gingival Epithelium

General Aspects of Gingival Epithelium Biology

Although it constitutes a continuous lining of stratified squamous epithelium, three different areas can be defined from the morphologic and functional points of view: the oral or outer epithelium, sulcular epithelium, and functional epithelium.

* A detailed description of gingival histology can be found in Schroeder HE: The Periodontium, New York, Springer-Verlag, 1986; and in Biological structure of the normal and diseased periodontium, Periodontology 2000 1997; (13).

The principal cell type of the gingival epithelium, as well as of other stratified squamous epithelia, is the *keratinocyte.* Other cells found in the epithelium are the clear cells or nonkeratinocytes, which include the Langerhans cells, Merkel cells, and melanocytes.

The main function of the gingival epithelium is to protect the deep structures while allowing a selective interchange with the oral environment. This is achieved by proliferation and differentiation of the keratinocyte.

Proliferation of keratinocytes takes place by mitosis in the basal layer and less frequently in the suprabasal layers, where a small proportion of cells remain as a proliferative compartment while a larger number begins to migrate to the surface.

Differentiation involves the process of keratinization, which consists of a sequence of biochemical and morphologic events that occur in the cell as it migrates from the basal layer (Fig. 1-9). The main morphologic change is a progressive flattening of the cell with an increasing prevalence of tonofilaments and intercellular junctions coupled to the production of keratohyaline granules and the disappearance of the nucleus. (See Schroeder" for further details.)

A complete keratinization process leads to the production of an *orthokeratinized* superficial horny layer similar to that of the skin with no nuclei in the stratum corneum and a well-defined stratum granulosum (Fig. 1-10). Only some areas of the outer gingival epithelium are orthokeratinized; the other gingival areas are covered by parakeratinized or nonkeratinized epithelium,20 considered to be

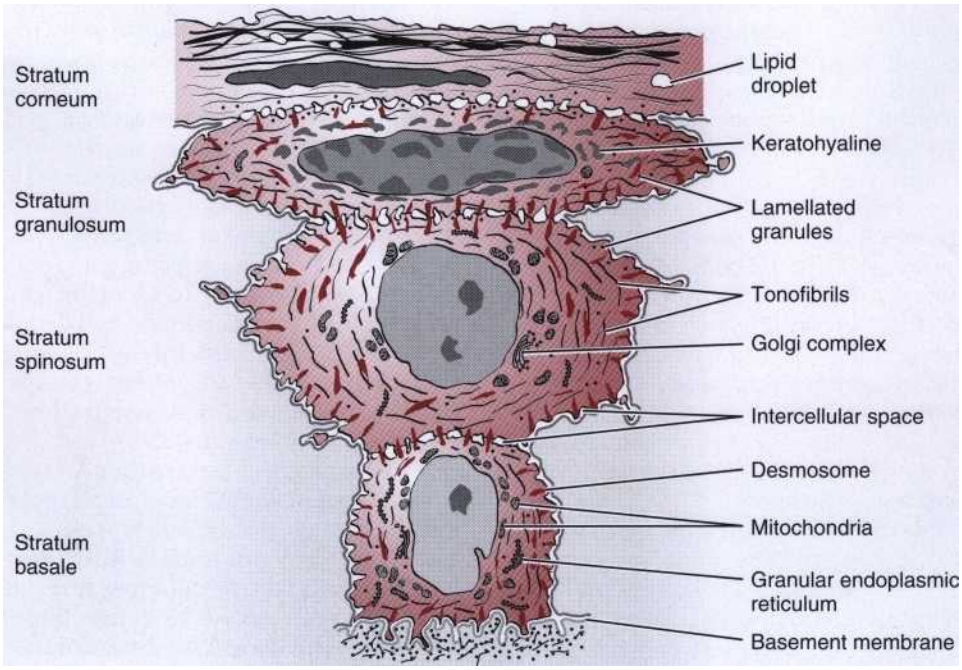

Fig. 1-9 Diagram showing representative cells from the various layers of stratified squamous epithelium as seen by electron microscopy. (Modified from Weinstock A. In: Ham AW: Histology, ed 7. Philadelphia, JB Lippincott, 1974.)

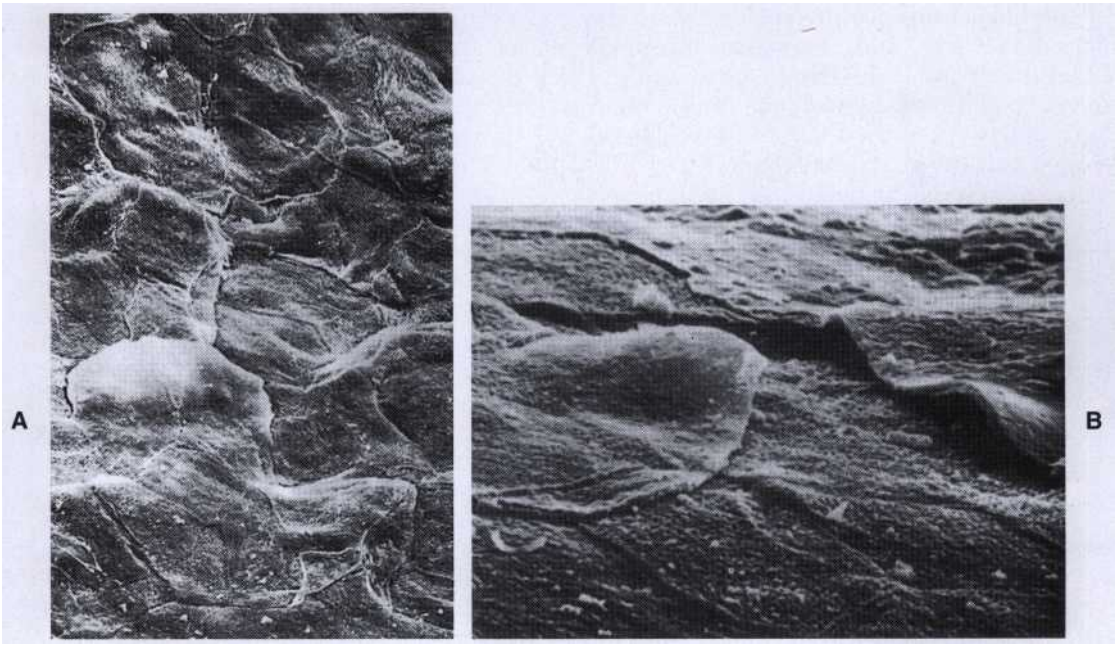

Fig. 1-10 A, Scanning electron micrograph of keratinized gingiva showing the flattened keratinocytes and their boundaries on the surface of the gingiva (x1000). B, Scanning electron micrograph of gingival margin at edge of gingival sulcus showing at close-up view several keratinocytes about to be exfoliated (x3000). (From Kaplan GB, Pameijer CH, Ruben MP: Scanning electron microscopy of sulcular and junctional epithelia correlated with histology [Part I]. J Periodontol 1977; 48:446.)

at intermediate stages of keratinization. These areas can progress to maturity or dedifferentiate under different physiologic or pathologic conditions.

In *parakeratinized epithelia,* the stratum corneum retains pyknotic nuclei and the keratohyalin granules are dispersed, not giving rise to a stratum granulosum. The *nonkeratinized epithelium* (although cytokeratins are the major component, as in all epithelia) has neither granulosum nor corneum strata, and superficial cells have viable nuclei.

Immunohistochemistry, gel electrophoresis, and immunoblot techniques have made identification of the characteristic pattern of cytokeratins possible in each epithelial type. The keratin proteins are composed of different polypeptide subunits characterized by their isoelectric points and molecular weights. They are numbered in a sequence contrary to their molecular weight. Generally, basal cells begin synthesizing lower molecular weight keratins (such as K19, 40 kd) and express other, higher molecular weight keratins as they migrate to the surface. K1 keratin polypeptide of 68 kd is the main component of the stratum corneum.[27]

Other proteins unrelated to keratins are synthesized during the maturation process. The most extensively studied are *keratolinin* and *involucrin,* which are precursors of a chemically resistant structure (the envelope) located below the cell membrane, and *filaggrin,* whose precursors are packed into the keratohyalin granules. In the sudden transition to the horny layer, the keratohyalin granules disappear and give rise to filaggrin, which forms the matrix of the most differentiated epithelial cell, the *corneocyte.*

Thus in the fully differentiated state, the corneocytes are mainly formed by bundles of keratin tonofilaments embedded in an amorphous matrix of filaggrin and surrounded by a resistant envelope under the cell membrane. The immunohistochemical patterns of the different keratin types, envelope proteins, and filaggrin, change under normal or pathologic stimuli, modifying the keratinization process.-[1-53]

Electron microscopy reveals that keratinocytes are interconnected by structures on the cell periphery called *desmosomes.*[63] These desmosomes have a typical structure consisting of two dense attachment plaques into which tonofibrils insert and an intermediate, electron-dense line in the extracellular compartment. Tonofilaments, which are the morphologic expression of the cytoskeleton of keratin proteins, radiate in brushlike fashion from the attachment plaques into the cytoplasm of the cells. The space between the cells shows cytoplasmic projections resembling microvilli that extend into the intercellular space and often interdigitate.

Less frequently observed forms of epithelial cell connections are tight junctions *(zonae occludens),* where the membranes of the adjoining cells are believed to be fused.[14,123] Evidence suggests that these structures allow ions and small molecules to pass from one cell to another.

Cytoplasmic organelle concentration varies among different epithelial strata. Mitochondria are more numerous in deeper strata and decrease toward the surface of the cell. Accordingly, histochemical demonstration of succinic dehydrogenase, nicotinamide-adenine dinucleotide, cytochrome oxidase, and other mitochondrial enzymes revealed a more active tricarboxylic cycle in

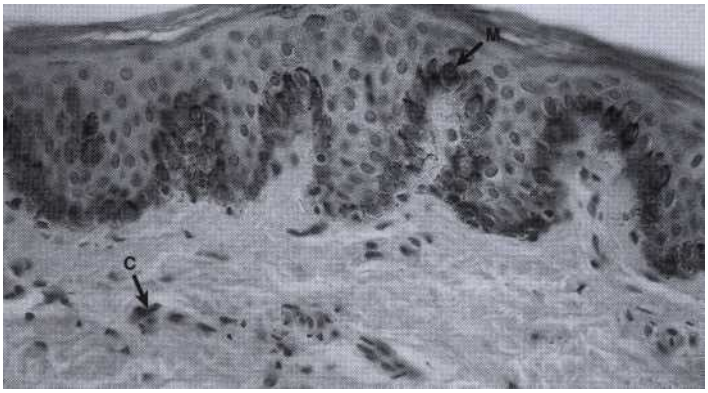

Fig. 1-11 Pigmented gingiva of dog, showing melanocytes (M) in the basal epithelial layer and melanophores (C) in the connective tissue (Glucksman technique).

basal and parabasal cells, where the proximity of the blood supply facilitates energy production through aerobic glycolysis.

Conversely, enzymes of the pentose shunt (an alternative pathway of glycolysis), such as glucose-6-phosphatase, increase their activity towards the surface. This pathway produces a larger amount of intermediate products for the production of ribonucleic acid (RNA), which in turn can be used for the synthesis of keratinization proteins. This histochemical pattern is in accordance with the increased volume and amount of tonofilaments observed in cells reaching the surface, and the intensity of activity is proportional to the degree of differentiation.[35,36,49,84]

The uppermost cells of the stratum spinosum contain numerous dense granules, *keratinosomes* or *Odland bodies,* which are modified lysosomes. They contain a large amount of acid phosphatase, an enzyme involved in the destruction of organelle membranes, which occurs suddenly between the granulosum and corneum strata and during the intercellular cementation of cornified cells. Thus acid phosphatase is another enzyme closely related to the degree of keratinization.[18,47,120]

Nonkeratinocyte cells are present in gingival epithelium as in other malpighian epithelia. *Melanocytes* are dendritic cells located in the basal and spinous layers of the gingival epithelium. They synthesize melanin in organelles called *premelanosomes* or *melanosomes*[30,90,107] (Fig. 1-11). These contain tyrosinase, which hydroxylates tyrosine to dihydroxyphenylalanine (dopa), which in turn is progressively converted to melanin. Melanin granules are phagocytosed and contained within other cells of the epithelium and connective tissue, called *melanophages* or *melanophores.*

Langerhans cells are dendritic cells located among keratinocytes at all suprabasal levels (Fig. 1-12). They belong to the mononuclear phagocyte system (reticuloendothelial system) as modified monocytes derived from the bone marrow. They contain elongated granules and are considered macrophages with possible antigenic properties.[32] Langerhans cells have an important role in the immune reaction as antigen-presenting cells for lymphocytes. They contain g-specific granules (Birbeck's granules) and have marked adenosine triphosphatase activity. They are found in oral epithelium of normal gingiva and in smaller amounts in the sulcular epithelium; they are probably absent from the junctional epithelium of normal gingiva.

Fig. 1-12 Human gingival epithelium, oral aspect. Immunoperoxidase technique showing Langerhans cells.

Merkel cells are located in the deeper layers of the epithelium, harbor nerve endings, and are connected to adjacent cells by desmosomes. They have been identified as tactile perceptors.[78]

The epithelium is joined to the underlying connective tissue by a *basal lamina 300* to 400 A thick, lying approximately 400 A beneath the epithelial basal layer.[19,96,108] The basal lamina consists of lamina lucida and lamina densa. Hemidesmosomes of the basal epithelial cells abut the lamina lucida, which is mainly composed of the glycoprotein laminin. The lamina densa is composed of type IV collagen. The basal lamina, clearly distinguishable at the ultrastructural level, is connected to a reticular condensation of the underlying connective tissue fibrils (mainly collagen type IV) by the anchoring fibrils.[77,85,111]

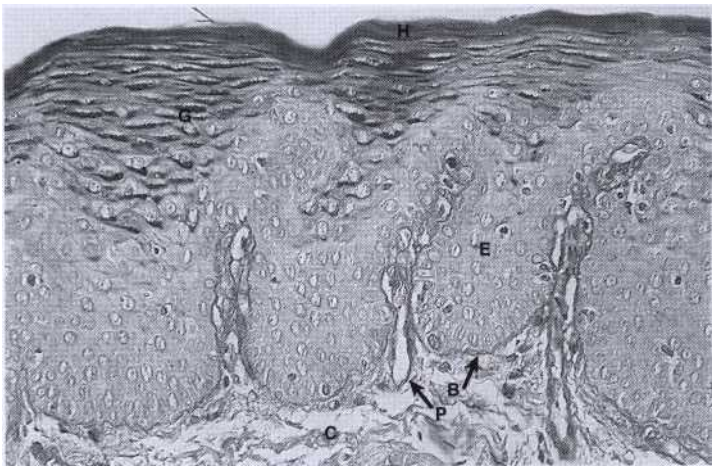

Fig. 1-13 Normal human gingiva stained with the periodic acid-Schiff (paS) histochemical method. The basement membrane (B) is seen between the epithelium (E) and the underlying connective tissue (C). In the epithelium, glycoprotein material occurs in cells and cell membrane of the superficial hornified (H) and underlying granular layers (G). The connective tissue presents a diffuse amorphous ground substance and collagen fibers. The blood vessel walls stand out clearly in the papillary projections of the connective tissue (P).

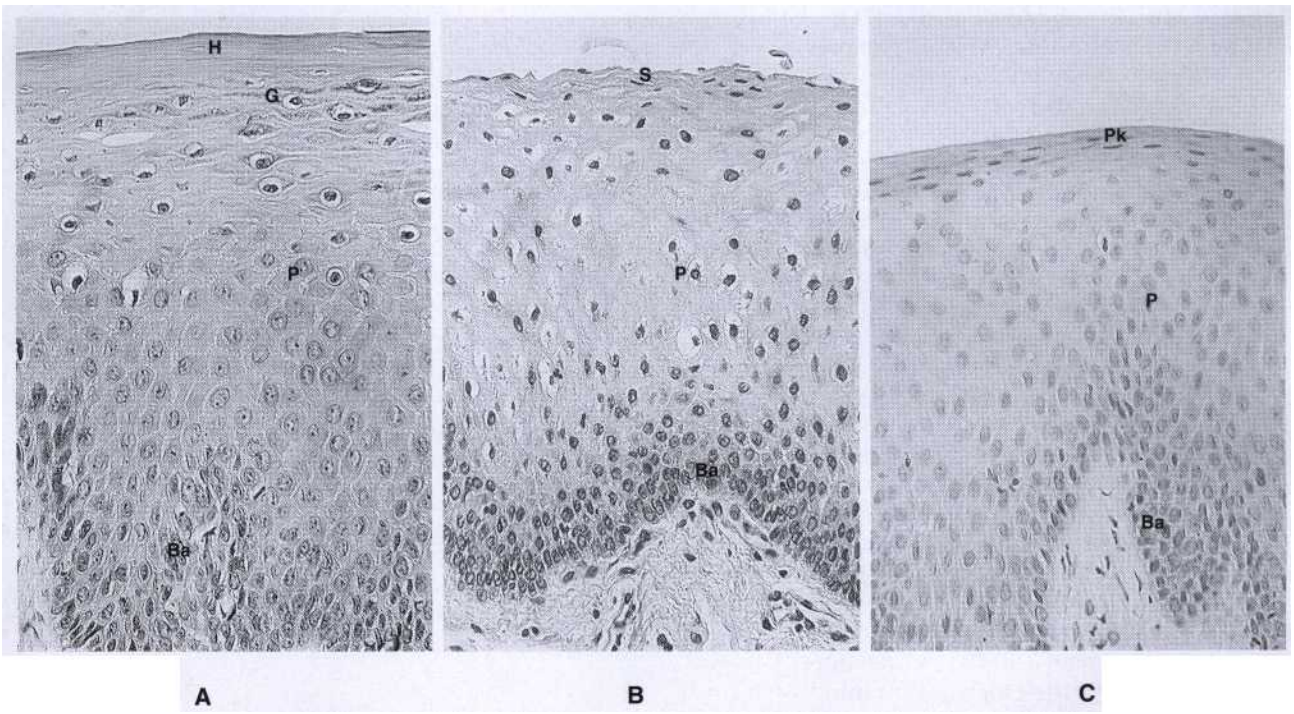

Fig. 1-14 Variations in gingival epithelium. A, Keratinized. B, Nonkeratinized. C, Parakeratinized. Horny layer (H), granular layer (G), prickle cell layer (P), basal cell layer (Bo), flattened surface cells (S), parakeratotic layer (Pk).

The complex of basal lamina and fibrils is the periodic acid-Schiff (paS) positive and argyrophilic line observed at the optical level.[9,11,12] (Fig. 1-13). The basal lamina is permeable to fluids but acts as a barrier to particulate matter.

Structural and Metabolic Characteristics of the Different Areas of Gingival Epithelium

ORAL OR OUTER EPITHELIUM. The oral or outer epithelium covers the crest and outer surface of the marginal gingiva and the surface of the attached gingiva. It is keratinized (Fig. 1-14) or parakeratinized or presents various combinations of these conditions. The prevalent surface, however, is parakeratinized.[13,20,121]

The degree of gingival keratinization diminishes with age and the onset of menopause[13] but is not necessarily related to the different phases of the menstrual cycle.[54] Keratinization of the oral mucosa varies in different areas in the following order: palate (most keratinized), gingiva, ventral aspect of the tongue, and cheek (least keratinized).[74]

Keratins K1, K2, and K10 to K12, which are specific of epidermal-type differentiation, are immunohistochemically expressed with high intensity in orthokeratinized areas and less intensity in parakeratinized areas. K6 and K16, characteristic of highly proliferative epithelia, and K5 and K14, stratification-specific cytokeratins, also are

present. Parakeratinized areas express K19, which is usually absent from orthokeratinized normal epithelia.[14,89]

In keeping with the complete or almost complete maturation, histoenzyme reactions for acid phosphatase and pentose-shunt enzymes are very strong.[19,49]

Glycogen can accumulate intracellularly when it is not completely degraded by any of the glycolytic pathways. Thus its concentration in normal gingiva is inversely related to the degree of keratinization[98,121] and inflammation.[31,116,119]

SULCULAR EPITHELIUM. The sulcular epithelium lines the gingival sulcus (Fig. 1-15). It is a thin, nonkeratinized stratified squamous epithelium without rete pegs and extends from the coronal limit of the junctional epithelium to the crest of the gingival margin (Fig. 1-16). It usually shows many cells with hydropic degeneration."

As with other nonkeratinized epithelia, it lacks granulosum and corneum strata and K1, K2, and K10-K12 cytokeratins, but it contains K4 and K13, the so-called esophageal type cytokeratins. It also expresses K19 and normally does not contain Merkel cells.

Histochemical studies of enzymes have consistently revealed a lower degree of activity than in the outer epithelium, particularly in the case of enzymes related to keratinization. Glucose-6-phosphate dehydrogenase expressed a faint and homogeneous reaction in all strata, unlike the increasing gradient toward the surface observed in cornified epithelia.[49] Acid phosphatase staining is negative,[18] although lysosomes have been described in exfoliated cells.[60]

Despite these morphologic and chemical characteristics, the sulcular epithelium has the potential to keratinize if (1) it is reflected and exposed to the oral cavity[7,21] or (2) the bacterial flora of the sulcus is totally eliminated.[22] Conversely, the outer epithelium loses its keratinization when it is placed in contact with the tooth.[22] These findings suggest that the local irritation of the sulcus prevents sulcular keratinization.

The sulcular epithelium is extremely important because it may act as a semipermeable membrane through which injurious bacterial products pass into the gingiva and tissue fluid from the gingiva seeps into the sulcus.[113]

JUNCTIONAL EPITHELIUM. The *junctional epithelium* consists of a collarlike band of stratified squamous nonkeratinizing epithelium. It is three to four layers thick in early life, but the number of layers increases with age to 10 or even 20 layers. These cells can be grouped in two strata: basal and suprabasal. The length of the junctional epithelium ranges from 0.25 to 1.35 mm.

The junctional epithelium is formed by the confluence of the oral epithelium and the reduced enamel epithelium during tooth eruption (Fig. 1-17). However, the reduced enamel epithelium is not essential for its formation; in fact, the junctional epithelium is completely restored after pocket instrumentation or surgery and forms around an implant.[62]

Cell layers not juxtaposed to the tooth exhibit numerous free ribosomes and prominent membrane-bound structures, such as Golgi complexes, and cytoplasmic vacuoles, presumably phagocytic. Lysosomelike bodies also are present, but the absence of keratinosomes (Odland bodies) and histochemically demonstrable acid phosphatase, correlated with the low degree of differentiation, may reflect a low defense power against microbial plaque accumulation in the gingival sulcus. Similar morphologic findings have been described in the gingiva of germfree rats. Polymorphonuclear neutrophil leukocytes

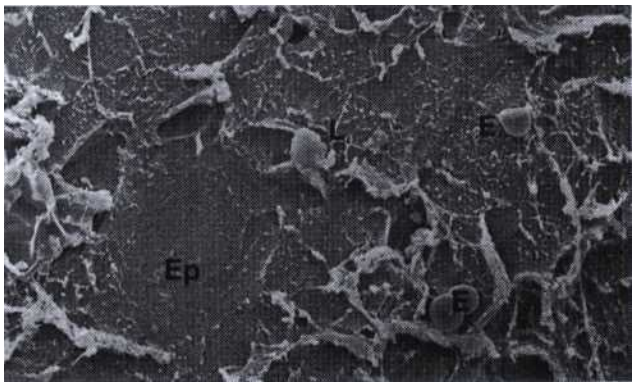

Fig. 1-15 Scanning electron microscopic view of epithelial surface facing the tooth in a normal human gingival sulcus. The epithelium (Ep) shows desquamating cells, some scattered erythrocytes (E), and a few emerging leukocytes (L) (x1000).

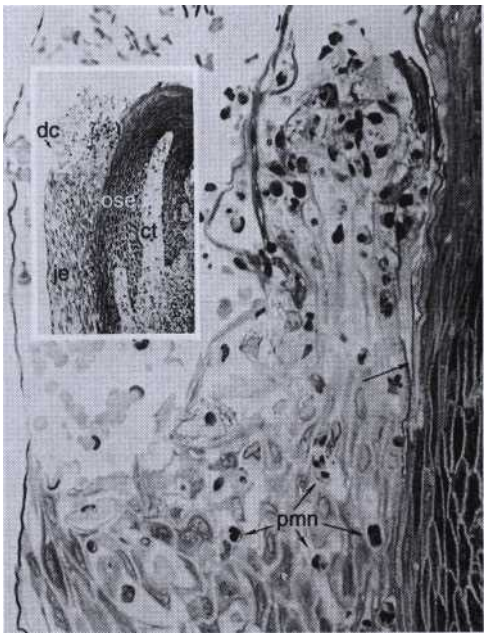

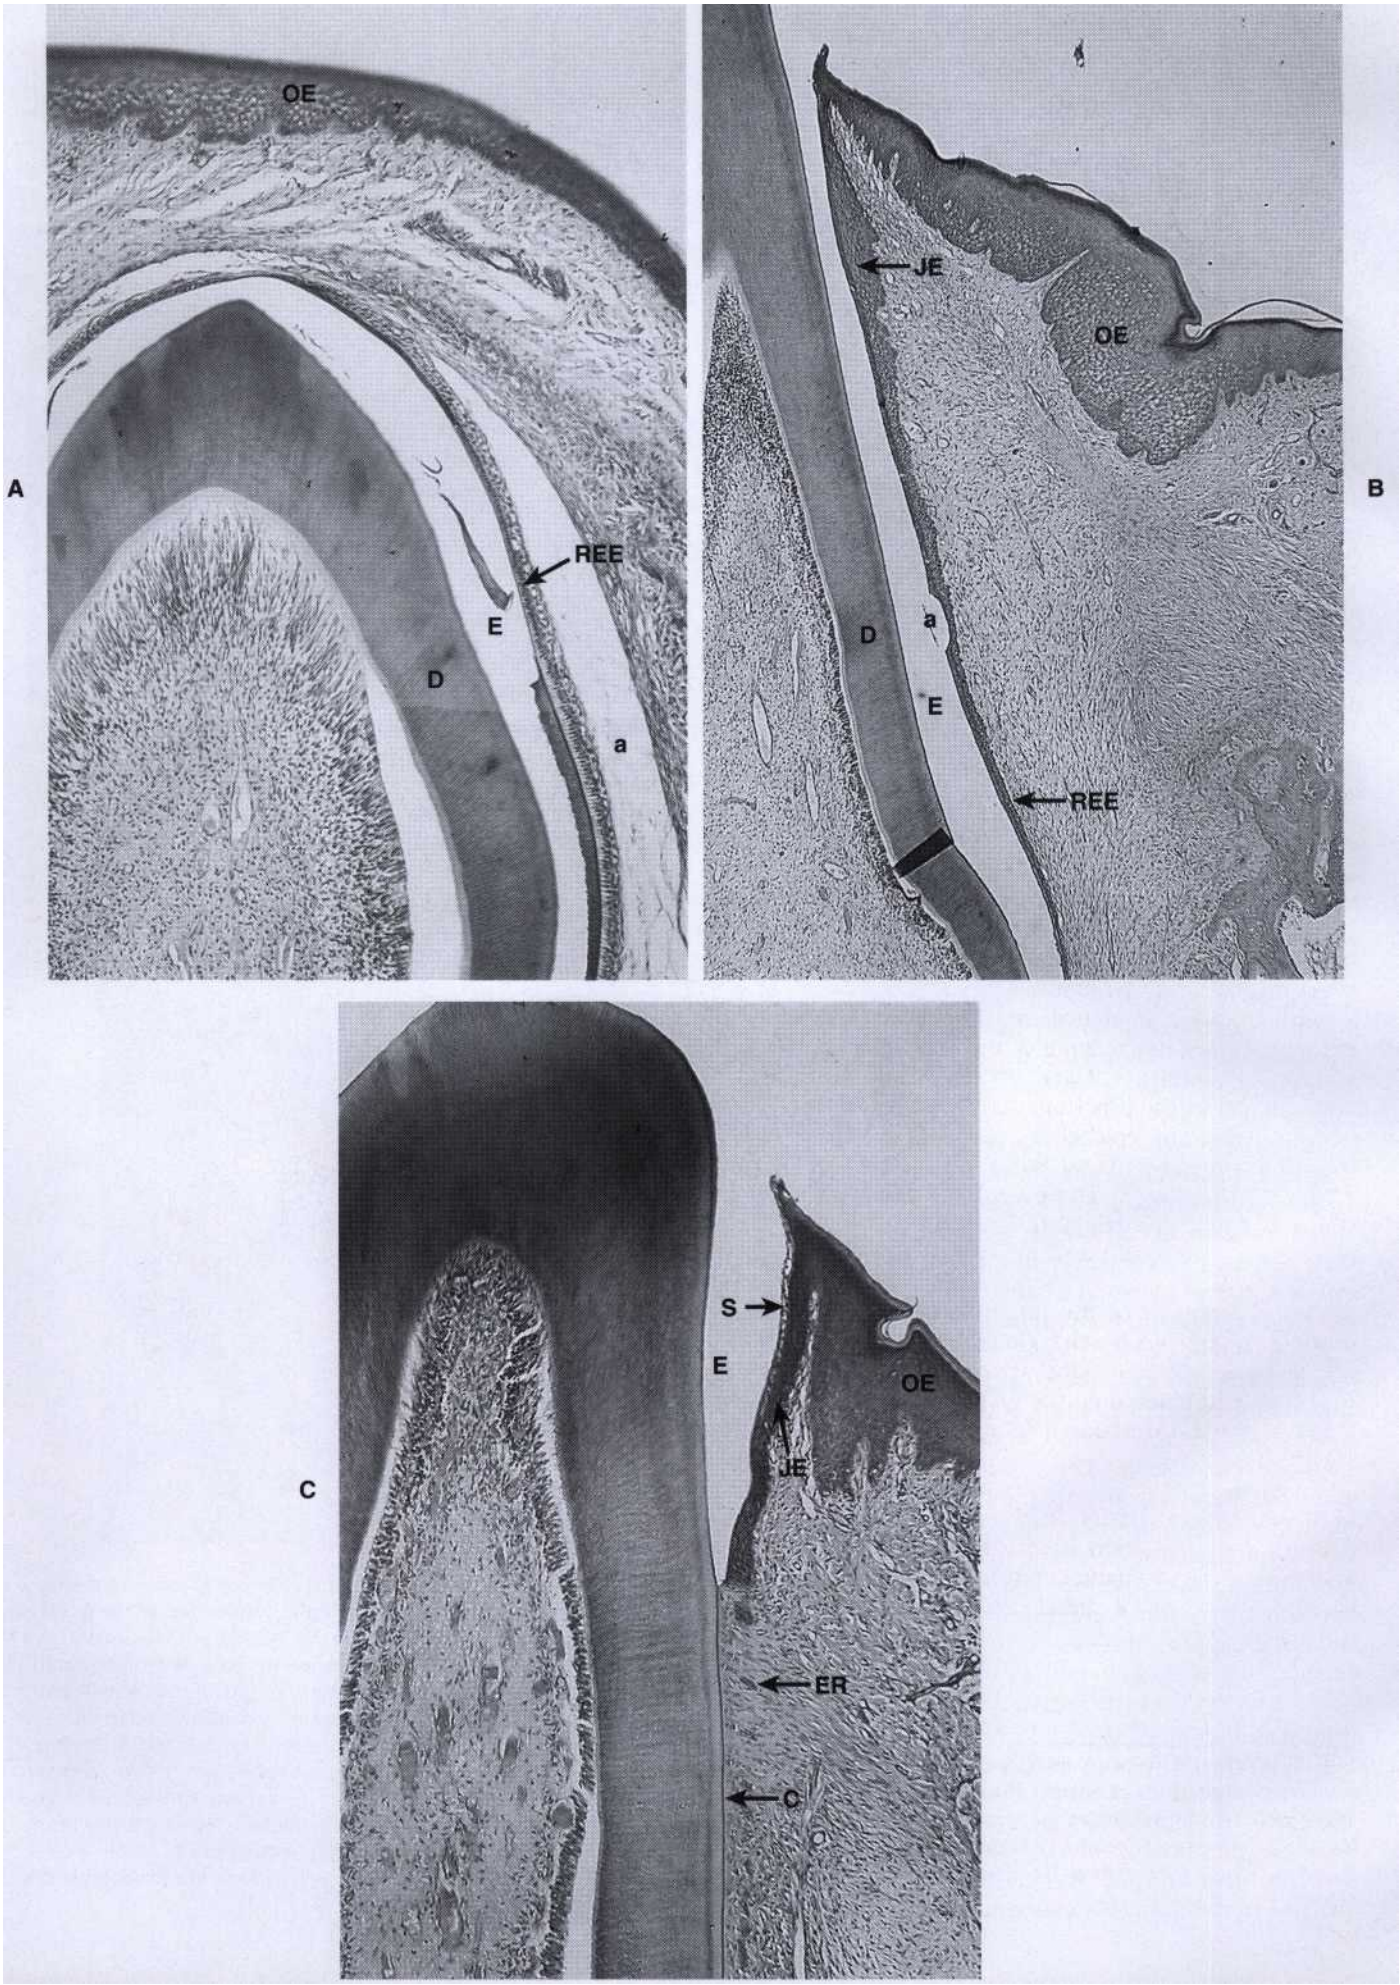

Fig. 1-16 An Epon-embedded human biopsy specimen showing a relatively normal gingival sulcus. The soft tissue wall of the gingival sulcus is made up of the oral sulcular epithelium *(ose)* and its underlying connective tissue (ct), whereas the base of the gingival sulcus is formed by the sloughing surface of the junctional epithelium (je). The enamel space is delineated by a dense cuticular structure (dc). A relatively sharp line of demarcation exists between the functional epithelium and the oral sulcular epithelium (arrow), and several polymorphonuclear leukocytes (prnn) can be seen traversing the junctional epithelium. The sulcus contains red blood cells resulting from the hemorrhage occurring at the time of biopsy (x391; inset x55). (From Schluger S, Youdelis R, Page RC: Periodontal Disease. Philadelphia, Lea & Febiger, 1977.)

are found routinely in the junctional epithelium of both conventional rats and germfree rats.127

The different keratin polypeptides of junctional epithelium have a particular histochemical pattern. It expresses K19, which is absent from keratinized epithelia, and the stratification-specific cytokeratins K5 and K14.[89] Morgan et all' reported that reactions to demonstrate K4 or K13 reveal a sudden change between sulcular and junctional epithelium, the junctional area being the only stratified nonkeratinized epithelium in the oral cavity that does not synthesize these specific polypeptides. Another particular behavior is the lack of expression of K6 and K16, which is usually linked to highly proliferative epithelia, although the turnover of the cells is very high.

Similar to sulcular epithelium, junctional epithelium exhibits lower glycolytic enzyme activity than outer epithelium and lacks acid phosphatase activity.[18,49]

The junctional epithelium is attached to the tooth surface (epithelial attachment) by means of an internal basal lamina and to the gingival connective tissue by an external basal lamina that has the same structure as other epithelial-connective tissue attachments elsewhere in the body.[64,69]

The internal basal lamina consists of a lamina densa (adjacent to the enamel) and a lamina lucida to which hemidesmosomes are attached. Organic strands from the enamel appear to extend into the lamina densa.110 The junctional epithelium attaches to afibrillar cementum present on the crown (usually restricted to an area within 1 mm of the cementoenamel junction)[95] and root cementum in a similar manner.

Histochemical evidence for the presence of neutral polysaccharides in the zone of the epithelial attachment has been reported.'" Data also have shown that the basal lamina of the junctional epithelium resembles that of endothelial and epithelial cells in its laminin content but differs in its internal basal lamina, which has no type IV collagen.[16,88] These findings indicate that the cells of the junctional epithelium are involved in the production of laminin and play a key role in the adhesion mechanism.

The attachment of the junctional epithelium to the tooth is reinforced by the gingival fibers, which brace the marginal gingiva against the tooth surface. For this reason, the junctional epithelium and the gingival fibers are considered a functional unit, referred to as the *dentogingival unit*.[66]

Development of the Gingival Sulcus

After enamel formation is complete, the enamel is covered with reduced enamel epithelium, which is attached to the tooth by a basal lamina and hemidesmosomes.[65,109] When the tooth penetrates the oral mucosa, the reduced enamel epithelium unites with the oral epithelium and transforms into the junctional epithelium. As the tooth erupts, this united epithelium condenses along the crown, and the ameloblasts, which form the inner layer of the reduced enamel epithelium (see Fig. 1-17), gradually become squamous epithelial cells. The transformation of the reduced enamel epithelium into a junctional epithelium proceeds in an apical direction without interrupting the attachment to the tooth. According to Schroeder and Listgarten, this process takes between 1 and 2 years.[95]

The junctional epithelium is a continually self-renewing structure with mitotic activity occurring in all cell layers.[65,109] The regenerating epithelial cells move toward the tooth surface and along it in a coronal direction to the gingival sulcus, where they are shed" (Fig. 1-18). The migrating daughter cells provide a continuous attachment to the tooth surface. The strength of the epithelial attachment to the tooth has not been measured.

The gingival sulcus is formed when the tooth erupts into the oral cavity. At that time, the junctional epithelium and reduced enamel epithelium form a broad band attached to the tooth surface from near the tip of the crown to the cementoenamel junction.

The gingival sulcus is the shallow, V-shaped space or groove between the tooth and gingiva that encircles the newly erupted tip of the crown. In the fully erupted

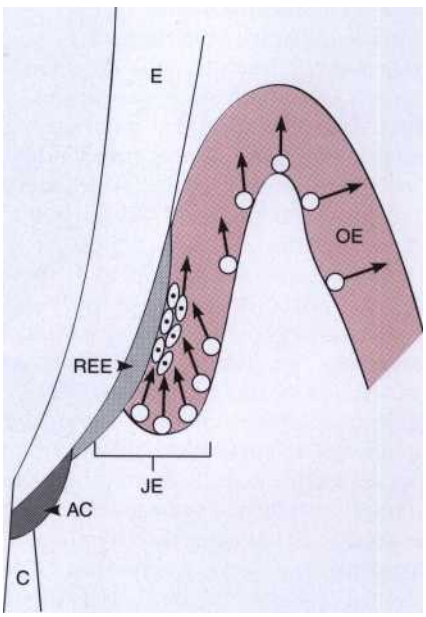

Fig. 1-18 junctional epithelium on an erupting tooth. The junctional epithelium *(JE)* **is formed by the joining of the oral epithelium** *(OE)* **and the reduced enamel epithelium** *(REE).* **Afibrillar cementum, sometimes formed on enamel after degeneration of the REE, is shown at AC. The arrows indicate the coronal movement of the regenerating epithelial cells, which multiply more rapidly in the JE than in the OE.** *E,* **Enamel; C, root cementum. A similar cell turnover pattern exists in the fully erupted tooth. (Modified from Listgarten MA: Changing concepts about the dentogingival junction. J Can Dent Assoc 1970; 36:70.)**

tooth, only the junctional epithelium persists. *The sulcus consists of the shallow space that is coronal to the attachment of the junctional epithelium and bounded by the tooth on one side and the Sulcular epithelium on the other. The coronal extent of the gingival sulcus is the gingival margin.*

Renewal of Gingival Epithelium

The oral epithelium undergoes continuous renewal. Its thickness is maintained by a balance between new cell formation in the basal and spinous layers and the shedding of old cells at the surface. The mitotic activity exhibits a 24-hour periodicity, with highest and lowest rates occurring in the morning and evening, respectively."° The mitotic rate is higher in nonkeratinized areas and is increased in gingivitis, without significant gender differences. Opinions differ as to whether the mitotic rate is increased [68,69,73] or decreased" with age.

The mitotic rate in experimental animals varies among different areas of the oral epithelium in descending order: buccal mucosa, hard palate, Sulcular epithelium, junctional epithelium, outer surface of the marginal gingiva, and attached gingiva. [6,45,68,117] The following have been reported as turnover times for different areas of the oral epithelium in experimental animals: palate, tongue, and cheek, 5 to 6 days; gingiva, 10 to 12 days, with the same or more time required with age; and junctional epithelium, 1 to 6 days.' .105

Cuticular Structures on the Tooth

The term *cuticle* describes a thin, acellular structure with a homogeneous matrix, sometimes enclosed within clearly demarcated, linear borders.

Listgarten has classified cuticular structures into coatings of developmental origin and acquired coatings .67 *Acquired coatings* include those of exogenous origin, such as saliva, bacteria, calculus, and surface stains (see Chapters 6 and 11). *Coatings of developmental origin* are those normally formed as part of tooth development. They include the reduced enamel epithelium, coronal cementum, and dental cuticle.

After enamel formation is completed, the ameloblastic epithelium is reduced to one or two layers of cells that remain attached to the enamel surface by hemidesmosomes and a basal lamina. This *reduced enamel epithelium* consists of postsecretory ameloblasts and cells from the stratum intermedium of the enamel organ.

In some animal species, the reduced enamel epithelium disappears entirely and very rapidly, thereby placing the enamel surface in contact with the connective tissue. Connective tissue cells then deposit a thin layer of cementum known as *coronal cementum* on the enamel. In humans, thin patches of afibrillar cementum sometimes may be seen in the cervical half of the crown.

Electron microscopy has shown a *dental cuticle* consisting of a layer of homogeneous organic material of variable thickness (approximately 0.25 micron) overlying the enamel surface. It is nonmineralized and not always present. In some instances near the cementoenamel junction, it is deposited over a layer of afibrillar cementum, which in turn overlies enamel. The cuticle may be present between the junctional epithelium and the tooth. Ultrastructural histochemical studies have shown the dental cuticle to be of proteinaceous nature,-' and it may be an accumulation of tissue fluid components. [39,92]

Gingival Fluid (Sulcular Fluid)

The gingival sulcus contains a fluid that seeps into it from the gingival connective tissue through the thin Sulcular epithelium. The gingival fluid is believed to 1) cleanse material from the sulcus, 2) contain plasma proteins that may improve adhesion of the epithelium to the tooth, 3) possess antimicrobial properties, and 4) exert antibody activity to defend the gingiva. (The gingival fluid and its significance in health and disease are discussed in detail in Chapter 15.)

Gingival Connective Tissue

The connective tissue of the gingiva is known as the *lamina propria* and consists of two layers: 1) a *papillary layer* subjacent to the epithelium, which consists of papillary projections between the epithelial rete pegs, and 2) a *reticular layer* contiguous with the periosteum of the alveolar bone. Connective tissue has a cellular and an extracellular compartment composed of fibers and ground substance.

The ground substance fills the space between fibers and cells, is amorphous, and has a high content of water. It is composed of proteoglycans, mainly hyaluronic acid and chondroitin sulfate, and glycoproteins, mainly fibronectin. Glycoproteins account for the faint pas positive reaction of the ground substance. [36] Fibronectin binds fibroblasts to the fibers and many other components of the intercellular matrix, helping mediate cell adhesion and migration. Laminin is another glycoprotein found in the basal laminae, which serves to attach it to epithelial cells.

The three types of connective tissue fibers are collagen, reticular, and elastic. Collagen type I forms the bulk of the lamina propria and provides the tensile strength to the gingival tissue. Type IV collagen (argyrophilic reticulum fiber) branches between the collagen type I bundles and is continuous with fibers of the basement membrane and blood vessel walls.69

The elastic fiber system is composed of oxytalan, elaunin, and elastin fibers distributed among collagen fibers . [26]

Gingival Fibers

The connective tissue of the marginal gingiva is densely collagenous, containing a prominent system of collagen fiber bundles called the *gingival fibers.* They consist of type I collagen.$- The gingival fibers have the following functions:

1. To brace the marginal gingiva firmly against the tooth
2. To provide the rigidity necessary to withstand the forces of mastication without being deflected away from the tooth surface
3. To unite the free marginal gingiva with the cementum of the root and the adjacent attached gingiva

The gingival fibers are arranged in three groups: gingivodental, circular, and transseptal.- [8]

GINGIVODENTAL GROUP. The gingivodental fibers are those on the facial, lingual, and interproximal

surfaces. They are embedded in the cementum just beneath the epithelium at the base of the gingival sulcus. On the facial and lingual surfaces, they project from the cementum in fanlike conformation toward the crest and outer surface of the marginal gingiva, terminating short of the epithelium (Figs. 1-19 and 1-20). They also extend externally to the periosteum of the facial and lingual alveolar bones and terminate in the attached gingiva or blend with the periosteum of the bone. Interproximally, the gingivodental fibers extend toward the crest of the interdental gingiva.

CIRCULAR GROUP. The circular fibers course through the connective tissue of the marginal and interdental gingivae and encircle the tooth in ringlike fashion.

TRANSSEPTAL GROUP. Located interproximally, the transseptal fibers form horizontal bundles that extend between the cementum of approximating teeth into which they are embedded. They lie in the area between the epithelium at the base of the gingival sulcus and the crest of the interdental bone and are sometimes classified with the principal fibers of the periodontal ligament.

Page and co-workers[82] also have described (1) a group of *semicircular fibers,* which attach at the proximal surface of a tooth, immediately below the cementoenamel junction, go around the facial or lingual marginal gingiva of the tooth, and attach on the other proximal surface of the same tooth; and (2) a group of *transgingival fibers,* that attach in the proximal surface of one tooth, traverse the interdental space diagonally, go around the facial or lingual surface of the adjacent tooth, again traverse diagonally the interdental space, and attach in the proximal surface of the next tooth.

Cellular Elements

The preponderant cellular element in the gingival connective tissue is the *fibroblast.* Numerous fibroblasts are found between the fiber bundles. As in connective tissue elsewhere in the body, fibroblasts synthesize collagen and elastic fibers as well as the glycoproteins and glycosaminoglycans of the amorphous intercellular substance. Fibroblasts also regulate collagen degradation.

Mast cells, which are distributed throughout the body, are numerous in the connective tissue of the oral mucosa and the gingiva.[24,103,104,124] *Fixed macrophages* and *histiocytes* are present in the gingival connective tissue as components of the mononuclear phagocyte system (reticuloendothelial system) and are derived from blood monocytes. *Adipose cells* and *eosinophils,* although scarce, also are present in the lamina propria.

In clinically normal gingiva, *small* foci of plasma cells and lymphocytes are found in the connective tissue near the base of the sulcus (Fig. 1-21). Neutrophils can be seen in relatively high numbers in both the gingival connective tissue and the sulcus. These inflammatory cells usually are present in small amounts in clinically normal gingiva.

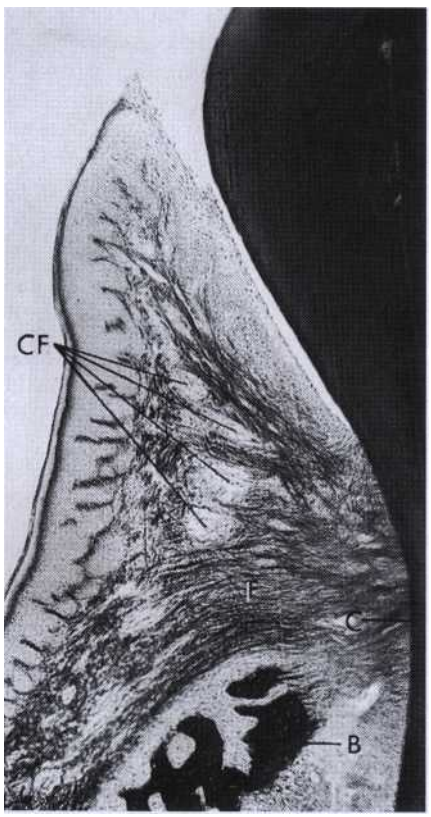

Fig. 1-19 Faciolingual section of marginal gingiva, showing gingival fibers (F) extending from the cementum (C) to the crest of the gingiva, to the outer gingival surface, and external to the periosteum of the bone (8). Circular fibers *(CF)* are shown in cross-section between the other groups. (Courtesy Sol Bernick.)

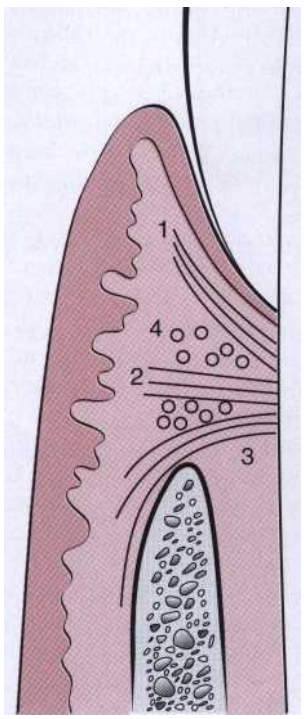

Fig. 1-20 Diagram of the gingivodental fibers extending from the cementum (1) to the crest of the gingiva, (2) to the outer surface, and (3) external to the periosteum of the labial plate. Circular fibers (4) are shown in cross-section.

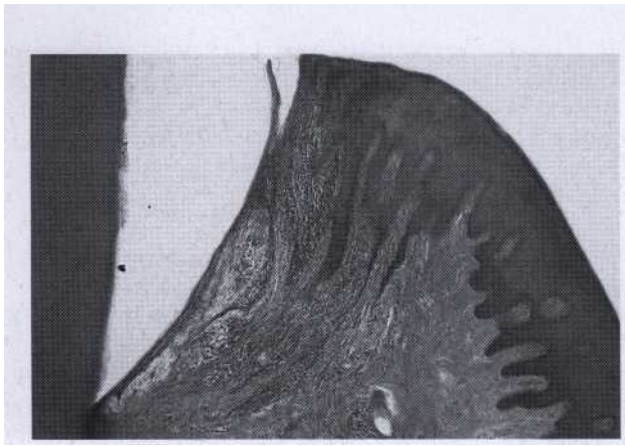

Fig. 1-21 Section of clinically normal gingiva, showing some degree of inflammation, which is almost always present near the base of the sulcus.

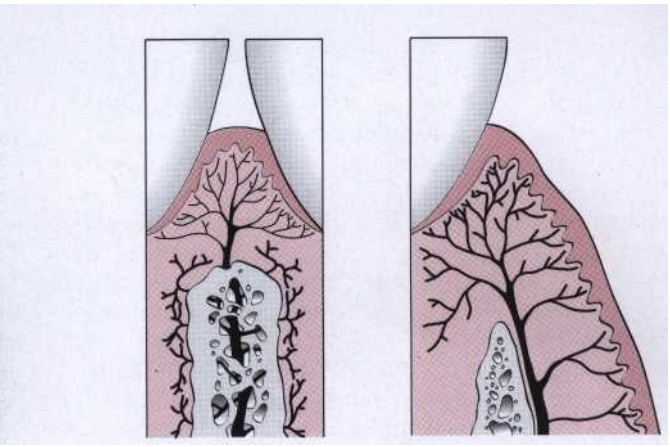

Fig. 1-22 Diagram of arteriole penetrating the interdental alveolar bone to supply the interdental tissues *(left)* **and a supraperiosteal arteriole overlying the facial alveolar bone, sending branches to the surrounding tissue** *(right).*

Speculations about whether small amounts of leukocytes should be considered a normal component of the gingiva or an incipient inflammatory infiltrate without clinical expression are of theoretic rather than practical importance. Lymphocytes are absent when gingival normalcy is judged by very strict clinical criteria or under very special experimental conditions[8,80] but are practically constant in healthy normal gingiva, even before complete tooth eruption.[61,70,11] Immunohistochemical studies using monoclonal antibodies have identified the different lymphocyte subpopulations. The infiltrate in the area below the junctional epithelium of healthy gingiva in recently erupted teeth in children is mainly composed of T-lymphocytes (helper, cytotoxic, suppressor and natural killer)[7,41,102] and thus could be interpreted as a normal lymphoid tissue involved in the early defense recognition system. As time elapses, B-lymphocytes and plasma cells appear in greater proportions to elaborate specific antibodies against already recognized antigens that are always present in the sulcus of clinically normal gingva.[97]

Blood Supply, Lymphatics, and Nerves

Blood vessels are easily evidenced in tissue sections by means of immunohistochemical reactions against proteins of endothelial cells (factor VIII and adhesion molecules). Before these techniques were developed, vascularization patterns of periodontal tissues had been described using histoenzymatic reactions for alkaline phosphatase and adenosine triphosphatase owing to the great activity of these enzymes in endothelial cells.[2-5,128] In experimental animals, the perfusion with India ink also was used to study vascular distribution. The injection and subsequent demonstration of peroxidase allows blood vessel identification and permeability studies.[101] The paS reaction also outlines vascular walls by a positive line in their basal membrane.[99] Endothelial cells also express 5-nucleotidase activity.[48] Scanning electron microscopy can be used after injection of plastic into the vessels through the carotid artery, followed by corrosion of the soft tissues.[37]

Three sources of blood supply to the gingiva are as follows (Figs. 1-22 and 1-23):

1. *Supraperiosteal arterioles* along the facial and lingual surfaces of the alveolar bone, from which capillaries extend along the sulcular epithelium and between the rete pegs of the external gingival surface.[34,46] Occasional branches of the arterioles pass through the alveolar bone to the periodontal ligament or run over the crest of the alveolar bone
2. *Vessels of the periodontal ligament,* which extend into the gingiva and anastomose with capillaries in the sulcus area.
3. *Arterioles,* which emerge from the crest of the interdental septa[37] and extend parallel to the crest of the bone to anastomose with vessels of the periodontal ligament, with capillaries in the gingival crevicular areas and vessels that run over the alveolar crest.

Beneath the epithelium on the outer gingival surface, capillaries extend into the papillary connective tissue between the epithelial rete pegs in the form of terminal hairpin loops with efferent and afferent branches, spirals, and varices[25,46] (Figs. 1-23 and 1-24). The loops are sometimes linked by cross-communications,[38] and flattened capillaries serve as reserve vessels when the circulation is increased in response to irritation.[42]

Along the sulcular epithelium, capillaries are arranged in a flat anastomosing plexus that extends parallel to the enamel from the base of the sulcus to the gingival margin." In the col area, a mixed pattern of anastomosing capillaries and loops occurs.

The *lymphatic drainage of the gingiva* brings in the lymphatics of the connective tissue papillae.[100] It progresses into the collecting network external to the periosteum of the alveolar process and then to the regional lymph nodes (particularly the submaxillary group). In addition, lymphatics just beneath the junctional epithelium extend into the periodontal ligament and accompany the blood vessels.

Gingival innervation is derived from fibers arising from nerves in the periodontal ligament and from the labial,

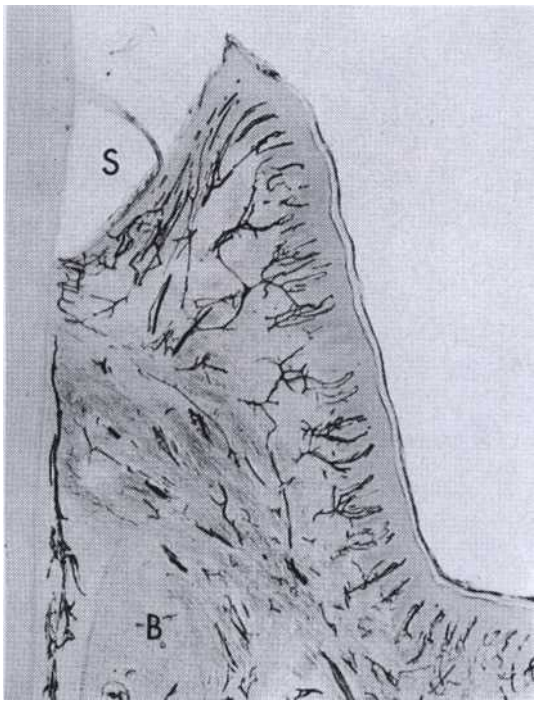

Fig. 1-23 Blood supply and peripheral circulation of the gingiva. Tissues perfused with India ink. Note the capillary plexus parallel to the sulcus (S) and the capillary loops in the outer papillary layer. Note also the supraperiosteal vessels external to the bone (8), which supply the gingiva, and a periodontal ligament vessel anastomosing with the sulcus plexus. (Courtesy Sol Bernick.)

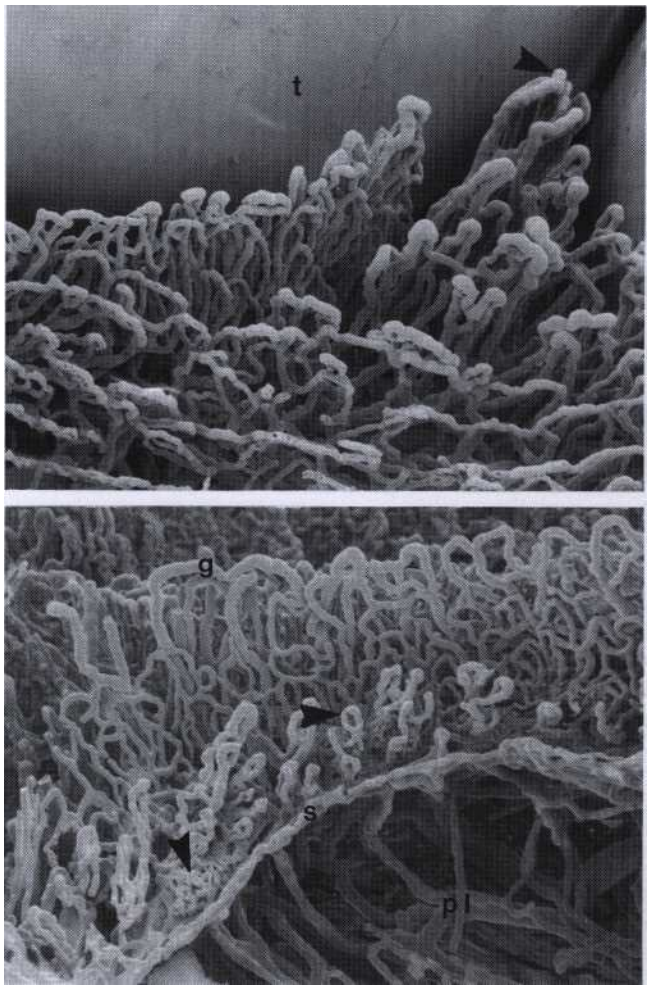

Fig. 1-24 Scanning electron microscopic view of gingival tissues of rat molar palatal gingiva after vascular perfusion of plastic and corrosion of soft tissue. A, Oral view of gingival capillaries: t tooth; interdental papilla (arrow) (x180). B, View from the tooth side. Note the vessels of the plexus next to the sulcular and junctional epithelium. The arrowheads point to vessels in sulcus area with mild inflammatory changes. G, Crest of marginal gingiva; s, bottom of gingival sulcus; pl, periodontal ligament vessels (x150). (Courtesy NJ Selliseth and K Selvig, University of Bergen, Norway.)

buccal, and palatal nerves." The following nerve structures are present in the connective tissue: a meshwork of terminal argyrophilic fibers, some of which extend into the epithelium; Meissner-type tactile corpuscles; Krause-type end bulbs, which are temperature receptors; and encapsulated spindles.

CORRELATION OF CLINICAL AND MICROSCOPIC FEATURES

An understanding of the normal clinical features of the gingiva requires the ability to interpret them in terms of the microscopic structures they represent.

Color

The color of the attached and marginal gingivae is generally described as coral pink and is produced by the vascular supply, the thickness and degree of keratinization of the epithelium, and the presence of pigment-containing cells. The color varies among different persons and appears to be correlated with the cutaneous pigmentation. It is lighter in blond individuals with fair complexions than in swarthy, dark-haired individuals (Color Fig. 1-1).

The attached gingiva is demarcated from the adjacent alveolar mucosa on the buccal aspect by a clearly defined mucogingival line. The alveolar mucosa is red, smooth, and shiny rather than pink and stippled. Comparison of the microscopic structure of the attached gingiva with that of the alveolar mucosa affords an explanation for the difference in appearance. The epithelium of the alveolar mucosa is thinner, is nonkeratinized, and contains no rete pegs (Fig. 1-25). The connective tissue of the alveolar mucosa is loosely arranged, and the blood vessels are more numerous.

Physiologic Pigmentation (Melanin). Melanin, a non-hemoglobin-derived brown pigment, is responsible for the normal pigmentation of the skin, gingiva, and remainder of the oral mucous membrane. It is present in all normal individuals, often not in sufficient quantities to be detected clinically, but is absent or severely diminished in albinos. Melanin pigmentation in the oral cavity is prominent in black individuals (see Color Fig. 1-1).

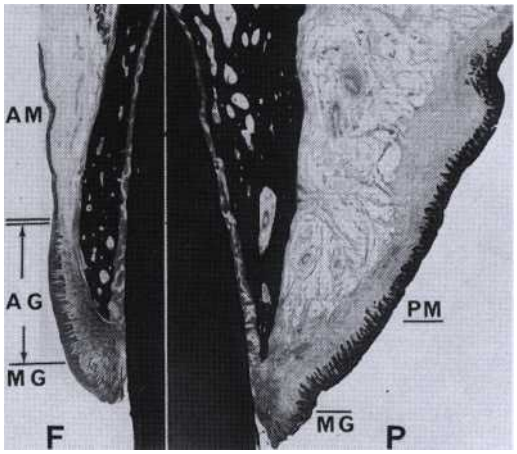

Fig. 1-25 Oral mucosa, facial, and palatal surfaces. The facial surface (F) shows the marginal gingiva (MG), attached gingiva (AG), and alveolar mucosa (AM). The double line marks the mucogingival junction. Note the differences in the epithelium and connective tissue in the attached gingiva and alveolar mucosa. The palatal surface (P) shows the marginal gingiva *(MG)* **and thick keratinized palatal mucosa (PM).**

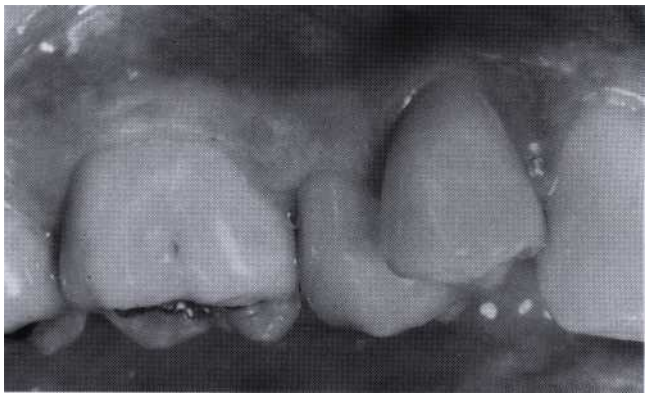

Fig. 1-26 Thickened shelflike contour of gingiva on tooth in lingual version aggravated by local irritation caused by plaque accumulation.

According to Dummett," the distribution of oral pigmentation in black individuals is as follows: gingiva, 60%; hard palate, 61%; mucous membrane, 22%; and tongue, *15%. Gingival pigmentation occurs as a diffuse, deep-purplish discoloration or as irregularly shaped brown and light brown patches.* It may appear in the gingiva as early as 3 hours after birth and often is the only evidence of pigmentation.33

Size

The size of the gingiva corresponds with the sum total of the bulk of cellular and intercellular elements and their vascular supply. Alteration in size is a common feature of gingival disease.

Contour

The contour or shape of the gingiva varies considerably and depends on the shape of the teeth and their alignment in the arch, the location and size of the area of proximal contact, and the dimensions of the facial and lingual gingival embrasures. The marginal gingiva envelops the teeth in collarlike fashion and follows a scalloped outline on the facial and lingual surfaces. It forms a straight line along teeth with relatively flat surfaces. On teeth with pronounced mesiodistal convexity (e.g., maxillary canines) or teeth in labial version, the normal arcuate contour is accentuated and the gingiva is located farther apically. On teeth in lingual version, the gingiva is horizontal and thickened (Fig. 1-26).

Shape

The shape of the interdental gingiva is governed by the contour of the proximal tooth surfaces and the location and shape of gingival embrasures. When the proximal surfaces of the crowns are relatively flat faciolingually, the roots are close together, the interdental bone is thin mesiodistally, and the gingival embrasures and interdental gingiva are narrow mesiodistally. Conversely, with proximal surfaces that flare away from the area of contact, the mesiodistal diameter of the interdental gingiva is broad (Fig. 1-27). The height of the interdental gingiva varies with the location of the proximal contact.

Consistency

The gingiva is *firm and resilient* and, with the exception of the movable free margin, tightly bound to the underlying bone. The collagenous nature of the lamina propria and its contiguity with the mucoperiosteum of the alveolar bone determine the firmness of the attached gingiva. The gingival fibers contribute to the firmness of the gingival margin.

Surface Texture

The gingiva presents a textured surface similar to an orange peel and is referred to as being stippled (see Color Fig. 1-1). Stippling is best viewed by drying the gingiva (see Color Fig. 1-1). *The attached gingiva is stippled; the marginal gingiva is not.* The central portion of the interdental papillae is usually stippled, but the marginal borders are smooth. The pattern and extent of stippling varies among individuals and different areas of the same mouth.[44,81] It is less prominent on lingual than facial surfaces and may be absent in some persons.

Stippling varies with age. It is absent in infancy, appears in some children at about 5 years of age, increases until adulthood, and frequently begins to disappear in old age.

Microscopically, stippling is produced by alternate rounded protuberances and depressions in the gingival surface. The papillary layer of the connective tissue projects into the elevations, and the elevated and depressed areas are covered by stratified squamous epithelium (Fig. 1-28). The degree of keratinization and the prominence of stippling appear to be related.

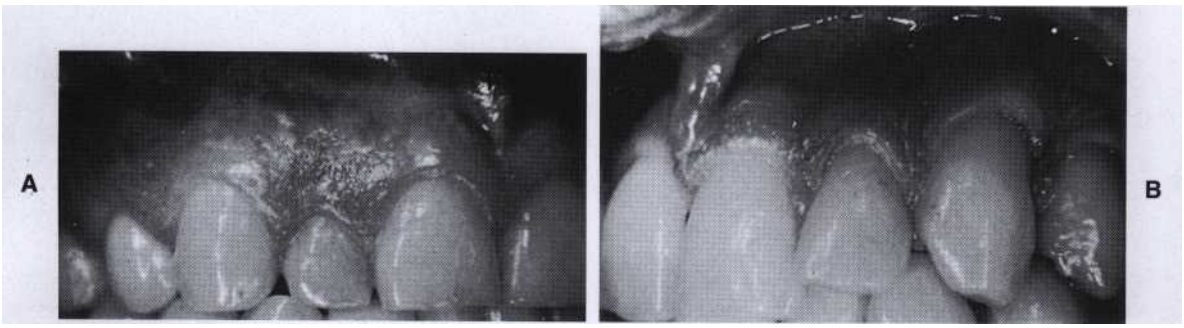

Fig. 1-27 Shape of interdental gingival papillae correlated with shape of teeth and embrasures. A, Broad interdental papillae. 8, Narrow interdental papillae.

Scanning electron microscopy has shown considerable variation in shape but a relatively constant depth. At low magnification a rippled surface is seen, interrupted by irregular depressions 50 microns in diameter. At higher magnification, cell micropits are seen .[28]

Stippling is a form of adaptive specialization or reinforcement for function. It is a feature of healthy gingiva, and reduction or loss of stippling is a common sign of gingival disease. When the gingiva is restored to health after treatment, the stippled appearance returns.

The surface texture of the gingiva also is related to the presence and degree of epithelial keratinization. Keratinization is considered a protective adaptation to function. It increases when the gingiva is stimulated by toothbrushing. However, research on free gingival grafts (see Chapter 66) has shown that when connective tissue is transplanted from a keratinized area to a nonkeratinized area, it becomes covered by a keratinized epithelium.[55] This finding suggests a connective tissue-based genetic determination of the type of epithelial surface.

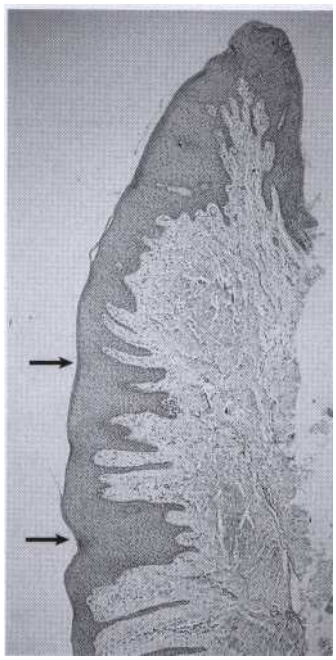

Fig. 1-28 Gingival biopsy of patient shown in Fig. 1-7, demonstrating alternate elevations and depressions *(arrows)* **in the attached gingiva responsible for stippled appearance.**

Position

The position of the gingiva refers to the level at which the gingival margin is attached to the tooth. When the tooth erupts into the oral cavity, the margin and sulcus are at the tip of the crown; as eruption progresses, they are seen closer to the root. During this eruption process, as described earlier, the junctional epithelium, oral epithelium, and reduced enamel epithelium undergo extensive alterations and remodeling, while at the same time maintaining the shallow physiologic depth of the sulcus. Without this remodeling of the epithelia, an abnormal anatomic relationship between the gingiva and the tooth would result.

Continuous Tooth Eruption. According to the concept of continuous eruption,[43] eruption does not cease when teeth meet their functional antagonists but continues throughout life. It consists of an active and a passive phase. Active eruption is the movement of the teeth in the direction of the occlusal plane, whereas passive eruption is the exposure of the teeth by apical migration of the gingiva.

This concept distinguishes between the anatomic crown (the portion of the tooth covered by enamel) and the anatomic root (the portion of the tooth covered by cementum) and between the clinical crown (the part of the tooth that has been denuded of its gingiva and projects into the oral cavity) and clinical root (the portion of the tooth covered by periodontal tissues). When the teeth reach their functional antagonists, the gingival sulcus and junctional epithelium are still on the enamel and the clinical crown is approximately two thirds of the anatomic crown.

Gottlieb believed that active and passive eruption proceed together. Active eruption is coordinated with attrition. The teeth erupt to compensate for tooth substance worn away by attrition. Attrition reduces the clinical crown and prevents it from becoming disproportionately

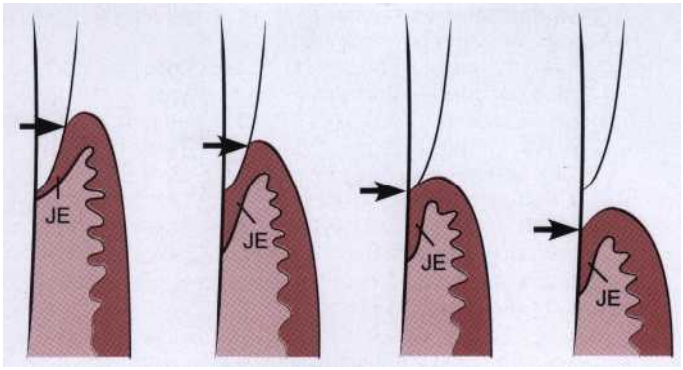

Fig. 1-29 Diagrammatic representation of the four steps in passive eruption according to Gottlieb and Orban. 45 1, Base of the gingival sulcus (arrow) and the junctional epithelium (JE) are on the enamel. 2, Base of the gingival sulcus (arrow) is on the enamel, and part of the junctional epithelium is on the root. 3, Base of the gingival sulcus (arrow) is at the cementoenamel line, and the entire junctional epithelium is on the root. 4, Base of the gingival sulcus (arrow) and the junctional epithelium are on the root.

long in relation to the clinical root, thus avoiding excessive leverage on the periodontal tissues. Ideally, the rate of active eruption keeps pace with tooth wear, preserving the vertical dimension of the dentition.

As teeth erupt, cementum is deposited at the apices and furcations of the roots, and bone is formed along the fundus of the alveolus and at the crest of the alveolar bone. In this way, part of the tooth substance lost by attrition is replaced by lengthening of the root, and socket depth is maintained to support the root.

Passive eruption is divided into four stages (Fig. *1-29).* Although this was originally thought to be a normal physiologic process, it is now considered a pathologic process.

Stage 1: The teeth reach the line of occlusion. The functional epithelium and base of the gingival sulcus are on the enamel.

Stage 2: The junctional epithelium proliferates so that part is on the cementum and part is on the enamel. The base of the sulcus is still on the enamel.

Stage 3: The entire junctional epithelium is on the cementum, and the base of the sulcus is at the cementoenamel junction. As the junctional epithelium proliferates from the crown onto the root, it does not remain at the cementoenamel junction any longer than at any other area of the tooth.

Stage 4: The junctional epithelium has proliferated farther on the cementum. The base of the sulcus is on the cementum, a portion of which is exposed. Proliferation of the junctional epithelium onto the root is accompanied by degeneration of gingival and periodontal ligament fibers and their detachment from the tooth. The cause of this degeneration is not understood. At present, it is believed to be the result of chronic inflammation and therefore a pathologic process.

As noted previously, apposition of bone accompanies active eruption. The distance between the apical end of the junctional epithelium and the crest of the alveolus remains constant throughout continuous tooth eruption (1.07 mm).40

Exposure of the tooth by the apical migration of the gingiva is called *gingival recession,* or *atrophy*. According to the concept of continuous eruption, the gingival sulcus may be located on the crown, cementoenamel junction, or root, depending on the age of the patient and stage of eruption. Therefore some root exposure with age would be considered normal and referred to as *physiologic recession.* As mentioned previously, this concept is not accepted at present. Excessive exposure is termed *pathologic recession* (see Chapter 17).

EXTERNAL FORCES AND THE PERIODONTIUM

VASCULARIZATION OF THE SUPPORTING STRUCTURES

The attachment apparatus of the tooth includes the periodontal ligament, cementum, and alveolar bone. The structure of these tissues will be considered first, followed by a description of their development, vascularization, innervation, and functions.

PERIODONTAL LIGAMENT

The periodontal ligament is the connective tissue that surrounds the root and connects it to the bone. It is continuous with the connective tissue of the gingiva and communicates with the marrow spaces through vascular channels in the bone.

Periodontal Fibers

The most important elements of the periodontal ligament are the *principal fibers,* which are collagenous, are arranged in bundles, and follow a wavy course when viewed in longitudinal sections (Fig. 2-1). Terminal portions of the principal fibers that insert into cementum and bone are termed *Sharpey's fibers* (Fig. 2-2). The principal fiber bundles consist of individual fibers that form a continuous anastomosing network between tooth and bone.[9,26]

Collagen is a protein composed of different amino acids, the most important of which are glycine, proline, hydroxylysine, and hydroxyproline.[22] The amount of collagen in a tissue can be determined by its hydroxyproline content.

Collagen biosynthesis occurs inside the fibroblasts to form tropocollagen molecules. These aggregate into microfibrils that are packed together to form fibrils. Collagen fibrils have a transverse striation with a characteristic periodicity of 64 nm; this striation is caused by the overlapping arrangement of the tropocollagen

Fig. 2-1 Principal fibers of the periodontal ligament follow a wavy course when sectioned longitudinally. The formative function of the periodontal ligament is illustrated by the newly formed osteoid and osteoblasts along a previously resorbed bone surface (left) and the cementoid and cementoblasts (right). Note the fibers embedded in the forming calcified tissues (arrows). V, Vascular channels.

molecules. In collagen types I and III, these fibrils associate to form fibers, and in collagen type I the fibers associate to form bundles (Fig. 2-3).

Collagen is synthesized by fibroblasts, chondroblasts, osteoblasts, odontoblasts, and other cells. The several types of collagen are all distinguishable by their chemical composition, distribution, function, and morphology.[63] The principal fibers are composed mainly of collagen type 1,[93] whereas reticular fibers are composed of collagen type III. Collagen type IV is found in the basal lamina.[94,95]

The molecular configuration of collagen fibers confers to them a tensile strength greater than that of steel. Consequently, collagen imparts a unique combination of flexibility and strength to the tissues wherein it lies.[13]

The principal fibers of the periodontal ligament are arranged in six groups that develop sequentially in the developing root: the transseptal, alveolar crest, horizontal, oblique, apical, and interradicular fibers (Fig. 2-4).

Transseptal group: Transseptal fibers extend interproximally over the alveolar bone crest and are embedded in the cementum of adjacent teeth (Fig. 2-S). They are a remarkably constant finding and are reconstructed even after destruction of the alveolar bone has occurred in periodontal disease. These fibers may be considered as belonging to the gingiva because they do not have osseous attachment.

Alveolar crest group: Alveolar crest fibers extend obliquely from the cementum just beneath the junctional epithelium to the alveolar crest (Fig. 2-6). Fibers also run from the cementum over the alveolar crest and to the fibrous layer of the periosteum covering the alveolar bone. The alveolar crest fibers prevent the extrusion of the tooth[24] and resist lateral tooth movements. Their incision does not significantly increase tooth mobility.[42]

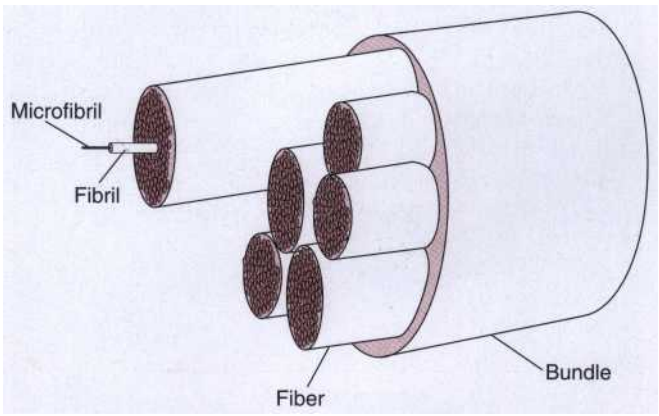

Fig. 2-3 Collagen microfibrils, fibrils, fibers, and bundles.

Horizontal group: Horizontal fibers extend at right angles to the long axis of the tooth from the cementum to the alveolar bone.

Oblique group: Oblique fibers, the largest group in the periodontal ligament, extend from the cementum in a coronal direction obliquely to the bone (see Fig. 2-4). They bear the brunt of vertical masticatory stresses and transform them into tension on the alveolar bone.

Apical group: The apical fibers radiate in a rather irregular fashion from the cementum to the bone at the apical region of the socket. They do not occur on incompletely formed roots.

interradicular fibers: The interradicular fibers fan out from the cementum to the tooth in the furcation areas of multirooted teeth.

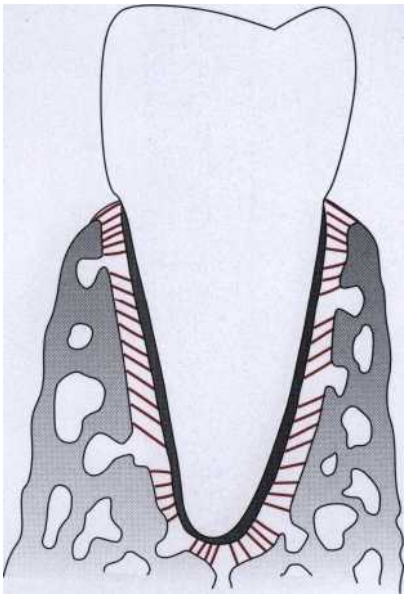

Fig. 2-4 Diagram of principal fiber groups.

Fig. 2-5 Transseptal fibers (F) at the crest of the interdental bone.

Other well-formed fiber bundles interdigitate at right angles or splay around and between regularly arranged fiber bundles. Less regularly arranged collagen fibers are found in the interstitial connective tissue between the principal fiber groups; this tissue contains the blood vessels, lymphatics, and nerves.

Although the periodontal ligament does not contain mature elastin, two immature forms are found-oxytaIan and eluanin. The so-called *oxytalan fibers*[37,46] run parallel to the root surface in a vertical direction and bend to attach to cementum" in the cervical third of the root. They are thought to regulate vascular flow.[36] An elastic meshwork has been described in the periodontal ligament[59] as being composed of many elastin lamellae with peripheral oxytalan fibers and eluanin fibers. Oxytalan

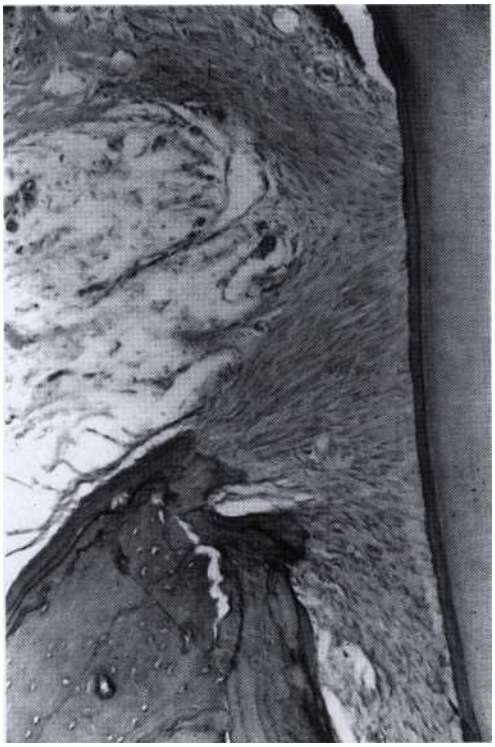

Fig. 2-6 Alveolar crest fibers in rat molar.

fibers have been shown to develop de novo in the regenerated periodontal ligament.[99]

The principal fibers are remodeled by the periodontal ligament cells to adapt to physiologic needs[108,125] and in response to different stimuli.'"

In addition to these fiber types, small collagen fibers associated with the larger principal collagen fibers have been described. These fibers run in all directions, forming a plexus called the *indifferent fiber plexus.*[104]

Cellular Elements

Four types of cells have been identified in the periodontal ligament: connective tissue cells, epithelial rest cells, ¡mmune system cells, and cells associated with neurovascular elements.$

Connective tissue cells include fibroblasts, cementoblasts, and osteoblasts. Fibroblasts are the most common cells in the periodontal ligament and appear as ovoid or elongated cells oriented along the principal fibers and exhibiting pseudopodialike processes.[92] These cells synthesize collagen and also possess the capacity to phagocytose "old" collagen fibers and degrade them[108] by enzyme hydrolysis. Thus collagen turnover appears to be regulated by fibroblasts in a process of intracellular degradation of collagen not involving the action of collagenase.[7]

Phenotypically distinct and functionally different subpopulations of fibroblasts exist in the adult periodontal ligament. They look identical at both light and electron microscopic levelss' but may have different

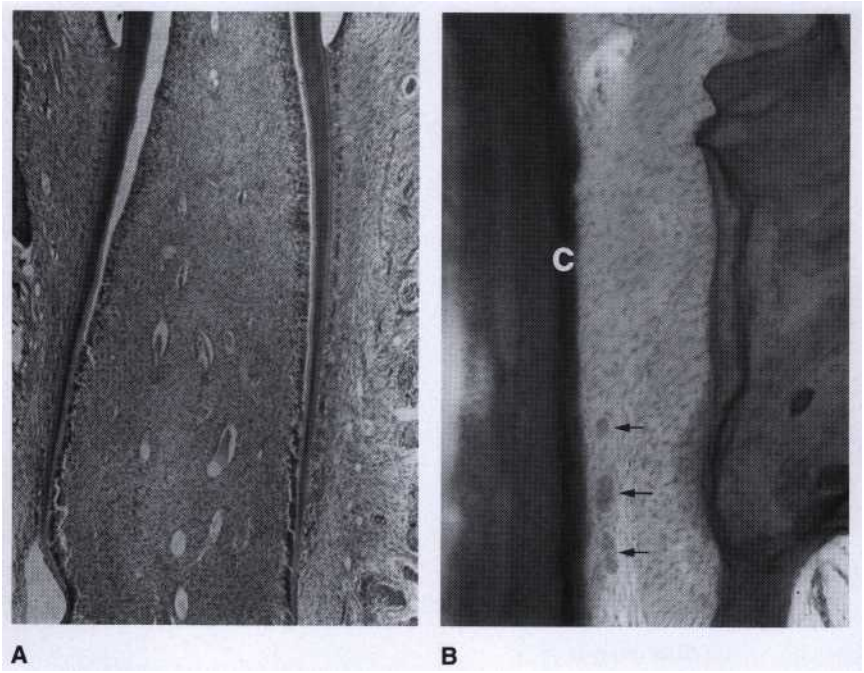

Fig. 2-7 Epithelial rests of Malassez. A, Erupting tooth in a cat. Fragmentation of Hertwig's epithelial root sheath giving rise to epithelial rests located along, and close to, the root surface. B, Human periodontal ligament with rosette-shaped epithelial rests (arrows) lying close to the cementum (C).

functions such as secretion of collagen of different types or production of collagenase.

Osteoblasts and cementoblasts, as well as osteoclasts and odontoclasts, also are seen in the cemental and osseous surfaces of the periodontal ligament.

The *epithelial rests of Malassez* form a latticework in the periodontal ligament and appear as either isolated clusters of cells or interlacing strands (Fig. 2-7), depending on the plane in which the microscopic section is cut. Continuity with the junctional epithelium in experimental animals has been suggested.[48] The epithelial rests are considered remnants of Hertwig's root sheath, which disintegrates during root development.

Epithelial rests are distributed close to the cementum throughout the periodontal ligament of most teeth and are most numerous in the apical$$ and cervical areas. They diminish in number with age[106] by degenerating and disappearing or undergoing calcification to become cementicles. The cells are surrounded by a distinct basal lamina, are interconnected by hemidesmosomes, and contain tonofilaments.[7] Epithelial rests proliferate when stimulated[109-112,116] and participate in the formation of periapical cysts and lateral root cysts.

The defense cells include neutrophils, lymphocytes, macrophages, mast cells, and eosinophils. These, as well as those cells associated with neurovascular elements, are similar to those in other connective tissues.

Ground Substance

The periodontal ligament also contains a large proportion of ground substance filling the spaces between fibers and cells. It consists of two main components: *glycosaminoglycans,* such as hyaluronic acid and proteoglycans, and *glycoproteins* such as fibronectin and laminin. It also has a high water content (70%).

The periodontal ligament also may contain calcified masses called *cementicles,* which are adherent to or detached from the root surfaces (Fig. 2-8). Cementicles may develop from calcified epithelial rests; around small spicules of cementum or alveolar bone traumatically displaced into the periodontal ligament; from calcified Sharpey's fibers; and from calcified, thrombosed vessels within the periodontal ligament.[75]

Functions of the Periodontal Ligament

The functions of the periodontal ligament are physical, formative and remodeling, nutritional, and sensory.

Physical Function. The physical functions of the periodontal ligament entail the following:

1. Provision of a soft tissue "casing" to protect the vessels and nerves from injury by mechanical forces
2. Transmission of occlusal forces to the bone
3. Attachment of the teeth to the bone
4. Maintenance of the gingival tissues in their proper relationship to the teeth
5. Resistance to the impact of occlusal forces (shock absorption)

RESISTANCE TO THE IMPACT OF OCCLUSAL FORCES (SHOCK ABSORPTION). Two theories relative to the mechanism of tooth support have been considered: the tensional and viscoelastic system theories.

Fig. 2-8 Cementicles in the periodontal ligament, one lying free and the other adherent to the tooth surface.

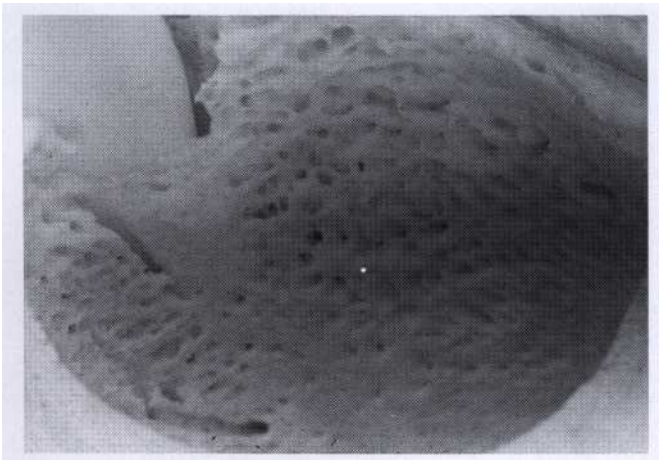

Fig. 2-9 Foramina perforating the lamina dura (dog jaw).

The *tensional theory* of tooth support ascribes to the principal fibers of the periodontal ligament the major responsibility in supporting the tooth and transmitting forces to the bone. When a force is applied to the crown, the principal fibers first unfold and straighten and then transmit forces to the alveolar bone, causing an elastic deformation of the bony socket. Finally, when the alveolar bone has reached its limit, the load is transmitted to the basal bone. Many investigators find this theory insufficient to explain available experimental evidence.

The *viscoelastic system theory* considers the displacement of the tooth to be largely controlled by fluid movements, with fibers having only a secondary role.[14,21]

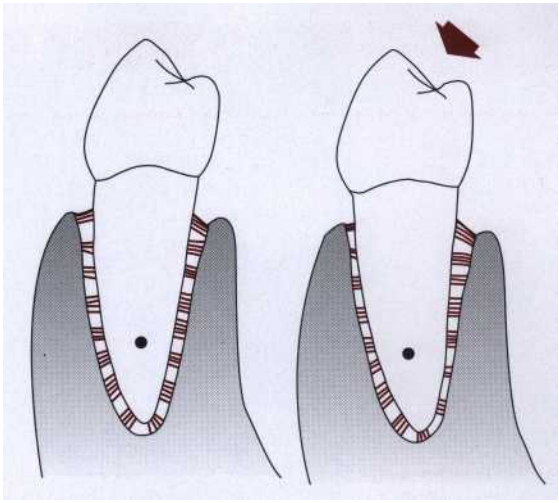

Fig. 2-10 *Right,* **Distribution of faciolingual forces** *(arrow)* **around the axis of rotation** *(black circle on root)* **in a mandibular premolar. The periodontal ligament fibers are compressed in areas of pressure and tension.** *Left,* **The same tooth in a resting state.**

When forces are transmitted to the tooth, the extracellular fluid passes from the periodontal ligament into the marrow spaces of bone through foramina in the cribriform plate. These perforations of the cribriform plate link the periodontal ligament with the cancellous portion of the alveolar bone and are more abundant in the cervical third than in the middle and apical thirds (Fig. 2-9).

After depletion of tissue fluids, the fiber bundles absorb the slack and tighten. This leads to blood vessel stenosis. Arterial back pressure causes ballooning of the vessels, and passage of blood ultrafiltrates into the tissues, thereby replenishing the tissue fluids.14

TRANSMISSION OF OCCLUSAL FORCES TO THE BONE. The arrangement of the principal fibers is similar to a suspension bridge or hammock. When an axial force is applied to a tooth, a tendency toward displacement of the root into the alveolus occurs. The oblique fibers alter their wavy, untensed pattern; assume their full length; and sustain the major part of the axial force. When a horizontal or tipping force is applied, two phases of tooth movement occur. The first is within the confines of the periodontal ligament, and the second produces a displacement of the facial and lingual bony plates.31 The tooth rotates about an axis that may change as the force is increased.

The apical portion of the root moves in a direction opposite to the coronal portion. In areas of tension, the principal fiber bundles are taut rather than wavy. In areas of pressure, the fibers are compressed, the tooth is displaced, and a corresponding distortion of bone exists in the direction of root movement.[85]

In single-rooted teeth, the axis of rotation is located in the area between the apical third and the middle third of the root (Fig. 2-10). The root apex78 and the coronal half of the clinical root have been suggested as other locations of the axis of rotation. The periodontal ligament, which is shaped like an hourglass, is narrowest in the region of the axis of rotation[29,61] (Table 2-1). In multirooted teeth, the axis of rotation is located in the bone

TABLE 2-1

Thickness of Periodontal Ligament of 172 Teeth from 15 Human Jaws

	Average of Alveolar Crest (mm)	Average of Mid-root (mm)	Average of Apex (mm)	Average of Tooth (mm)
Ages 11-16				
83 teeth from 4 jaws	0.23	0.17	0.24	0.21
Ages 32-50				
36 teeth from 5 jaws	0.20	0.14	0.19	0.18
Ages 51-67				
35 teeth from 5 jaws	0.17	0.12	0.16	0.15
Age 24 (1 case)				
18 teeth from 1 jaw	0.16	0.09	0.15	0.13

Modified from Coolidge ED: The thickness of the human periodontal membrane. J Am Dent Assoc 1937; 24:1260.

between the roots (Fig. 2-11). In compliance with the physiologic mesial migration of the teeth, the periodontal ligament is thinner on the mesial root surface than on the distal surface.

Formative and Remodeling Function. Cells of the periodontal ligament participate in the formation and resorption of cementum and bone, which occur in physiologic tooth movement; in the accommodation of the periodontium to occlusal forces; and in the repair of injuries. Variations in cellular enzyme activity[39-41] are correlated with the remodeling process.

Cartilage formation in the periodontal ligament, although unusual, may represent a metaplastic phenomenon in the repair of this ligament after injury.[4]

The periodontal ligament is constantly undergoing remodeling. Old cells and fibers are broken down and replaced by new ones, and mitotic activity can be observed in the fibroblasts and endothelial cells." Fibroblasts form the collagen fibers, and the residual mesenchymal cells develop into osteoblasts and cementoblasts. Therefore the rate of formation and the differentiation of osteoblasts, cementoblasts, and fibroblasts affect the rate of formation of collagen, cementum, and bone.

Radioautographic studies with radioactive thymidine, proline, and glycine indicate a very high turnover rate of collagen in the periodontal ligament. The rate of collagen synthesis is twice as fast as that in the gingiva and four times as fast as that in the skin, as established in the rat molar. A rapid turnover of sulfated glycosaminoglycans in the cells and amorphous ground substance of the periodontal ligament also occurs.'

It should be noted that most of these studies have been performed in rodents, and information on primates and humans is scarce.100

Nutritional and Sensory Functions. The periodontal ligament supplies nutrients to the cementum, bone, and gingiva by way of the blood vessels and provides lymphatic drainage (see later discussion).

The periodontal ligament is abundantly supplied

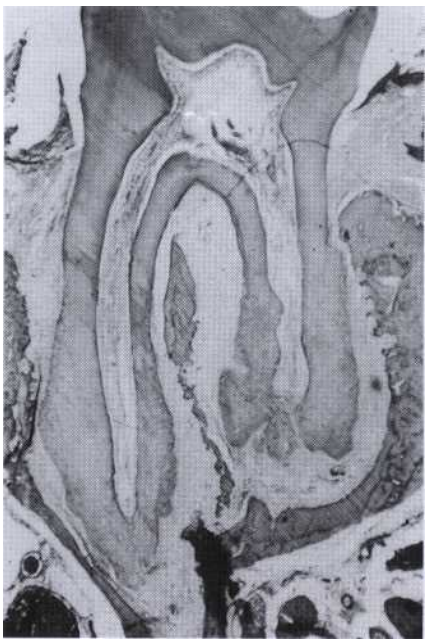

Fig. 2-11 Microscopic view of rat molar subjected to occlusohorizontal forces. Note the widened and narrowed areas of the periodontal ligament. The axis of rotation is in the interradicular space.

with sensory nerve fibers capable of transmitting tactile, pressure, and pain sensations by the trigeminal pathways.[3,13] Nerve bundles pass into the periodontal ligament from the periapical area and through channels from the alveolar bone that follow the course of the blood vessels. They divide into single myelinated fibers, which ultimately lose their myelin sheaths and end in one of four types of neural termination: free endings, which have a treelike configuration and carry pain sensation; Ruffini-like mechanoreceptors, located primarily in the apical area; coiled Meissner's corpuscles, also mechanoreceptors, found mainly in the midroot region; and spindlelike pressure and vibration endings, which

are surrounded by a fibrous capsule and located mainly in the apex.

CEMENTUM

Cementum is the calcified avascular mesenchymal tissue that forms the outer covering of the anatomic root. The two main types of cementum are acellular (primary) and cellular (secondary) cementum .[47] Both consist of a calcified interfibrillar matrix and collagen fibrils.

The two sources of collagen fibers in cementum are Sharpey's (extrinsic) fibers, which are the embedded portion of the principal fibers of the periodontal ligament[94] and are formed by the fibroblasts, and fibers that belong to the cementum matrix per se (intrinsic) and are produced by the cementoblasts. [102] Cementoblasts also form the noncollagenous components of the interfibrillar ground substance, such as proteoglycans, glycoproteins, and phosphoproteins.

Acellular cementum is the first to be formed and covers approximately the cervical third or half of the root; it does not contain cells (Fig. 2-12). This cementum is formed before the tooth reaches the occlusal plane, and its thickness ranges from 30 to 230 Am.i°° Sharpey's fibers comprise most of the structure of acellular cementum, which has a principal role in supporting the tooth. Most fibers are inserted at approximately right angles into the root surface and penetrate deep into the cementum, but others enter from several different directions. Their size, number, and distribution increase with functions' Sharpey's fibers are completely calcified, with the mineral crystals oriented parallel to the fibrils as in dentin and bone, except in a 10- to 50-gm-wide zone near the cementodentinal junction, where they are only partially calcified. The peripheral portions of Sharpey's fibers in actively mineralizing cementum tend to be more calcified than the interior regions, according to evidence obtained by scanning electron microscopy.[61] Acellular cementum also contains intrinsic collagen fibrils that are calcified and irregularly arranged or parallel to the surface.'°°

Cellular cementum, formed after the tooth reaches the occlusal plane, is more irregular and contains cells (cementocytes) in individual spaces (lacunae) that communicate with each other through a system of anastomosing canaliculi (Fig. 2-13). Cellular cementum is less calcified than the acellular type.[58] Sharpey's fibers occupy a smaller portion of cellular cementum and are separated by other fibers that are arranged either parallel to the root surface or at random. Sharpey's fibers may be completely or partially calcified or have a central, uncalcified core surrounded by a calcified border.[60,102]

Both acellular cementum and cellular cementum are arranged in lamellae separated by incremental lines parallel to the long axis of the root (see Figs. 2-12 and 2-13). These lines represent rest periods in cementum formation and are more mineralized than the adjacent cementum.[96] In addition, loss of the cervical part of the reduced enamel epithelium at the time of tooth eruption may place portions of mature enamel in contact with the connective tissue, which then will deposit over it an acellular afibrillar type of cementum.[69]

Based on these findings, Schroeder'°° has classified cementum as follows:

Acellular afibrillar cementum (AAC) contains neither cells nor extrinsic or intrinsic collagen fibers, apart from a mineralized ground substance. It is a product of cementoblasts and is found as coronal cementum in humans, with a thickness of 1 to 15 Am.

Acellular extrinsic fiber cementum (AEFC) is composed almost entirely of densely packed bundles of Sharpey's fibers and lacks cells. It is a product of fibroblasts and cementoblasts and is found in the cervical third of roots in humans but may extend further apically. Its thickness is between 30 and 230 Am.

Cellular mixed stratified cementum (CMSC) is composed of extrinsic (Sharpey's) and intrinsic fibers and may contain cells. It is a co-product of fibroblasts and cementoblasts, and in humans it appears primarily in the apical third of the roots and apices and in furcation areas. Its thickness ranges from 100 to 1000 gym.

Cellular intrinsic fiber cementum (CIFC) contains cells but no extrinsic collagen fibers. It is formed by cementoblasts, and in humans it fills resorption lacunae.

Intermediate cementum is an ill-defined zone near the cementodentinal junction of certain teeth that appears to contain cellular remnants of Hertwig's sheath embedded in calcified ground substance .[33,68]

The inorganic content of cementum (hydroxyapatite; $Ca_{10}[Po_4]_6[OH]_2$) is 45% to 50%, which is less than that of bone (65%), enamel (97%), or dentin (70%).'[2]' Opinions differ about whether the microhardness increases or decreases with age,[122] and no relationship has been established between aging and the mineral content of cementum.

Permeability of Cementum

In very young animals, cellular and acellular cementum are very permeable and permit the diffusion of dyes from the pulp and external root surface. In cellular cementum, the canaliculi in some areas are contiguous with the dentinal tubuli. The permeability of cementum diminishes with age."

Cementoenamel junction

The cementum at and immediately subjacent to the cementoenamel junction is of particular clinical importance in root scaling procedures. Three types of relationships involving the cementum may exist at the cementoenamel junction.$° In about 60% to 65% of cases, cementum overlaps the enamel (Fig. 2-14); in about 30% an edge-to-edge butt joint exists; and in 5% to 10% the cementum and enamel fail to meet. In the last instance, gingival recession may result in accentuated sensitivity because the dentin is exposed.

Thickness of Cementum

Cementum deposition is a continuous process that proceeds at varying rates throughout life. Cementum

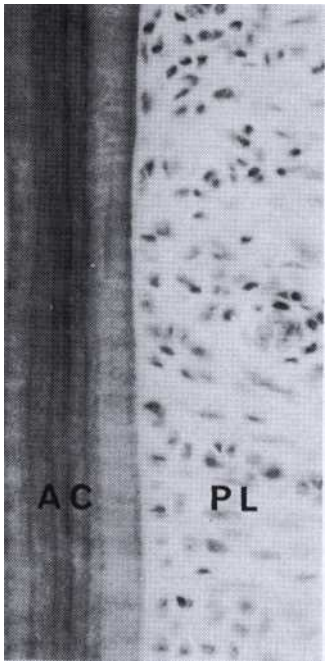

Fig. 2-12 Acellular cementum (AC) showing incremental lines running parallel to the long axis of the tooth. These lines represent the appositional growth of cementum. Note the thin, light lines running into the cementum perpendicular to the surface; these represent Sharpey's fibers of the periodontal ligament (PL). *D,* Dentin. (Magnification x300.)

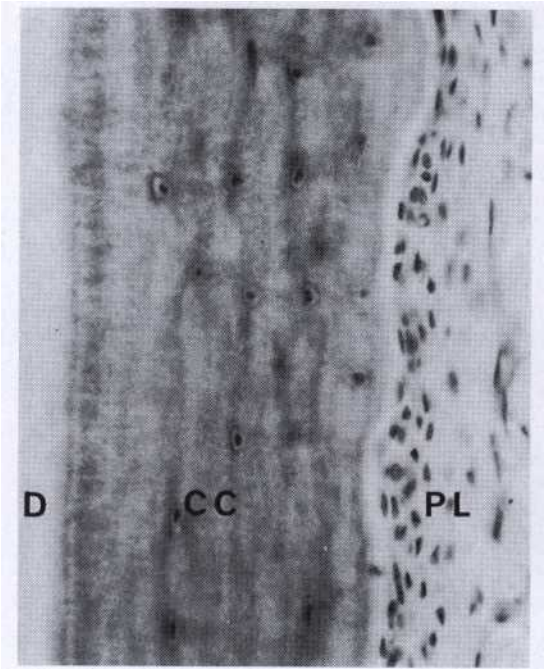

Fig. 2-13 Cellular cementum (CC) showing cementocytes lying within lacunae. Cellular cementum is thicker than acellular cementum (cf. Fig. 2-16). Evidence of incremental lines also exists, but they are less distinct than in acellular cementum. The cells adjacent to the surface of the cementum in the periodontal ligament *(PL)* space are cementoblasts. *D,* Dentin. (Magnification x300.)

formation is most rapid in the apical regions, where it compensates for tooth eruption, which itself compensates for attrition. The thickness of cementum on the coronal half of the root varies from 16 to 60 Am, or about the thickness of a hair. It attains its greatest thickness (up to 150 to 200 Am) in the apical third and in the furcation areas. It is thicker in distal surfaces than in mesial surfaces, probably because of functional stimulation from mesial drift over time.[30] Between the ages of 11 and 70, the average thickness of the cementum increases threefold, with the greatest increase in the apical region. Average thicknesses of 95 Am at age 20 and 215 Am at age 60 have been reported.[126]

The term *hypercementosis* (cementum hyperplasia) refers to a prominent thickening of the cementum. It may be localized to one tooth or affect the entire dentition. Because of considerable physiologic variation in the thickness of cementum among different teeth in the same person and also among different persons, distinguishing between hypercementosis and physiologic thickening of cementum is sometimes difficult.

Hypercementosis occurs as a generalized thickening of the cementum, with nodular enlargement of the apical third of the root. It also appears in the form of spikelike excrescences (cemental spikes) created by either the coalescence of cementicles that adhere to the root or the calcification of periodontal fibers at the sites of insertion into the cementum.[68]

The etiology of hypercementosis varies and is not completely understood. The spikelike type of hypercementosis generally results from excessive tension from orthodontic appliances or occlusal forces. The generalized type occurs in a variety of circumstances. In teeth without antagonists, hypercementosis is interpreted as an effort to keep pace with excessive tooth eruption. In teeth subject to low-grade periapical irritation arising from pulp disease, it is considered compensation for the destroyed fibrous attachment to the tooth. The cementum is deposited adjacent to the inflamed periapical tissue. Hypercementosis of the entire dentition may occur in patients with Paget's disease.[98]

Cernenturn Resorption and Repair

Permanent teeth do not undergo physiologic resorption as do primary teeth. However, the cementum of erupted as well as unerupted teeth is subject to resorptive changes that may be of microscopic proportion or sufficiently extensive to present a radiographically detectable alteration in the root contour. Microscopic cementum resorption is extremely common. In one study, it occurred in 236 of 261 teeth (90.5%).s[4] The average number of resorption areas per tooth was 3.5. Of the 922 areas of resorption, 708 (76.8%) were located in the apical third of the root, 177 (19.2%) in the middle third, and 37 (4.0%) in the gingival third. Approximately 70% of all resorption areas were confined to the cementum without involving the dentin.

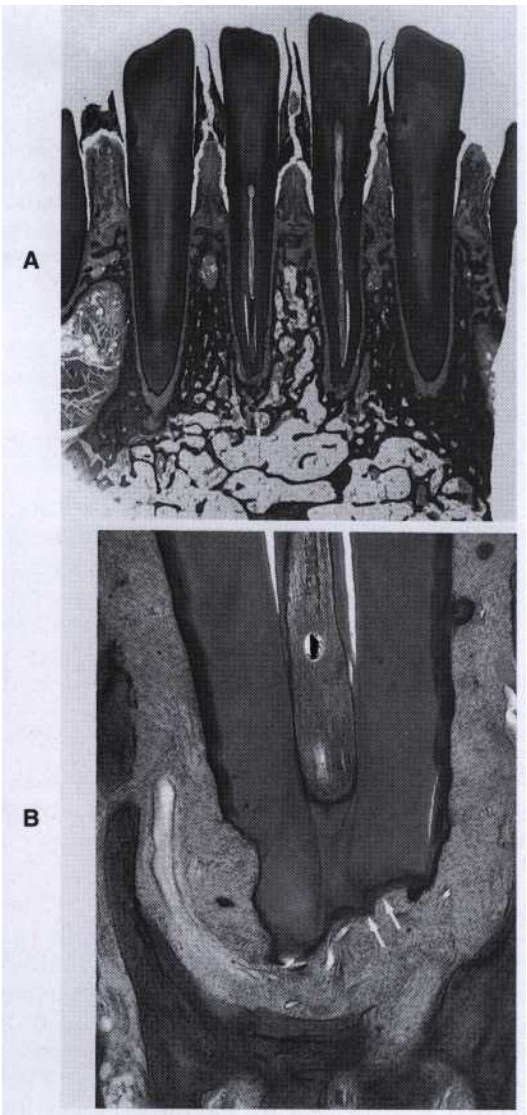

Fig. 2-15 Cemental resorption associated with excessive occlusal forces. A, Low-power histologic section of mandibular anterior teeth. B, High-power micrograph of apex of left central incisor shortened by resorption of cementum and dentin. Note partial repair of the eroded areas (arrows) and cementicle at upper right.

Cementum resorption may be caused by local or systemic causes or may occur without apparent etiology (i.e., idiopathic). Among the local conditions in which it occurs are trauma from occlusion[12] (Fig. 2-15); orthodontic movement;[53,81,97] pressure from malaligned erupting teeth, cysts, and tumors;[66] teeth without functional antagonists; embedded teeth; replanted and transplanted teeth;[1,60] periapical disease; and periodontal disease. Among the systemic conditions mentioned as predisposing to or inducing cemental resorption are calcium deficiency,[62] hypothyroidism,' hereditary fibrous osteodystrophy,[114] and Paget's disease.[98]

Cementum resorption appears microscopically as baylike concavities in the root surface (Fig. 2-16). Multinucleated giant cells and large mononuclear macrophages are generally found adjacent to cementum undergoing active resorption (Fig. 2-17). Several sites of resorption may coalesce to form a large area of destruction. The resorptive process may extend into the underlying dentin and even into the pulp, but it is usually painless. Cementum resorption is not necessarily continuous and may alternate with periods of repair and the deposition of new cementum. The newly formed cementum is demarcated from the root by a deeply staining irregular line, termed a *reversal line,* which delineates the border of the previous resorption (Fig. 2-18). Embedded fibers of the periodontal ligament reestablish a functional relationship in the new cementum. Cementum repair requires the presence of viable connective tissue. If epithelium proliferates into an area of resorption, repair will not take place. Cementum repair can occur in devitalized as well as in vital teeth.

Ankylosis. Fusion of the cementum and alveolar bone with obliteration of the periodontal ligament is termed *ankylosis.* Ankylosis occurs in teeth with cemental resorption, which suggests that it may represent a form of abnormal repair. Ankylosis also may develop

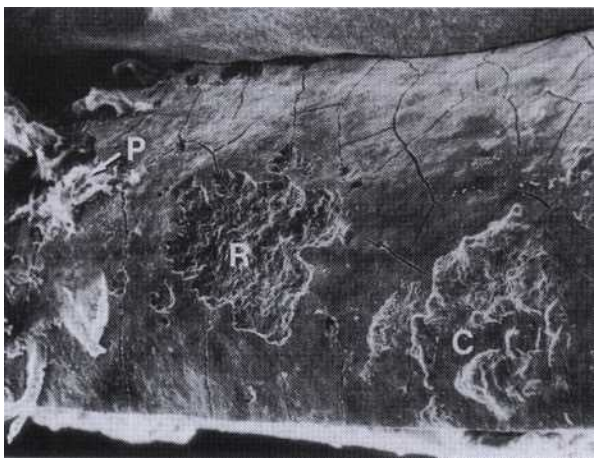

Fig. 2-16 Scanning electron micrograph of root exposed by periodontal disease showing large resorption bay (R). Remnants of the periodontal ligament (P) and calculus (C are visible. Cracking of the tooth surface occurs as a result of the preparation technique. (Magnification x160.) (Courtesy John Sottosanti, San Diego, Calif.)

after chronic periapical inflammation, tooth replantation, and occlusal trauma and around embedded teeth.

Ankylosis results in resorption of the root and its gradual replacement by bone tissue. For this reason, reimplanted teeth that ankylose will lose their roots after 4 to 5 years and exfoliate.

When titanium implants are placed in the jaw, healing results in bone formed in direct apposition to the implant without any intervening connective tissue. This may be interpreted as a form of ankylosis. Because resorption of the metallic implant cannot occur, the implant remains indefinitely "ankylosed" to the bone. Also, a true periodontal pocket will not form because apical proliferation of the epithelium along the root, a key element of pocket formation, is not possible owing to the ankylosis.

Exposure of Cementum to the Oral Environment

Cementum becomes exposed to the oral environment in cases of gingival recession and as a consequence of loss of attachment in pocket formation. The cementum is sufficiently permeable to be penetrated in these cases by organic substances, inorganic ions, and bacteria. Bacterial invasion of the cementum occurs commonly in periodontal disease (see Chapter 22). Caries of the cementum also can develop (see Chapter 30).

ALVEOLAR PROCESS

The *alveolar process is* the portion of the maxilla and mandible that forms and supports the tooth sockets (alveoli). It forms when the tooth erupts to provide the osseous attachment to the forming periodontal ligament; it disappears gradually after the tooth is lost.

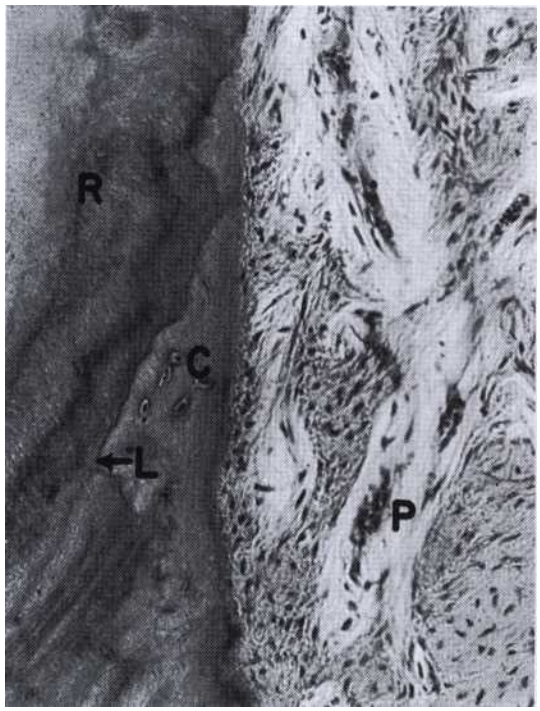

Fig. 2-18 Section showing repair of previously resorbed root. The defect is filled in with cellular cementum (C), which is separated from the older cementum (R) by an irregular line (L) that indicates the preexisting outline of the resorbed root. P, Periodontal ligament.

The alveolar process consists of the following:

1. An external plate of cortical bone formed by haversian bone and compacted bone lamellae
2. The inner socket wall of thin, compact bone called the *alveolar bone proper,* which is seen as the lamina dura in radiographs. Histologically, it contains a series of openings *(cribri form plate)* through which neurovascular bundles link the periodontal ligament with the central component of the alveolar bone, the cancellous bone.
3. Cancellous trabeculae, between these two compact layers, which act as supporting alveolar bone. The *interdental septum* consists of cancellous supporting bone enclosed within a compact border (Fig. 2-19).

In addition, the jaw bones consist of the *basal bone,* which is the portion of the jaw located apically but unrelated to the teeth (Fig. 2-20).

The alveolar process is divisible into separate areas on an anatomic basis, but it functions as a unit, with all parts interrelated in the support of the teeth. Figs. 2-21 and 2-22 show the relative proportions of cancellous bone and compact bone that form the alveolar process. Most of the facial and lingual portions of the sockets are formed by compact bone alone; cancellous bone surrounds the lamina dura in apical, apicolingual, and interradicular areas.

Cells and Intercellular Matrix

Osteoblasts, the cells that produce the organic matrix of bone, are differentiated from pluripotent follicle cells.

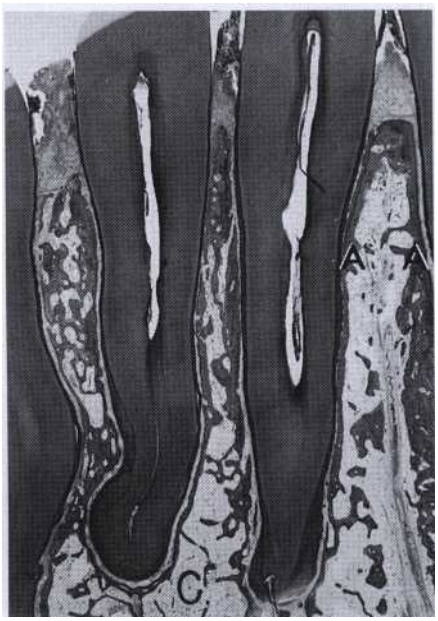

Fig. 2-19 Mesiodistal section through mandibular canine and premolars showing interdental bony septa. The dense bony plates (A) represent the alveolar bone proper (cribriform plates) and are supported by cancellous bony trabeculae (C). Note the vertical blood vessels within a nutrient canal in the interdental septum at the right.

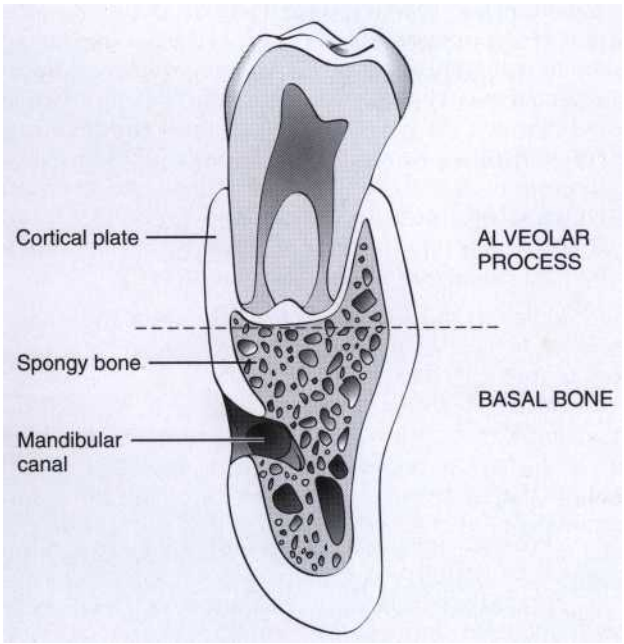

Fig. 2-20 Section through human jaw with tooth in situ. The dotted line indicates the separation between basal bone and alveolar bone. (Redrawn from Ten Cate AR: Oral Histology. Development, Structure, and Function, ed 4. St Louis, Mosby, 1994.)

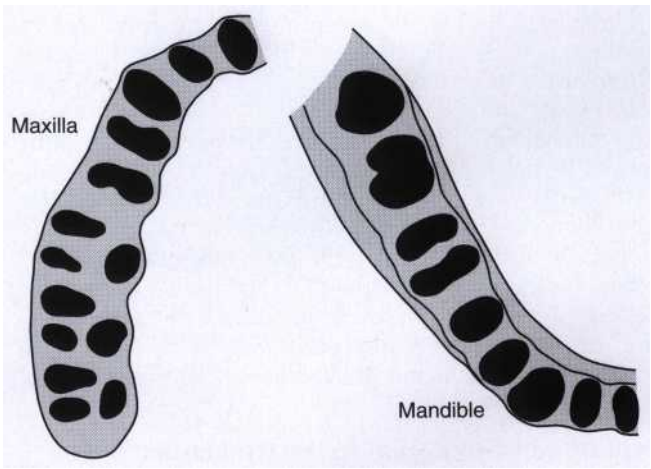

Fig. 2-22 Shape of roots and surrounding bone distribution in a transverse section of maxilla and mandible at mid-root level.

Alveolar bone is formed during fetal growth by intramembranous ossification and consists of a calcified matrix with osteocytes enclosed within spaces called lacunae. The osteocytes extend processes into canaliculi that radiate from the lacunae. The canaliculi form an anastomosing system through the intercellular matrix of the bone, which brings oxygen and nutrients to the osteocytes through the blood and removes metabolic waste products. Blood vessels branch extensively and travel through the periosteum The endosteum lies adjacent to the marrow vasculature Bone growth occurs by apposition of an

organic matrix that is deposited by osteoblasts. Haversian systems (osteons) are the internal mechanisms that bring a vascular supply to bones too thick to be supplied only by surface vessels. These are found primarily in the outer cortical plates and the alveolar bone proper.

Bone consists of two-thirds inorganic matter and one-third organic matrix. The inorganic matter is composed principally of the minerals calcium and phosphate, along with hydroxyl, carbonate, citrate, and trace amounts of other ions[44] such as sodium, magnesium, and fluorine. The mineral salts are in the form of hydroxyapatite crystals of ultramicroscopic size and constitute approximately two thirds of the bone structure.

The organic matrix[32] consists mainly (90%) of collagen type I,[76] with small amounts of noncollagenous proteins such as osteocalcin, osteonectin, bone morphogenetic protein, phosphoproteins, and proteoglycans.[87]

Although the alveolar bone tissue is constantly changing in its internal organization, it retains approximately the same form from childhood through adult life. Bone deposition by osteoblasts is balanced by resorption by osteoclasts during tissue remodeling and renewal.

Remodeling is the major pathway of bony changes in shape, resistance to forces, repair of wounds, and calcium and phosphate homeostasis in the body.

Bone contains 99% of calcium ions of the body and therefore is the major source for calcium release when the calcium blood levels decrease, this is monitored by the parathyroid gland. Blood calcium decrease is mediated by receptors on the chief cells of the parathyroid glands, which then release parathyroid hormone (PTH). PTH stimulates osteoblasts to release interleukin 1 and 6, which stimulates monocytes to migrate into the bone area. Leukemia inhibiting factor (LIF), secreted by osteoblasts, coalesce monocytes into multinucleated osteoclasts, which then resorb bone, releasing calcium ions from hydroxyapatite into the blood. This release normalizes the blood level of calcium. A feedback mechanism of normal blood levels of calcium turns off the parathyroid gland secretion of PTH. In the meantime, osteoclasts have resorbed organic matrix along with hydroxyapatite. The breakdown of collagen from the organic matrix releases various osteogenic substrates, which are covalently bound to collagen, and this in turn stimulates the differentiation of osteoblasts, which ultimately deposit bone. This interdependency of osteoblasts and osteoclasts in remodeling is called *coupling.*

The bone matrix that is laid down by osteoblasts is nonmineralized *osteoid.* While new osteoid is being deposited, the older osteoid located below the surface becomes mineralized as the mineralization front advances.

Bone resorption is a complex process morphologically related to the appearance of eroded bone surfaces (Howship's lacunae) and large, multinucleated cells (osteoclasts) (Fig. 2-23). Osteoclasts originate from hematopoietic tissue[21,50,7°] and are formed by the fusion of mononuclear cells of asynchronous populations .[10,64,84,113] When osteoclasts are active as opposed to resting, they possess an elaborately developed ruffled border from which hydrolytic enzymes are believed to be secreted.[118] These enzymes digest the organic portion of bone. The activity of osteoclasts and morphology of the ruffled border can be modified and regulated by hormones such as parathormone (indirectly) and calcitonin, which has receptors on the osteoclast membrane.

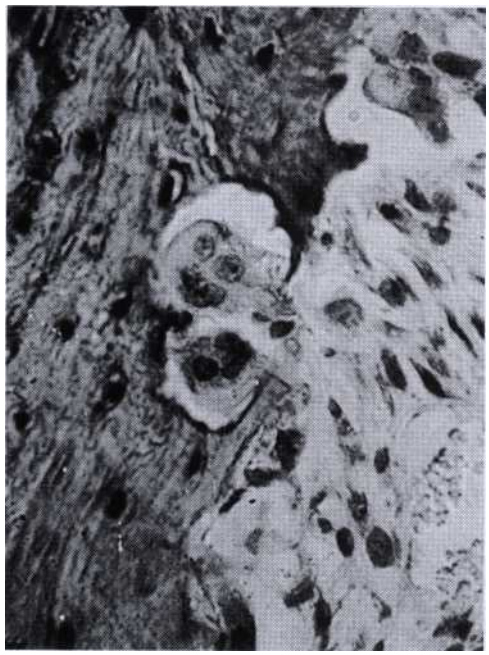

Fig. 2-23 Rat alveolar bone. Histologic view of two multinucleated osteoclasts in a Howship lacuna.

Another mechanism of bone resorption consists of the creation of an acidic environment on the bone surface, leading to the dissolution of the mineral component of bone. This event can be produced by different conditions, among them a proton pump through the cell membrane of the osteoclast," bone tumors, or local pressure,'° translated through the secretory activity of the osteoclast.

Ten Cate described the sequence of events in the resorptive process as follows:

1. Attachment of osteoclasts to the mineralized surface of bone
2. Creation of a sealed acidic environment through action of the proton pump, which demineralizes bone and exposes the organic matrix
3. Degradation of the exposed organic matrix to its constituent amino acids by the action of released enzymes, such as acid phosphatase and cathepsine
4. Sequestering of mineral ions and aminoacids within the osteoclast

Socket Wall

The socket wall consists of dense, lamellated bone, some of which is arranged in haversian systems, and bundle bone. *Bundle bone is* the term given to bone adjacent to the periodontal ligament that contains a great number of Sharpey's fibers (Fig. 2-24).[123] It is characterized by thin lamellae arranged in layers parallel to the root, with intervening appositional lines (Fig. 2-2S). Bundle bone is localized within the alveolar bone proper. Some

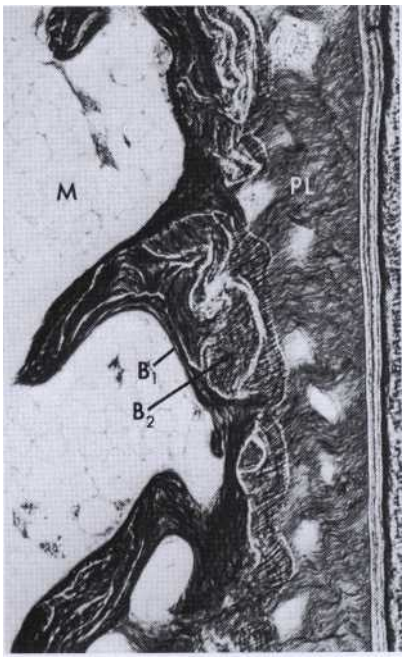

Fig. 2-24 Deep penetration of Sharpey's fibers into bundle bone. The darkly stained bone (B,) is lamellar bone. Bundle bone *(B2)* **takes up less stain and shows numerous white lines running more or less parallel to each other; these lines correspond to Sharpey's fibers. M, Fatty marrow; PL, periodontal ligament.**

Sharpey's fibers are completely calcified, but most contain an uncalcified central core within a calcified outer layer.[o2] Bundle bone is not unique to the jaws; it occurs throughout the skeletal system wherever ligaments and muscles are attached.

The cancellous portion of the alveolar bone consists of trabeculae that enclose irregularly shaped marrow spaces lined with a layer of thin, flattened endosteal cells. Wide variation occurs in the trabecular pattern of cancellous bone, which is affected by occlusal forces. The matrix of the cancellous trabeculae consists of irregularly arranged lamellae separated by deeply staining incremental and resorption lines indicative of previous bone activity, with an occasional haversian system.

Cancellous bone is found predominantly in the interradicular and interdental spaces and in limited amounts facially or lingually, except in the palate. In the adult human, more cancellous bone exists in the maxilla than in the mandible.

Bone Marrow

In the embryo and newborn, the cavities of all bones are occupied by red hematopoietic marrow. The red marrow gradually undergoes a physiologic change to the fatty or yellow inactive type of marrow. In the adult, the marrow of the jaw is normally of the latter type, and red marrow is found only in the ribs, sternum, vertebrae, skull, and humerus. However, foci of red bone marrow are occasionally seen in the jaws, often accompanied by resorption of bony trabeculae.[19] Common locations are the maxillary tuberosity (Fig. 2-26), the maxillary and mandibular molar and premolar areas, and the mandibular symphysis and ramus angle, which may be visible radiographically as zones of radiolucency.

Periosteum and Endosteum

All bone surfaces are covered by layers of differentiated osteogenic connective tissue. The tissue covering the outer surface of bone is termed *periosteum,* whereas the tissue lining the internal bone cavities is called *endosteum.*

The periosteum consists of an inner layer composed of osteoblasts surrounded by osteoprogenitor cells, which have the potential to differentiate into osteoblasts, and an outer layer rich in blood vessels and nerves and composed of collagen fibers and fibroblasts. Bundles of periosteal collagen fibers penetrate the bone, binding the periosteum to the bone. The endosteum is composed of a single layer of osteoblasts and sometimes a small amount of connective tissue. The inner layer is the osteogenic layer and the outer is the fibrous layer.

Interdental Septum

The interdental septum consists of cancellous bone bordered by the socket wall cribriform plates (lamina dura or alveolar bone proper) of approximating teeth and the facial and lingual cortical plates (Fig. 2-27). If the interdental space is narrow, the septum may consist of only the cribriform plate. For example, the space between mandibular second premolars and first molars consists of cribriform plate and cancellous bone in 85% of the cases and only cribriform plate in the remaining 15%.[s2] If roots are too close together, an irregular "window" can appear in the bone between adjacent roots (Fig. 2-28). Between maxillary molars, the septum consists of cribriform plate and cancellous bone in 66.6% of cases, is composed of only cribriform plate in 20.8% of cases, and has a fenestration in 12.5% of cases.[s2] Determining root proximity radiographically is important (see Chapter 31). The mesiodistal angulation of the crest of the interdental septum usually parallels a line drawn between the cementoenamel junctions of the approximating teeth.[91] The distance between the crest of the alveolar bone and the cementoenamel junction in young adults varies between 0.75 and 1.49 mm (average 1.08 mm). This distance increases with age to an average of 2.81 mm. However, this phenomenon may not be as much a function of age as of periodontal disease.

The mesiodistal and faciolingual dimensions and shape of the interdental septum are governed by the size and convexity of the crowns of the two approximating teeth, as well as by the position of the teeth in the jaw and their degree of eruption.

Osseous Topography

The bone contour normally conforms to the prominence of the roots, with intervening vertical depressions that taper toward the margin (Fig. 2-29). Alveolar bone anatomy varies among patients and has important

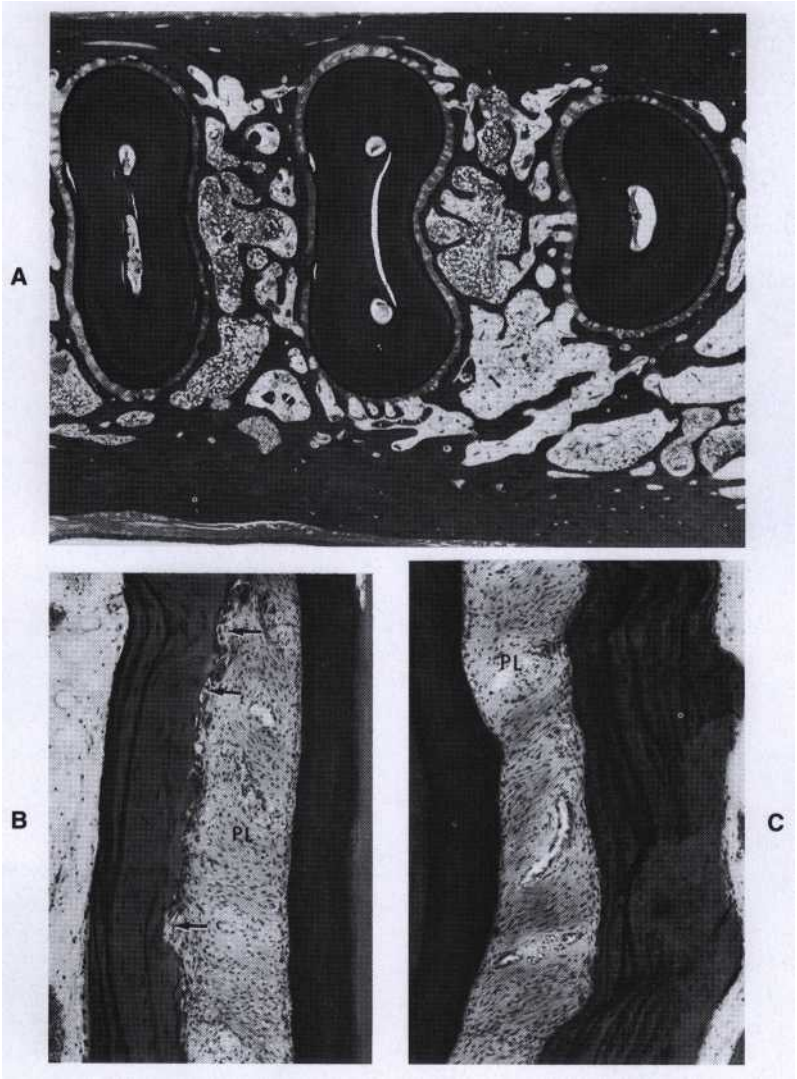

Fig. 2-25 Bundle bone associated with physiologic mesial migration of the teeth. A, Horizontal section through molar roots in the process of mesial migration *(left,* mesial; right, distal). B, Mesial root surface showing osteoclasis of bone (arrows). C, Distal root surface showing bundle bone that has been partially replaced with dense bone on the marrow side. PL, Periodontal ligament.

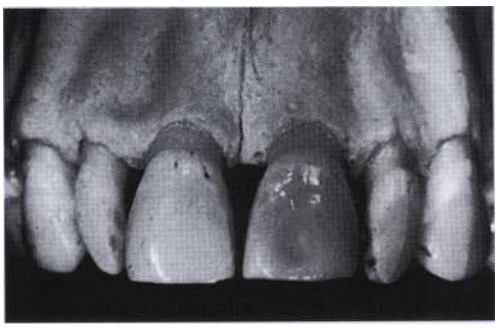

Fig. 2-29 Normal bone contour conforms to the prominence of the roots.

clinical implications. The height and thickness of the facial and lingual bony plates are affected by the alignment of the teeth, angulation of the root to the bone, and occlusal forces.

On teeth in labial version, the margin of the labial bone is located farther apically than on teeth in proper alignment. The bone margin is thinned to a knife edge and presents an accentuated arc in the direction of the apex. On teeth in lingual version, the facial bony plate is thicker than normal. The margin is blunt and rounded and horizontal rather than arcuate. The effect of the root-to-bone angulation on the height of alveolar bone is most noticeable on the palatal roots of maxillary molars. The bone margin is located farther apically on the roots, which form relatively acute angles with the palatal bone." The cervical portion of the alveolar plate is sometimes considerably thickened on the facial surface, apparently as reinforcement against occlusal forces (Fig. 2-30).

Fenestrations and Dehiscences

Isolated areas in which the root is denuded of bone and the root surface is covered only by periosteum and overlying gingiva are termed *fenestrations.* In these instances the marginal bone is intact. When the denuded areas extend through the marginal bone, the defect is called a *dehiscence* (Fig. 2-31). Such defects occur on approximately 20% of the teeth; they occur more often on the facial bone than on the lingual, are more common on anterior teeth than on posterior teeth, and are frequently bilateral. Microscopic evidence of lacunar resorption may be

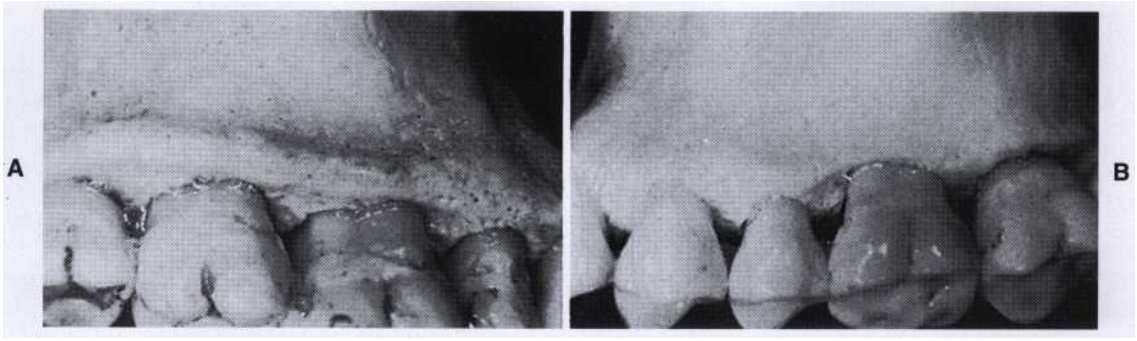

Fig. 2-30 Variation in the cervical portion of the buccal alveolar plate. A, Shelflike conformation. B, Comparatively thin buccal plate.

Fig. 2-31 Dehiscence on the canine and fenestration of the first premolar.

present at the margins. The cause of these defects is not clear. Prominent root contours, malposition, and labial protrusion of the root combined with a thin bony plate are predisposing factors.[34] Fenestration and dehiscence are important because they may complicate the outcome of periodontal surgery.

Remodeling of Alveolar Bone

In contrast to its apparent rigidity, alveolar bone is the least stable of the periodontal tissues because its structure is in a constant state of flux. A considerable amount of internal remodeling takes place by means of resorption and formation, which are regulated by local and systemic influences. Local influences include functional requirements on the tooth and age-related changes in bone cells. Systemic influences are probably hormonal (e.g., parathyroid hormone, calcitonin, or vitamin D[3]).

The remodeling of the alveolar bone affects its height, contour, and density, and it is manifested in the following three areas: adjacent to the periodontal ligament, in relation to the periosteum of the facial and lingual plates, and along the endosteal surface of the marrow spaces.

DEVELOPMENT OF THE ATTACHMENT APPARATUS

After the crown has formed, the stratum intermedium and the stellate reticulum of the enamel organ disappear. The outer and inner epithelia of the enamel organ remain and form the so-called *reduced enamel epithelium*. The apical portion of this constitutes *Hertwig's epithelial root sheath,* which will continue to grow apically and determines the shape of the root. Before the beginning of root formation, the root sheath bends horizontally at the future cementoenamel junction, narrowing the cervical opening and forming the *epithelial diaphragm*. The epithelial diaphragm separates the dental follicle from the dental papilla.

After root dentin formation starts, Hertwig's root sheath breaks up and partially disappears; the remaining cells form the epithelial clusters or strands known as *epithelial rests of Malassez* (see Fig. 2-7, A). In multirooted teeth, the epithelial diaphragm grows in such a way that tonguelike extensions develop horizontally, leaving spaces for each of the future roots to form.

Cementum

The rupture of Hertwig's root sheath allows the mesenchymal cells of the dental follicle to contact the dentin, where they start forming a continuous layer of cementoblasts. Based on immunochemical and ultrastructural studies, Thomas'" and others [18,73] have speculated that cementoblasts also can be of epithelial origin (Hertwig's root sheath), which would undergo an epithelial mesenchymal transformation.

Cementum formation begins by deposition of a meshwork of irregularly arranged collagen fibrils sparsely distributed in a ground substance or matrix called *precementum* or *cementoid.* This is followed by a phase of matrix maturation, which subsequently mineralizes to form cementum. Cementoblasts, which are initially separated from the cementum by uncalcified cementoid, sometimes become enclosed within the matrix and are trapped. Once they are enclosed, they are referred to as *cementocytes* and will remain viable in a fashion similar to that of osteocytes.

The enamel organ-including the epithelial root sheath as it develops-is surrounded by a layer of con-

nective tissue known as the *dental sac.* The zone immediately in contact with the dental organ and continuous with the ectomesenchyme of the dental papilla is called the *dental follicle* and consists of undifferentiated fibroblasts.

Periodontal Ligament

As the crown approaches the oral mucosa during tooth eruption, these fibroblasts become active and start producing collagen fibrils. These initially lack orientation, but they soon acquire an orientation oblique to the tooth. The first collagen bundles then appear in the region immediately apical to the cementoenamel junction and give rise to the gingivodental fiber groups. As tooth eruption progresses, additional oblique fibers appear and become attached to the newly formed cementum and bone. The transseptal and alveolar crest fibers develop when the tooth merges into the oral cavity. Alveolar bone deposition occurs simultaneously with periodontal ligament organization. [m]

Studies of the squirrel monkey have shown that during eruption, cemental Sharpey's fibers appear first, followed by Sharpey's fibers emerging from bone. Sharpey's fibers are fewer in number and more widely spaced than those emerging from the cementum. At a later stage, alveolar fibers extend into the middle zone to join the lengthening cemental fibers and attain their classic orientation, thickness, and strength when occlusal function is established.

Early investigators had suggested that the individual fibers, rather than being continuous, consisted of two separate parts spliced together midway between the cementum and the bone in a zone that is called the *intermediate plexus.* The plexus has been reported in the periodontal ligament of continuously growing incisors but not in the posterior teeth of rodents", [74,128] and in actively erupting human and monkey teeth, but not after they reach occlusal contact. Rearrangement of the fiber ends in the plexus is supposed to accommodate tooth eruption without necessitating the embedding of new fibers into the tooth and the bone. [14] The existence of such a plexus, however, has not been confirmed by radioautographic data and other studies, and it is considered a microscopic artifact.

Alveolar Bone

Just before mineralization, osteoblasts start producing matrix vesicles .'z These vesicles contain enzymes such as alkaline phosphatase that help jump-start the nucleation of hydroxyapatite crystals. As these crystals grow and develop, they form coalescing bone nodules, which, with fast-growing nonoriented collagen fibers, are the substructure of woven bone, the first bone formed in the alveolus. Later, through bone deposition, remodeling, and the secretion of oriented collagen fibers in sheets, mature lamellar bone is formed. [12]

The hydroxyapatite crystals are generally aligned with their long axes parallel to the collagen fibers and appear to be deposited on and within the collagen fibers in mature lamellar bone. In this fashion, bone matrix is able to withstand the heavy mechanical stresses applied to it during function.

The alveolar bone develops around each tooth follicle during odontogenesis. When a deciduous tooth is shed, its alveolar bone is resorbed. The succedaneous permanent tooth moves into place, developing its own alveolar bone from its own dental follicle. As the tooth root forms and the surrounding tissues develop and mature, alveolar bone merges with the separately developing basal bone and the two become one continuous structure. Although alveolar bone and basal bone have different intermediate origins, both are ultimately derived from neural crest ectomesenchyme.

Mandibular basal bone begins mineralization at the exit of the mental nerve from the mental foramen, whereas the maxillary basal bone begins at the exit of the infraorbital nerve from the infraorbital foramen.

Physiologic Migration of the Teeth

Tooth movement does not end when active eruption is completed and the tooth is in functional occlusion. With time and wear, the proximal contact areas of the teeth are flattened and the teeth tend to move mesially. This is referred to as physiologic *mesial migration.* By age 40, it results in a reduction of about 0.5 cm in the length of the dental arch from the midline to the third molars. Alveolar bone is reconstructed in compliance with the physiologic mesial migration of the teeth. Bone resorption is increased in areas of pressure along the mesial surfaces of the teeth, and new layers of bundle bone are formed in areas of tension on the distal surfaces (Fig. 2-32; see also Fig. 2-25).

EXTERNAL FORCES AND THE PERIODONTIUM

The periodontium exists for the purpose of supporting teeth during function and depends on the stimulation it receives from function for the preservation of its structure. Therefore a constant and sensitive balance is present between external forces and the periodontal structures.

Alveolar bone undergoes constant physiologic remodeling in response to external forces, particularly occlusal forces. Bone is removed from areas where it is no longer needed and added to areas where it is presently needed. The socket wall reflects the responsiveness of alveolar bone to external forces. Osteoblasts and newly formed osteoid line the socket in areas of tension; osteoclasts and bone resorption occur in areas of pressure. Forces exerted on the tooth also influence the number, density, and alignment of cancellous trabeculae. The bony trabeculae are aligned in the path of the tensile and compressive stresses to provide maximal resistance to the occlusal force with a minimum of bone substance (Fig. 2-33).[43] When forces are increased, the cancellous bony trabeculae increase in number and thickness, and bone may be added to the external surface of the labial and lingual plates.

The periodontal ligament also depends on stimulation provided by function to preserve its structure.

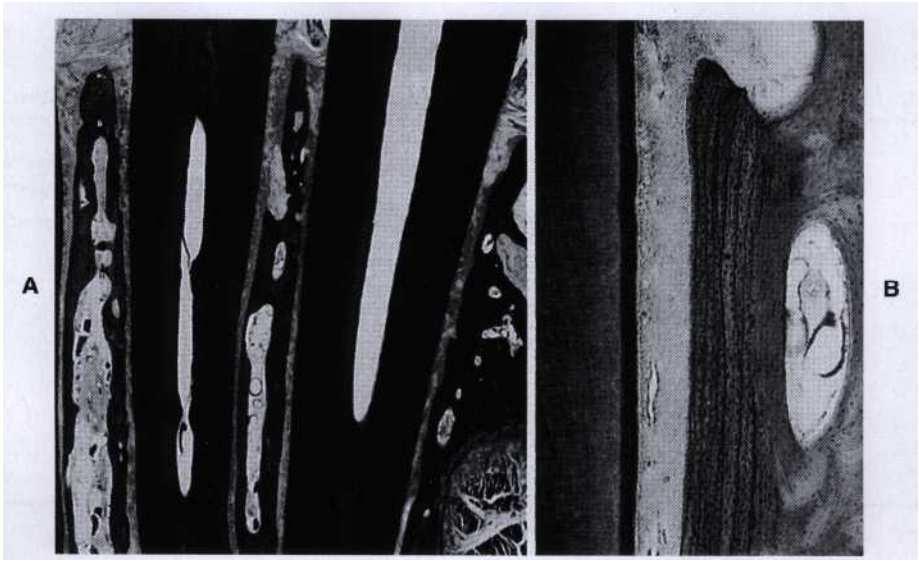

Fig. 2-32 Bone response to physiologic mesial migration. A, Interdental septa between the canine *(left)* **and first and second premolars. B, Interdental septum between the first and second premolars, showing lamellae of newly apposed bone opposite the distal of the first premolar** *(left)* **and resorption opposite the mesial of the second premolar** *(right).*

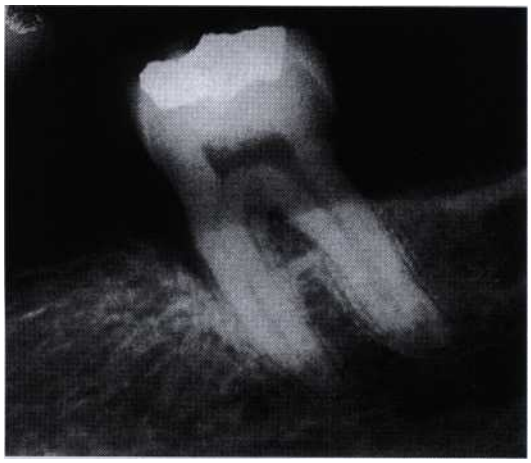

Fig. 2-33 Bony trabeculae realigned perpendicular to the mesial root of tilted molar.

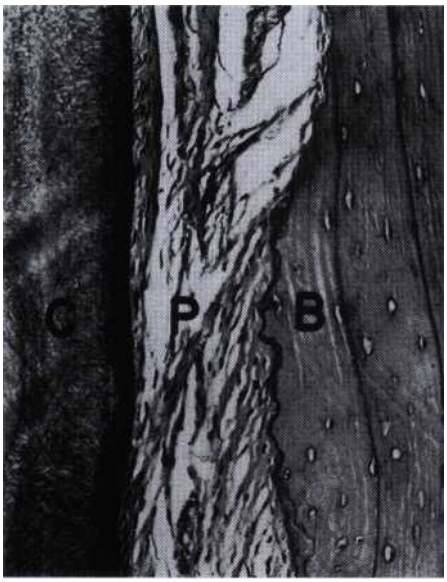

Fig. 2-34 Atrophic periodontal ligament (P) of a tooth devoid of function. Note the scalloped edge of the alveolar bone (8), indicating that resorption has occurred. C, Cementum.

Within physiologic limits, the periodontal ligament can accommodate increased function with an increase in width (Table 2-2), a thickening of its fiber bundles, and an increase in diameter and number of Sharpey's fibers. Forces that exceed the adaptive capacity of the periodontium produce injury called *trauma from occlusion.* This condition is described in Chapter *24.*

When occlusal forces are reduced, the number and thickness of the trabeculae are reduced.[28] The periodontal ligament also atrophies, appearing thinned, and the fibers are reduced in number and density, disoriented[2,90] and ultimately arranged parallel to the root surface (Fig. *2-34).* This is termed *disuse* or *a functional atrophy*. In this condition, the cementum is either unaffected[28] or thickened and the distance from the cementoenamel junction to the alveolar crest is increased.[86]

VASCULARIZATION OF THE SUPPORTING STRUCTURES

The blood supply to the supporting structures of the tooth is derived from the inferior and superior alveolar arteries to the mandible and maxilla, respectively, and

TABLE 2-2

Comparison of Periodontal Width of Functioning and Functionless Teeth in a 38-Year-Old Man

	Average Width of Periodontal Space at Entrance of Alveolus (mm)	Average Width of Periodontal Space at Middle of Alveolus (mm)	Average Width of Periodontal Space at Fundus of Alveolus (mm)
Heavy Function: Left upper 2nd bicuspid	*0.35*	*0.28*	*0.30*
Light Function: Left lower 1St bicuspid	*0.14*	*0.10*	*0.12*
Functionless: Left upper 3rd molar	*0.10*	*0.06*	*0.06*

Modified from Kronfeld R: Histologic study of the influence of function on the human periodontal membrane. J Am Dent Assoc 1931; 18:1242.

reaches the periodontal ligament from three sources: apical vessels, penetrating vessels from the alveolar bone, and anastomosing vessels from the gingva" The branches of the apical vessels supply the apical region of the periodontal ligament before the vessels enter the dental pulp. The transalveolar vessels are branches of the intraseptal vessels that perforate the lamina dura and enter the ligament. The intraseptal vessels continue to vascularize the gingiva; these gingival vessels in turn anastomose with the periodontal ligament vessels of the cervical region.

The vessels within the periodontal ligament are contained in interstitial spaces of loose connective tissue between the principal fibers and are connected in a netlike plexus that runs longitudinally and closer to the bone than the cementum (Figs. 2-35 and 2-36). The blood supply increases from the incisors to the molars; is greatest in the gingival third of single-rooted teeth, less in the apical third, and least in the middle; is equal in the apical and middle thirds of multirooted teeth; is slightly greater on the mesial and distal surfaces than on the facial and lingual; and is greater on the mesial surfaces of mandibular molars than on the distal.

(Courtesy NJ Selliseth and K Selvig, University of Bergen, Norway.)

The vascular supply to the bone enters the interdental septa through nutrient canals together with veins, nerves, and lymphatics. Dental arterioles, which also branch off the alveolar arteries, send tributaries through the periodontal ligament, and some small branches enter the marrow spaces of the bone through the perforations in the cribriform plate. Small vessels emanating from the facial and lingual compact bone also enter the marrow and spongy bone.

The venous drainage of the periodontal ligament accompanies the arterial supply. Venules receive the blood through the abundant capillary network; also, arteriovenous anastomoses bypass the capillaries. These are more frequent in apical and interradicular regions, and their significance is unknown.

Lymphatics supplement the venous drainage system. Those draining the region just beneath the functional epithelium pass into the periodontal ligament and accompany the blood vessels into the periapical region.[20] From there they pass through the alveolar bone to the inferior dental canal in the mandible or the infraorbital canal in the maxilla and then to the submaxillary lymph nodes.

- **Cementum**
- **Alveolar Bone**
- **Bacterial Plaque**
- **Immune Responses**

EFFECTS OF AGING ON THE PROGRESSION OF PERIODONTAL DISEASES

EFFECTS OF AGING ON THE RESPONSE TO TREATMENT OF THE PERIODONTIUM

The successes of both increased health awareness and preventive dentistry have led to decreasing tooth loss for all age groups. The effects of this shift in tooth retention on the periodontal needs of a population with increased life expectancy and oral health expectations need to be considered carefully. It is important not only to review aging effects in isolation but also from the perspectives of their clinical significance to the disease process and their possible effects on treatment outcomes.

The evidence base is not without problems, many of which make it difficult to draw conclusions on the effects of aging. Some of these problems include inconsistency in the definition of a true "aged" group, inadequate exclusion of adults with systemic diseases that can modify study findings, and attempts to extrapolate results from animal research. For the purposes of this chapter, the effects of aging will be limited to a narrow review of possible biologic and microbiologic changes.* The reader should be fully aware that this excludes many important age-associated phenomena, including the reduction in an individual's cognitive or motor function skills, which may have a direct impact on periodontal management (see Chapter 39).

*** For further reading on the effects of aging on the dental and periodontal patient, the reader should consult P. Holm-Pederson's Text-***book of Geriatric Dentistry,* **ed 2; and Ellen EP (ed): Periodontal disease among older adults, Periodontology 2000 1998; 16.**

EFFECTS OF AGING ON THE PERIODONTIUM

Gingival Epithelium

Thinning and decreased keratinization of the gingival epithelium have been reported with age.[31] The significance of these findings could mean an increase in epithelial permeability to bacterial antigens, a decreased resistance to functional trauma, or both, which might influence long-term periodontal outcomes. However, other studies have found no age-related differences in the gingival epithelium of humans or dogs.[7,16] Other reported changes with aging include the flattening of rete pegs and altered cell density. Conflicting data regarding surgical regeneration times for gingival epithelium have been ascribed to problems in research methodology.[33]

The effect of aging on the location of the junctional epithelium has been the subject of much speculation.

Some reports show migration of the junctional epithelium from its position in healthy individuals (i.e., on enamel) to a more apical position on the root surface with accompanying gingival recession.' However, in other animal studies, no apical migration has been noted. With continuing gingival recession, the width of the attached gingiva would be expected to decrease with age, but the opposite appears to be true .[2,3] Alternatively, the migration of the junctional epithelium to the root surface could be caused by the tooth erupting through the gingiva in an attempt to maintain occlusal contact with its opposing tooth (passive eruption) as a result of tooth surface loss from attrition (Fig. 3-1). The consensus is that gingival recession is not an inevitable physiologic process of aging but is explained by cumulative effects of inflammation or trauma on the periodontium[6-7] (see later discussion) (Fig. 3-2).

Gingival Connective Tissue

Increasing age results in coarser and more dense gingival connective tissues.[36] Qualitative and quantitative changes to collagen have been reported. These include an increased rate of conversion of soluble to insoluble collagen, increased mechanical strength, and increased denaturing temperature. These results indicate increased collagen stabilization caused by changes in the macromolecular conformation.[23] Not surprisingly, a greater collagen content has been found in the gingiva of older animals despite a lower rate of collagen synthesis decreasing with age.[7,23,33]

Periodontal Ligament

Changes in the periodontal ligament that have been reported with aging include decreased numbers of fibroblasts and a more irregular structure, paralleling the changes in the gingival connective tissues. [7,23,33] Other findings include decreased organic matrix production and epithelial cell rests and increased amounts of elastic fiber .[33] Conflicting results have been reported for changes in the width of periodontal ligament in human and animal models. Although true variation might exist, this finding probably reflects the functional status of the teeth in the studies because the width of the space will decrease if the tooth is unopposed (hypofunction) or will increase with excessive occlusal loading.[23,33] Both scenarios might be anticipated as a result of tooth loss in this population. These effects also might explain the variability in studies reporting qualitative changes within the periodontal ligament.

Cementum

Some consensus regarding aging effects on cementum exists. An increase in cemental width is a common finding; this increase may be 5 to 10 times with increasing age.' This finding is not surprising because deposition continues after tooth eruption. The increase in width is greater apically and lingually.[33] Although cementum has limited capacity for remodeling, an accumulation of resorption bays explains the finding of increasing surface irregularity.[13]

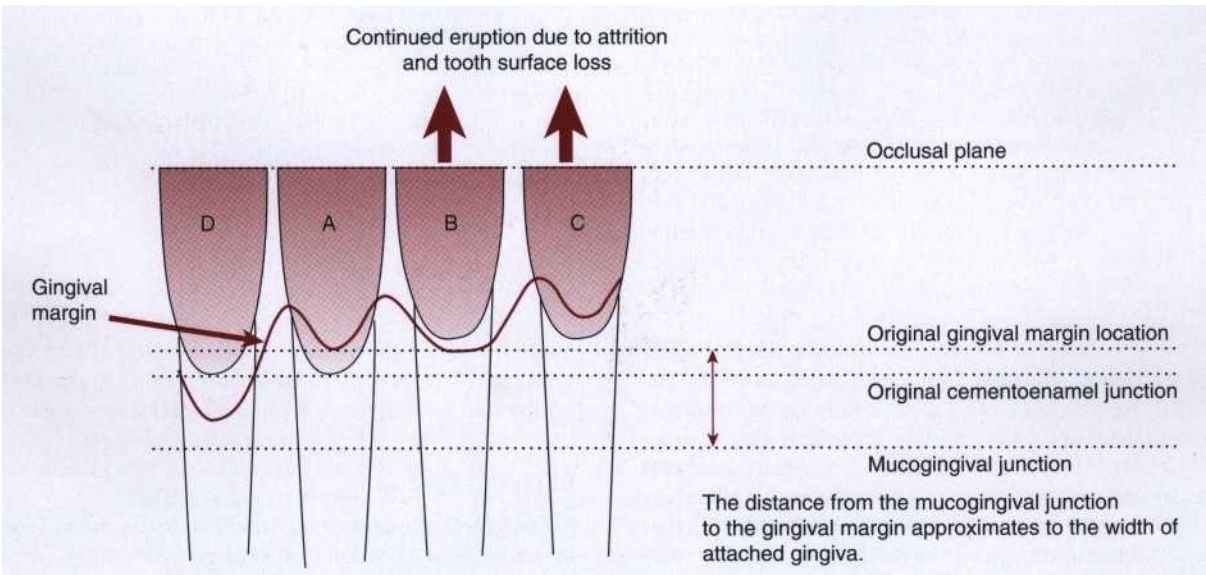

Fig. 3-1 Diagram showing the relationship of the gingival margin with the crown and root surface. A, Normal relationship with the gingival margin 1 to 2 mm above the cementoenamel junction. B, Wear of the incisal edge and continued tooth eruption. The gingival margin remains in the same position as in A, therefore the root surface is exposed and clinical recession is evident. The width of the attached gingiva has not changed. C, Wear of the incisal edge and continued tooth eruption. The gingival margin has moved with the tooth, therefore the entire dentogingival complex has moved coronally with a resulting increase in the width of the attached gingiva. D, No wear of incisal edge is evident. Gingiva has moved apically, and clinical recession is evident. The width of attached gingiva is reduced.

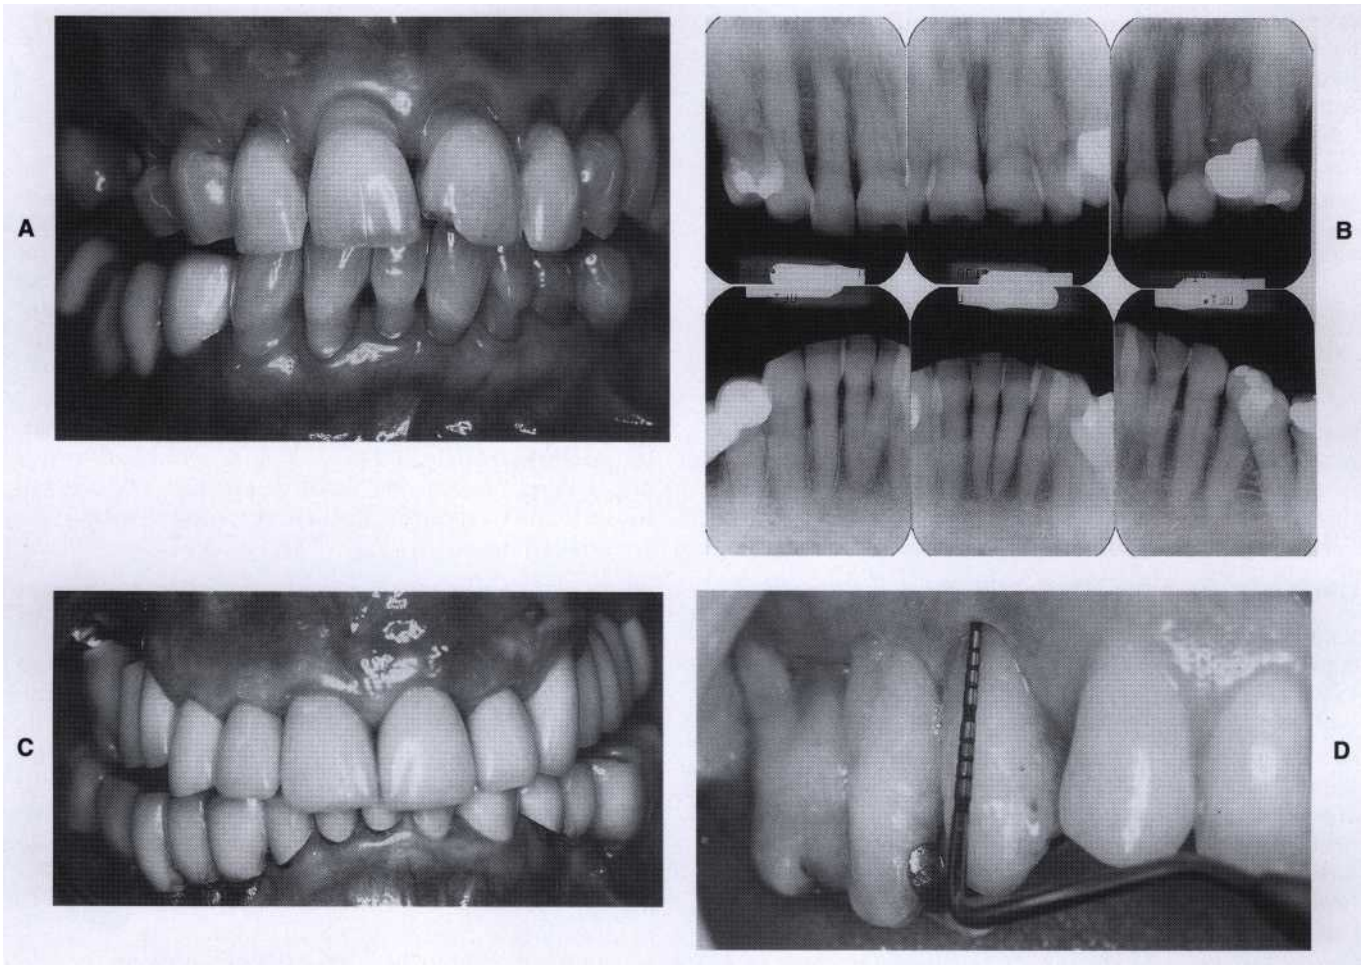

Fig. 3-2 Three scenarios illustrating the variation of the position of the gingival margin with age. A, Overeruption with recession in older individual (68-year-old woman) with generalized recession and previous (treated) history of periodontitis. Note some overeruption of lower anterior teeth and wear of teeth related to oral hygiene measures. B, Radiographs of the patient in A. G, Overeruption without recession in an older individual (72-year-old woman) with no periodontitis but marked lower incisor tooth wear and overeruption. Note how the gingival margin has migrated coronally with the erupting teeth. D, Extensive recession in young individual (32-year-old man) with marked recession and no history of periodontitis. The recession has resulted from a combination of anatomically thin tissues and toothbrush-related trauma.

Alveolar Bone

Reports of morphologic changes in alveolar bone mirror age-related changes in other bony sites. Specific to the periodontium are findings of a more irregular periodontal surface of bone and less regular insertion of collagen fibers. Although age is a risk factor for the bone mass reductions in osteoporosis, it is not causative and therefore should be distinguished from physiologic aging processes. Overriding the diverse observations of bony changes with age is the important finding that the healing rate of bone in extraction sockets appears to be unaffected by increasing age.[4] Indeed, the success of osseointegrated dental implants, which relies on intact bone healing responses, does not appear to be age related.[1] However, balancing this view is the recent observation that bone graft preparations (decalcified freeze-dried bone) from donors more than 50 years old possessed significantly less osteogenic potential than graft material from younger donors. The possible significance of this phenomenon on normal healing responses needs to be investigated.

Bacterial Plaque

Dentogingival plaque accumulation has been suggested to increase with age.[11] This might be explained by the increase in hard tissue surface area as a result of gingival recession and the surface characteristics of the exposed root surface as a substrate for plaque formation compared with enamel. Other studies have shown no difference in plaque quantity with age. This contradiction might reflect the different age ranges of experimental groups as variable degrees of gingival recession and root

surface exposure. For supragingival plaque, no real qualitative differences have been shown for plaque composition." For subgingival plaque, one study has shown similar subgingival flora to a normal flora, whereas another study reported increased numbers of enteric rods and pseudomonads in older adults .[27,32] Mombelli suggests caution in the interpretation of this finding because of increased oral carriage of these species among older adults .[26] It has been speculated that a shift occurs in the importance of certain periodontal pathogens with age, specifically including an increased role for *Porphyromonas gingivalis* and a decreased role for *Actinobacillus actinomycetemcomitans.* However, differentiating true age effects from the changes in ecological determinants for periodontal bacteria will be difficult. This topic is considered in more detail in a recent review.[26]

Immune Responses

Recent advances in the study of the effects of aging on the immune response (immunosenescence) have altered the understanding of this phenomenon. In particular, more recent studies have set tighter controls on excluding individuals with systemic conditions known to affect the immune response. As a result, age has been recognized as having much less effect in altering the host response than previously thought. [17,24] Differences between young and older individuals can be demonstrated for T and B cells, cytokines, and natural killer cells but not for polymorphonuclear cells and macrophage activity. McArthur concludes, "Measurement of indicators of immune and inflammatory competency suggested that, within the parameters tested, there was no evidence for age-related changes in host defenses correlating with periodontitis in an elderly (65 to 75 years) group of individuals, with and without disease."" Age-related differences in the inflammatory response in gingivitis have been clearly demonstrated and are discussed later in this textbook.

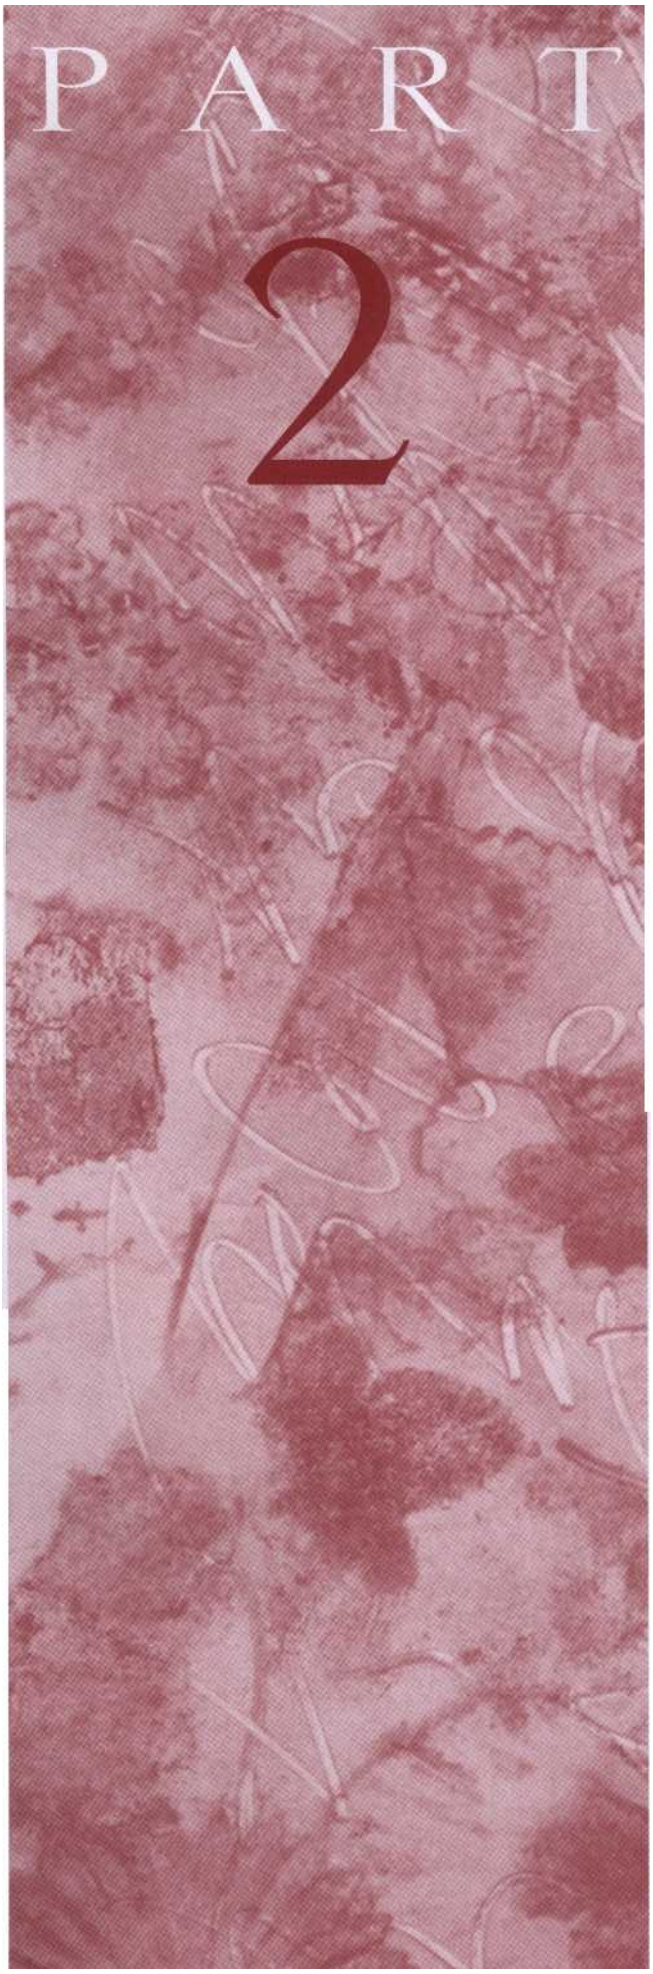
In summary, although many contradictions exist, a survey of the literature demonstrates that some age-related changes are evident in the periodontium and host response. Whether these changes are significant in altering the progression of periodontal diseases or the response of an older adult to periodontal treatment will be examined next.

EFFECTS OF AGING ON THE PROGRESSION OF PERIODONTAL DISEASES

In a classic experimental gingivitis study, subjects were rendered plaque free and inflammation free through frequent professional cleaning. Once this was achieved, the subjects abstained from oral hygiene measures for periods of 3 weeks to allow gingivitis to develop.[22] In this experimental model, a comparison of developing gingivitis between young and older individuals demonstrated a greater inflammatory response in older subjects, both in humans and dogs.[7,11,12,14] In the older age group (65 to 80 years), the findings included a greater size of infiltrated connective tissue, increased gingival crevicular fluid flow, and increased gingival index.'[1,12] Other studies have not demonstrated differences between subjects; this may be related to smaller differences between the ages of the younger and older experimental groups .3' intriguingly, even at the baseline level of excellent gingival health before commencing plaque accumulation, differences may exist between groups, with older individuals demonstrating more inflammation."[,]"

The phrase "getting long in the tooth" expresses a widespread belief that age is inevitably associated with an increased loss of connective tissue attachment. However, this observation might equally well reflect a cumulative exposure to a number of potentially destructive processes. These exposures might include plaque-associated periodontitis, chronic mechanical trauma from tooth brushing, and iatrogenic damage from unfavorable restorative dentistry or repeated scaling and root planing. The effects of these exposures act in one direction only (i.e., increased loss of attachment).[34]

In an attempt to differentiate the effects of age from these other processes, several studies have been designed to eliminate confounding issues and address more clearly the question of age as a risk factor for periodontitis. A *risk factor is* defined as an exposure or factor that increases the probability that the disease (periodontitis) will occur.[28] The conclusions from these studies are strikingly consistent and show that the effect of age is either nonexistent or provides a small and clinically insignificant increased risk of loss of periodontal support. [9,21,28,29] Indeed, in comparison with the odds ratio of 20.52 for poor oral hygiene status and periodontitis, the odds ratio for age was only 1.24.[1] Therefore age has been suggested to be not a true risk factor but a background or an associated factor for periodontitis.[28] In addition, the recent reports of a genetic basis for susceptibility to severe forms of periodontitis underline the overriding importance of plaque, smoking, and susceptibility in explaining most of the variation in periodontal disease severity between individuals. [18,25]



EFFECTS OF AGING ON THE RESPONSE TO TREATMENT OF THE PERIODONTIUM

The successful treatment of periodontitis requires both meticulous home-care plaque control by the patient and meticulous supragingival and subgingival debridement by the therapist.'° Unfortunately, only a few studies have directly compared such an approach among patients of different age groups. The few studies that have done so clearly demonstrate that despite the histologic changes in the periodontium with aging, no differences in response to nonsurgical or surgical treatment have been shown for periodontitis.[5,20,35] However, if plaque control is not ideal, continued loss of attachment is inevitable.

A purely biologic or physiologic review indicates that the effects of aging on the structure of the periodontium, function of the immune response, and nature of either supragingival or subgingival plaque have a negligible impact on an individual's experience of periodontal diseases. Aging might affect other aspects of managing the periodontal diseases (see Chapter 39), and the resulting difficulties should not be underestimated.

Classification and Epidemiology of Periodontal Diseases

Michael G. Newman

isease classifications are useful for the purpose of diagnosis, prognosis, and treatment planning. Different classifications of periodontal diseases have been used over the years and have been replaced as new knowledge has improved our understanding of the etiology and pathology of the diseases of the periodontium.

Part 2 also includes information about the epidemiology of periodontal diseases that will aid the student and the clinician to analyze a disease and base their diagnostic and **therapeutic decisions on its prevalence, incidence, and distribution** in large populations or groups. Knowledge of the epidemiology of a disease improves our understanding and sharpens our decisions on individual cases.

Classification of Diseases and Conditions Affecting the Periodontium

Localized Tooth-Related Factors That Modify or Predispose to Plaque-induced Gingival Diseases or Periodontitis
Mucogingival Deformities and Conditions around Teeth
Mucogingival Deformities and Conditions on Edentulous Ridges
Occlusal Trauma

Our understanding of the etiology and pathogenesis of oral diseases and conditions is continually changing with increased scientific knowledge. In light of this, a classification can be most consistently defined by the differences in the clinical manifestations of diseases and conditions because they are clinically consistent and require little, if any, clarification by scientific laboratory testing. The classification presented in this chapter is based on the most recent, internationally accepted, consensus opinion of the diseases and conditions affecting the tissues of the periodontium and was presented and discussed at the 1999 International Workshop for the Classification of the Periodontal Diseases organized by the American Academy of Periodontology (AAP).[2] The overall classification system is presented in Box 4-1 and each of the diseases or conditions are discussed where clarification is needed. In each case, the reader is referred to pertinent reviews on the subject and specific chapters within this book that discuss the topics in more detail.

GINGIVAL DISEASES

Dental Plaque-Induced Gingival Diseases

Gingivitis that is associated with dental plaque formation' is the most common form of gingival disease (Box 4-2), and its epidemiology (Chapter 5), its etiology (Chapters 6 through 15), and its clinical characteristics (Chapters 16 through 21) are discussed elsewhere in this textbook and in other sources.[7,10,12,19,20] Gingivitis has been previously characterized by the presence of clinical signs of inflammation that are confined to the gingiva and associated with teeth showing no attachment loss. Gingivitis also has been observed to affect the gingiva of periodontitis-affected teeth that have previously lost attachment but have received periodontal therapy to stabilize any further attachment loss. In these treated cases, plaque-induced gingival inflammation may reoccur but without any evidence of further attachment loss. In light of this evidence, it has been concluded that *plaque-induced gingivitis may occur on a periodontium with no*

BOX 4-1

Classification of Periodontal Diseases and Conditions'

Gingival Diseases
Plaque-induced gingival diseases*
Non–plaque-induced gingival lesions

Chronic Periodontitis**
Localized
Generalized

Aggressive Periodontitis
Localized
Generalized

Periodontitis as a Manifestation of Systemic Diseases

Necrotizing Periodontal Diseases
Necrotizing ulcerative gingivitis (NUG)
Necrotizing ulcerative periodontitis (NUP)

Abscesses of the Periodontium
Gingival abscess
Periodontal abscess
Pericoronal abscess

Periodontitis Associated with Endodontic Lesions
Endodontic–periodontal lesion
Periodontal–endodontic lesion
Combined lesion

Developmental or Acquired Deformities and Conditions
Localized tooth-related factors that predispose to plaque-induced gingival diseases or periodontitis
Mucogingival deformities and conditions around teeth
Mucogingival deformities and conditions on edentulous ridges
Occlusal trauma

* These diseases may occur on a periodontium with no attachment loss or on a periodontium with attachment loss that is stable and not progressing.

** Aggressive periodontitis can be further classified on the basis of extent and severity. As a general guide, extent can be characterized as localized (<30% of sites involved) or generalized (>30% of sites involved). Severity can be characterized on the basis of the amount of clinical attachment loss (CAL) as follows: Slight = 1 or 2 mm CAL; moderate = 3 or 4 mm CAL; and severe >_ 5 mm CAL.

attachment loss or on a periodontium with previous attachment loss that is stable and not progressing. This implies that gingivitis may be the diagnosis for inflamed gingival tissues associated with a tooth with no previous attachment loss or with a tooth that has previously undergone attachment and bone loss (reduced periodontal support) but is not currently losing attachment or bone even though gingival inflammation is present. For this diagnosis to be made, longitudinal records of periodontal status, including clinical attachment levels, should be available.

Gingivitis Associated with Dental Plaque Only

Plaque-induced gingival disease is the result of an interaction between the microorganisms found in the dental plaque biofilm and the tissues and inflammatory cells of the host. The plaque-host interaction can be altered by the effects of local factors, systemic factors, or both; medications; and malnutrition that can influence the severity and duration of the response. Local factors that may contribute to gingivitis, in addition to plaque-retentive calculus formation on crown and root surfaces, are discussed in "Developmental or Acquired Deformities and Conditions." These factors are contributory because of their ability to retain plaque microorganisms and inhibit their removal by patient-initiated plaque control techniques.

Gingival Diseases Modified by Systemic Factors

Systemic factors[10,12,19] contributing to gingivitis, such as the endocrine changes associated with puberty, the menstrual cycle, pregnancy, and diabetes, may be exacerbated because of alterations in the gingival inflammatory response to plaque. This appears to be caused by the effects of the systemic conditions on the cellular and immunologic functions of the host. These changes are most apparent during pregnancy, when the prevalence and severity of gingival inflammation may increase even in the presence of low levels of plaque. Blood dyscrasias such as leukemia may alter immune function by disturbing the normal balance of immunologically competent white blood cells supplying the periodontium. Gingival enlargement and bleeding are common findings and may be associated with swollen, spongy gingival tissues caused by excessive infiltration of blood cells.

Gingival Diseases Modified by Medications

Gingival diseases modified by medications',[12,20] are increasingly prevalent because of the increased use of anticonvulsant drugs known to induce gingival enlargement, such as phenytoin, immunosuppressive drugs such as cyclosporine A, and calcium channel blockers such as nifedipine, verapamil, diltiazem, and sodium valproate. The development and severity of gingival enlargement in response to medications is patient specific and may be influenced by uncontrolled plaque accumulation. The increased use of oral contraceptives by premenopausal women has been associated with a higher incidence of gingival inflammation and development of gingival enlargement that may be reversed by discontinuation of the oral contraceptive.

Gingival Diseases Modified by Malnutrition

Gingival diseases modified by malnutrition'' have received attention because of clinical descriptions of bright red, swollen, and bleeding gingiva associated with severe ascorbic acid (vitamin C) deficiency or scurvy. Nutritional deficiencies are known to affect immune function and may have an impact on the host's ability to protect

BOX 4-2

Gingival Diseases[9,12]

Dental Plaque–Induced Gingival Diseases

These diseases may occur on a periodontium with no attachment loss or on one with attachment loss that is stable and not progressing.

I. Gingivitis associated with dental plaque only
  A. Without local contributing factors
  B. With local contributing factors (see Box 4-4)
II. Gingival diseases modified by systemic factors
  A. Associated with the endocrine system:
    1. Puberty-associated gingivitis
    2. Menstrual cycle–associated gingivitis
    3. Pregnancy associated
      a. Gingivitis
      b. Pyogenic granuloma
    4. Diabetes mellitus–associated gingivitis
  B. Associated with blood dyscrasias
    1. Leukemia-associated gingivitis
    2. Other
III. Gingival diseases modified by medications
  A. Drug-influenced gingival diseases
    1. Drug-influenced gingival enlargements
    2. Drug-influenced gingivitis
      a. Oral contraceptive–associated gingivitis
      b. Other
IV. Gingival diseases modified by malnutrition
  A. Ascorbic acid deficiency gingivitis
  B. Other

Non–Plaque-Induced Gingival Lesions

I. Gingival diseases of specific bacterial origin
  A. *Neisseria gonorrhea*
  B. *Treponema pallidum*
  C. Streptococcal species
  D. Other
II. Gingival diseases of viral origin
  A. Herpesvirus infections
    1. Primary herpetic gingivostomatitis
    2. Recurrent oral herpes
    3. Varicella zoster
  B. Other
III. Gingival diseases of fungal origin
  A. *Candida*-species infections: Generalized gingival candidosis
  B. Linear gingival erythema
  C. Histoplasmosis
  D. Other
IV. Gingival lesions of genetic origin
  A. Hereditary gingival fibromatosis
  B. Other
V. Gingival manifestations of systemic conditions
  A. Mucocutaneous lesions
    1. Lichen planus
    2. Pemphigoid
    3. Pemphigus vulgaris
    4. Erythema multiforme
    5. Lupus erythematosus
    6. Drug induced
    7. Other
  B. Allergic reactions
    1. Dental restorative materials
      a. Mercury
      b. Nickel
      c. Acrylic
      d. Other
    2. Reactions attributable to
      a. Toothpastes or dentifrices
      b. Mouthrinses or mouthwashes
      c. Chewing gum additives
      d. Foods and additives
    3. Other
VI. Traumatic lesions (factitious, iatrogenic, or accidental)
  A. Chemical injury
  B. Physical injury
  C. Thermal injury
VII. Foreign body reactions
VIII. Not otherwise specified

itself against some of the detrimental effects of cellular products such as oxygen radicals. Unfortunately, little scientific evidence is available to support a role for specific nutritional deficiencies in the development or severity of gingival inflammation or periodontitis in humans.

Non-Plaque-Induced Gingival Lesions

Oral manifestations of systemic conditions that produce lesions in the tissues of the periodontium are rare. They are observed in lower socioeconomic groups, developing countries, and immunocompromised individuals.'

Gingival Diseases of Specific Bacterial Origin

Gingival diseases of specific bacterial origin [21,23] are increasing in prevalence especially as a result of sexually transmitted diseases such as gonorrhea *(Neisseria gonorrhoeae)* and to a lesser degree, syphilis *(Treponema pallidum).* Oral lesions may be secondary to systemic infection or may occur through direct infection. Streptococcal gingivitis or gingivostomatitis also is a rare condition that may present as an acute condition with fever, malaise, and pain associated with acutely inflamed, diffuse, red, and swollen gingiva with increased bleeding and occasional gingival abscess formation. The gingival infections usually are preceded by tonsillitis and have

been associated with group A ß-hemolytic streptococcal infections.

Gingival Diseases of Viral Origin

Gingival diseases of viral origin [9,21,23] may be caused by a variety of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) viruses, the most common being the herpes viruses. Lesions are frequently related to reactivation of latent viruses, especially as a result of reduced immune function. The oral manifestations of viral infection have been comprehensively reviewed.9, [21,23]

Gingival Diseases of Fungal Origin

Gingival diseases of fungal origin9,[23,25] are relatively uncommon in the immunocompetent individual but occur more frequently in individuals who are immunocompromised or in whom the normal oral flora has been disturbed by the long-term use of broad-spectrum antibiotics. The most common oral fungal infection is candidiasis caused by infection with *Candida albicans,* which also can be seen under prosthetic devices, in individuals using topical steroids, and in individuals with decreased salivary flow, increased salivary glucose, or decreased salivary pH. A generalized candidal infection may manifest as white patches on the gingiva, tongue, or oral mucous membrane that can be removed with gauze, leaving a red, bleeding surface. In HIV-infected individuals, candidal infection may present as erythema of the attached gingiva and has been referred to as *linear gingival erythema* or *HIV-associated gingivitis* (see Chapter 29). Diagnosis of candidal infection can be made by culture, smear, and biopsy. Several less-common fungal infections, in addition to candidal infections, have been previously described. [23,25]

Gingival Diseases of Genetic Origin

Gingival diseases of genetic origin may involve the tissues of the periodontium and have been previously described in detail.' One of the most clinically evident conditions is hereditary gingival fibromatosis that exhibits autosomal dominant or (rarely) autosomal recessive modes of inheritance. The gingival enlargement may completely cover the teeth, delay eruption, and present as an isolated finding or be associated with several more generalized syndromes.

Gingival Manifestations of Systemic Conditions

Gingival manifestations of systemic conditions9, [18,24] may appear as desquamative lesions, ulceration of the gingiva, or both. These conditions, including those listed in Box 4-2, have been previously described in detail. [18,24] Allergic reactions that manifest with gingival changes are uncommon but have been observed in association with several restorative materials, toothpastes, mouthwashes, chewing gum, and foods (see Box 4-2). The diagnosis of these conditions may prove difficult and may require an extensive history and selective elimination of potential culprits.

Traumatic Lesions

Traumatic lesions' may be factitial (produced by artificial means; unintentionally produced) as in the case of toothbrush trauma resulting in gingival ulceration, recession or both; iatrogenic (trauma to the gingiva induced by the dentist or health professional) as in the case of preventive or restorative care that may lead to traumatic injury of the gingiva; or accidental as in the case of damage to the gingiva through minor burns from hot foods and drinks.

Foreign Body Reactions

Foreign body reactions' lead to localized inflammatory conditions of the gingiva and are caused by the introduction of foreign material into the gingival connective tissues through breaks in the epithelium. Common examples are the introduction of amalgam into the gingiva during the placement of a restoration or extraction of a tooth, leaving an amalgam tattoo, or the introduction of abrasives during polishing procedures.

PERIODONTITIS

Periodontitis is defined as "an inflammatory disease of the supporting tissues of the teeth caused by specific microorganisms or groups of specific microorganisms, resulting in progressive destruction of the periodontal ligament and alveolar bone with pocket formation, recession, or both." The clinical feature that distinguishes periodontitis from gingivitis is the presence of clinically detectable attachment loss. This often is accompanied by periodontal pocket formation and changes in the density and height of subjacent alveolar bone. In some cases, recession of the marginal gingiva may accompany attachment loss, thus masking ongoing disease progression if pocket depth measurements are taken without measurements of clinical attachment levels. Clinical signs of inflammation, such as changes in color, contour, and consistency and bleeding on probing, may not always be positive indicators of ongoing attachment loss. However, the presence of continued bleeding on probing at sequential visits has proven to be a reliable indicator of the presence of inflammation and the potential for subsequent attachment loss at the bleeding site. The attachment loss associated with periodontitis has been shown to progress either continuously or in episodic bursts of disease activity.

Although many classifications of the different clinical manifestations of periodontitis have been presented over the past 20 years, consensus workshops in North America in 1989[5] and in Europe in 1993[3] (Table 4-1) identified that periodontitis may present in early onset, adult-onset, and necrotizing forms. In addition, the AAP consensus concluded that periodontitis may be associated with systemic conditions such as diabetes and HIV infection and that some forms of periodontitis may be refractory to conventional therapy. Early onset disease was distinguished from adult-onset disease by the age of onset (35 years of age was set as an arbitrary separation of diseases), the rate of disease progression, and the presence of alterations in host defenses. The early onset diseases were more aggressive, occurred in individuals younger than 35 years old, and were associated with defects in host defenses, whereas adult forms of disease were slowly progressive, began in the fourth decade of life, and were not associated with defects in host defenses. In addition, early onset periodontitis was subclassified into prepubertal,

juvenile, and rapidly progressive forms with localized or generalized disease distributions. Extensive clinical and basic scientific research of these disease entities has been performed in many countries, and some disease characteristics outlined 10 years ago no longer stand up to rigid scientific scrutiny.[6,11,26] In particular, supporting evidence was lacking for the distinct classifications of adult periodontitis, refractory periodontitis, and the various different forms of early onset periodontitis as outlined by the America Academy of Periodontology (AAP) Workshop for the International Classification of Periodontal Diseases in 1999[2] (see Table 4-1). It has been observed that chronic periodontal destruction, due to the accumulation of local factors such as plaque and calculus, can occur prior to the age of 35 years and that the aggressive disease seen in young patients may be independent of age but has a familial (genetic) association. With respect to refractory periodontitis, little evidence supports that this is indeed a distinct clinical entity because the causes of continued loss of clinical attachment and alveolar bone after periodontal therapy are currently poorly defined and apply to many disease entities. In addition, the clinical and etiologic manifestations of the different diseases outlined in North America in 1989 and in Europe in 1993 were not consistently observed in different countries around the world and did not always fit the models presented. As a result, the AAP held an International Workshop for the Classification of Periodontal Diseases in 1999[2] to further clarify a classification system based on current clinical and scientific data. The resulting classification of the different forms of periodontitis was simplified to describe three general clinical manifestations of periodontitis: chronic periodontitis, aggressive periodontitis, and periodontitis as a manifestation of systemic diseases (see Table 4-1 and Box 4-3).

Chronic Periodontitis

Chronic periodontitis[6] is the most common form of periodontitis and the characteristics of this form of periodontitis are outlined in Box 4-3. Chronic periodontitis is most prevalent in adults but can be observed in children;

TABLE 4-1

Classification of the Various Forms of Periodontitis

Classification	Forms of Periodontitis	Disease Characteristics
AAP World Workshop in Clinical Periodontics, 1989[5]	Adult periodontitis	Age of onset >35 years Slow rate of disease progression No defects in host defenses
	Early onset periodontitis (may be prepubertal, juvenile, or rapidly progressive)	Age of onset <35 years Rapid rate of disease progression Defects in host defenses Associated with specific microflora
	Periodontitis associated with systemic disease	Systemic diseases that predispose to rapid rates of periodontitis Diseases: diabetes, Down syndrome, HIV infection, and Papillon-Lefevre syndrome
	Necrotizing ulcerative periodontitis	Similar to acute necrotizing ulcerative gingivitis but with associated clinical attachment loss
	Refractory periodontitis	Recurrent periodontitis that does not respond to treatment
European Workshop on Periodontology, 1993[3]	Adult periodontitis	Age of onset: fourth decade of life Slow rate of disease progression No defects in host response
	Early onset periodontitis	Age of onset: prior to fourth decade of life Rapid rate of disease progression Defects in host defenses
	Necrotizing periodontitis	Tissue necrosis with attachment and bone loss
AAP International Workshop for Classification of Periodontal Diseases, 1999[1]	Chronic periodontitis	See Box 4-3
	Aggressive periodontitis	See Box 4-3
	Periodontitis as a manifestation of systemic diseases	See Box 4-3

therefore the age range of >35 years previously designated for the classification of this disease has been discarded. Chronic periodontitis is associated with the accumulation of plaque and calculus and generally has a slow to moderate rate of disease progression, but periods of more rapid destruction may be observed. Increases in the rate of disease progression may be caused by the impact of local, systemic, or environmental factors that may influence the normal host-bacterial interaction. Local factors may influence plaque accumulation (Box 4-4); systemic diseases such as diabetes mellitus and HIV infection may influence the host defenses; environmental factors such as cigarette smoking and stress also may influence the response of the host to plaque accumulation.

BOX 4-3

Periodontitis

The disease periodontitis can be subclassified into the following three major types based on clinical, radiographic, historical, and laboratory characteristics.[6,11,26]

Chronic Periodontitis

The following characteristics are common to patients with chronic periodontitis:

- Prevalent in adults but can occur in children
- Amount of destruction consistent with local factors
- Associated with a variable microbial pattern
- Subgingival calculus frequently found
- Slow to moderate rate of progression with possible periods of rapid progression
- Possibly modified by or associated with the following:
  Systemic diseases such as diabetes mellitus and HIV infection
  Local factors predisposing to periodontitis (see Box 4-3)
  Environmental factors such as cigarette smoking and emotional stress

Chronic periodontitis may be further subclassified into localized and generalized forms and characterized as slight, moderate, or severe based on the common features described above and the following specific features:

Localized form: <30% of sites involved
Generalized form: >30% of sites involved
Slight: 1 to 2 mm of clinical attachment loss
Moderate: 3 to 4 mm of clinical attachment loss
Severe: ≥5 mm of clinical attachment loss

Aggressive Periodontitis

The following characteristics are common to patients with aggressive periodontitis:

- Otherwise clinically healthy patient
- Rapid attachment loss and bone destruction
- Amount of microbial deposits inconsistent with disease severity
- Familial aggregation of diseased individuals

The following characteristics are common but not universal:

- Diseased sites infected with *Actinobacillus actinomycetemcomitans*
- Abnormalities in phagocyte function
- Hyperresponsive macrophages, producing increased PGE_2 and IL-1β
- In some cases, self-arresting disease progression

Aggressive periodontitis may be further classified into localized and generalized forms based on the common features described here and the following specific features:

Localized form:

- Circumpubertal onset of disease
- Localized first molar or incisor disease with proximal attachment loss on at least two permanent teeth, one of which is a first molar
- Robust serum antibody response to infecting agents

Generalized form:

- Usually affecting persons under 30 years of age (however, may be older)
- Generalized proximal attachment loss affecting at least three teeth other than first molars and incisors
- Pronounced episodic nature of periodontal destruction
- Poor serum antibody response to infecting agents

Periodontitis as a Manifestation of Systemic Diseases

Periodontitis may be observed as a manifestation of the following systemic diseases:

1. Hematologic disorders
   a. Acquired neutropenia
   b. Leukemias
   c. Other
2. Genetic disorders
   a. Familial and cyclic neutropenia
   b. Down syndrome
   c. Leukocyte adhesion deficiency syndromes
   d. Papillon-Lefévre syndrome
   e. Chediak-Higashi syndrome
   f. Histiocytosis syndromes
   g. Glycogen storage disease
   h. Infantile genetic agranulocytosis
   i. Cohen syndrome
   j. Ehlers-Danlos syndrome (Types IV and VIII AD)
   k. Hypophosphatasia
   l. Other
3. Not otherwise specified

Chronic periodontitis may occur as a localized disease wherein <30% of evaluated sites demonstrate attachment and bone loss, or as a more generalized disease wherein >30% of sites are affected. The disease also may be described by the severity of disease as slight, moderate, or severe based on the amount of clinical attachment loss (see Box 4-3).

Aggressive Periodontitis

Aggressive periodontitis[15-26] differs from the chronic form primarily by the rapid rate of disease progression seen in an otherwise healthy individual, an absence of large accumulations of plaque and calculus, and a family history of aggressive disease suggestive of a genetic trait (see Box 4-3). This form of periodontitis was previously classified as early onset periodontitis (see Table 4-1) and therefore still includes many of the characteristics previously identified with the localized and generalized forms of early onset periodontitis. Although the clinical presentation of aggressive disease appears to be universal, the etiologic factors involved are not always consistent. Additional clinical, microbiologic, and immunologic characteristics of aggressive disease that may be present are outlined in Box 4-3. As was previously described for early onset disease, aggressive forms of disease usually affect young individuals at or after puberty and may be observed during the second and third decade of life (i.e., 10 to 30 years of age). The disease may be localized as previously described for localized juvenile periodontitis (LJP) or generalized as previously described for generalized juvenile periodontitis (GJP) and rapidly progressive periodontitis (RPP) (see Table 4-1). The common features of the localized and generalized forms of aggressive periodontitis are outlined in Box 4-3.

BOX 4-4

Developmental or Acquired Deformities and Conditions[4,8,17]

Localized Tooth-Related Factors That Modify or Predispose to Plaque-Induced Gingival Diseases or Periodontitis
1. Tooth anatomic factors
2. Dental restorations or appliances
3. Root fractures
4. Cervical root resorption and cemental tears

Mucogingival Deformities and Conditions around Teeth
1. Gingival or soft tissue recession
   A. Facial or lingual surfaces
   B. Interproximal (papillary)
2. Lack of keratinized gingiva
3. Decreased vestibular depth
4. Aberrant frenum or muscle position
5. Gingival excess
   A. Pseudopocket
   B. Inconsistent gingival margin
   C. Excessive gingival display
   D. Gingival enlargement (see Box 4-2)
   E. Abnormal color

Mucogingival Deformities and Conditions on Edentulous Edges
1. Vertical and/or horizontal ridge deficiency
2. Lack of gingiva or keratinized tissue
3. Gingival or soft tissue enlargements
4. Aberrant frenum or muscle position
5. Decreased vestibular depth
6. Abnormal color

Occlusal Trauma
1. Primary occlusal trauma
2. Secondary occlusal trauma

Periodontitis as a Manifestation of Systemic Diseases

Several hematologic and genetic disorders have been associated with the development of periodontitis in affected individuals[10,11] (see Box 4-3). The majority of these observations of effects on the periodontium are the result of case reports, and few research studies have been performed to investigate the exact nature of the effect of the specific condition on the tissues of the periodontium. It is speculated that the major effect of these disorders is through alterations in host defense mechanisms that have been clearly described for disorders such as neutropenia and leukocyte adhesion deficiencies but are less well understood for many multifaceted syndromes. The clinical manifestation of many of these disorders appears at an early age and may be confused with aggressive forms of periodontitis with rapid attachment loss and the potential for early tooth loss. With the introduction of this form of periodontitis in this and previous classification systems (see Table 4-1), the potential exists for overlap and confusion between periodontitis as a manifestation of systemic disease and both the aggressive and chronic forms of disease when a systemic component is suspected. At present, periodontitis as a manifestation of systemic disease is the diagnosis to be used when the systemic condition is the major predisposing factor and local factors such as large quantities of plaque and calculus are not clearly evident. In the case where periodontal destruction is clearly the result of local factors but has been exacerbated by the onset of such conditions as diabetes mellitus or HIV infection, then the diagnosis should be chronic periodontitis modified by the systemic condition.

NECROTIZING PERIODONTAL DISEASES

The clinical characteristics of necrotizing periodontal diseases may include but are not limited to ulcerated and necrotic papillary and marginal gingiva covered by a yellowish-white or grayish slough or pseudomembrane, blunting and cratering of papillae, bleeding on

provocation or spontaneous bleeding, pain, and fetid breath. These diseases may be accompanied by fever, malaise, and lymphadenopathy, although these characteristics are not consistent. Two forms of necrotizing periodontal disease have been described: necrotizing ulcerative gingivitis (NUG) and necrotizing ulcerative periodontitis (NUP). NUG has been previously classified under gingival diseases or gingivitis because clinical attachment loss is not a consistent feature, whereas NUP has been classified as a form of periodontitis because attachment loss is present. Recent reviews of the etiologic and clinical characteristics of NUG and NUP have suggested that the two diseases represent clinical manifestations of the same disease, except that distinct features of NUP are clinical attachment and bone loss. As a result, both NUG and NUP have been determined as a separate group of diseases that has tissue necrosis as a primary clinical feature (see Box 4-1).

Necrotizing Ulcerative Gingivitis

The clinical and etiologic characteristics of NUG[22] are described in detail in Chapter 21. The defining characteristics of NUG are its bacterial etiology, its necrotic lesion, and predisposing factors such as psychologic stress, smoking, and immunosuppression. In addition, malnutrition may be a contributing factor in developing countries. NUG is usually seen as an acute lesion that responds well to antimicrobial therapy combined with professional plaque and calculus removal and improved oral hygiene.

Necrotizing Ulcerative Periodontitis

NUP" differs from NUG in that loss of clinical attachment and alveolar bone is a consistent feature. All other characteristics appear to be the same between the two forms of necrotizing disease. The characteristics of NUP are described in detail in Chapter 27. NUP may be observed among patients with HIV infection and manifests as local ulceration and necrosis of gingival tissue with exposure and rapid destruction of underlying bone, spontaneous bleeding, and severe pain. HIV-infected patients with NUP are 20.8 times more likely to have CD4+ cell counts below 200 cells/mm3 of peripheral blood than HIV-infected patients without NUP, suggesting that immunosuppression is a major contributing factor. In addition, the predictive value of NUP for HIV-infected patients with CD4+ cell counts below 200 cells/mm3 was 95.1%, and a cumulative probability of death within 24 months of a NUP diagnosis in HIV-infected individuals had a 72.9% cumulative probability of death within 24 months of NUP diagnosis. In developing countries, NUP also has been associated with severe malnutrition that in some instances may lead to immunosuppression.

ABSCESSES OF THE PERIODONTIUM

A periodontal abscess[13] is a localized purulent infection of periodontal tissues and is classified by its tissue of origin. The clinical, microbiologic, immunologic, and predisposing characteristics are discussed in detail in Chapters 4-6.

PERIODONTITIS ASSOCIATED WITH ENDODONTIC LESIONS

Classification of lesions affecting the periodontium and pulp is based on the disease process sequence.[4]

Endodontic-Periodontal Lesions

In endodontic-periodontal lesions, pulpal necrosis precedes periodontal changes. A periapical lesion originating in pulpal infection and necrosis may drain to the oral cavity through the periodontal ligament, resulting in destruction of the periodontal ligament and adjacent alveolar bone. This may present clinically as a localized, deep, periodontal pocket extending to the apex of the tooth. Pulpal infection also may drain through accessory canals, especially in the area of the furcation, and may lead to furcal involvement through loss of clinical attachment and alveolar bone.

Periodontal-Endodontic Lesions

In periodontal-endodontic lesions, bacterial infection from a periodontal pocket associated with loss of attachment and root exposure may spread through accessory canals to the pulp, resulting in pulpal necrosis. In the case of advanced periodontal disease, the infection may reach the pulp through the apical foramen. Scaling and root planing removes cementum and underlying dentin and may lead to chronic pulpitis through bacterial penetration of dentinal tubules. However, many periodontitis-affected teeth that have been scaled and root planed show no evidence of pulpal involvement.

Combined Lesions

Combined lesions occur when pulpal necrosis and a periapical lesion occur on a tooth that also is periodontally involved. A radiographically evident intrabony defect is seen when infection of pulpal origin merges with infection of periodontal origin.

In all cases of periodontitis associated with endodontic lesions, the endodontic infection should be controlled before beginning definitive management of the periodontal lesion, especially when regenerative or bone-grafting techniques are planned.

DEVELOPMENTAL OR ACQUIRED DEFORMITIES AND CONDITIONS

Localized Tooth-Related Factors That Modify or Predispose to Plaque-Induced Gingival Diseases or Periodontitis

In general, these factors[4] are considered to be those local factors that contribute to the initiation and progression of periodontal disease through an enhancement of plaque accumulation or the prevention of effective

plaque removal by normal oral hygiene measures (see Box 4-4). These factors fall into three subgroups.

Tooth Anatomic Factors

These factors are associated with malformations of tooth development or tooth location. Anatomic factors such as cervical enamel projections and enamel pearls have been associated with clinical attachment loss, especially in furcation areas. Cervical enamel projections are found on *15%* to *24%* of mandibular molars and 9% to *25%* of maxillary molars, and strong associations have been observed with furcation involvement. Palatogingival grooves, found primarily on maxillary incisors, are observed in *8.5%* of individuals and are associated with increased plaque accumulation, clinical attachment, and bone loss. Proximal root grooves on incisors and maxillary premolars also predispose to plaque accumulation, inflammation, and loss of clinical attachment and bone. Tooth location is considered important in the initiation and development of disease. Tooth malalignment predisposes to plaque accumulation and inflammation in children and may predispose to clinical attachment loss in adults, especially when associated with poor oral hygiene. In addition, open contacts have been associated with increased loss of alveolar bone, most probably through food impaction.

Dental Restorations or Appliances

Dental restorations or appliances are frequently associated with the development of gingival inflammation, especially when they are located subgingivally. This may apply to subgingivally placed onlays, crowns, fillings, and orthodontic bands. Restorations may impinge on the biologic width by being placed deep in the sulcus or within the junctional epithelium. This may promote inflammation and loss of clinical attachment and bone with apical migration of the junctional epithelium and reestablishment of the attachment apparatus at a more apical level.

Root Fractures

Root fractures caused by traumatic forces or restorative or endodontic procedures may lead to periodontal involvement through an apical migration of plaque along the fracture when the fracture originates coronal to the clinical attachment and is exposed to the oral environment.

Cervical Root Resorption and Cemental Tears

Cervical root resorption and cemental tears may lead to periodontal destruction when the lesion communicates with the oral cavity and allows bacteria to migrate subgingivally.

Mucogingival Deformities and Conditions around Teeth

Mucogingival is defined as "a generic term used to describe the mucogingival junction and its relationship to the gingiva, alveolar mucosa, frenula, muscle attachments, vestibular fornices, and the floor of the mouth."

A *mucogingival deformity* may be defined as "a significant departure from the normal shape of gingiva and alveolar mucosa" and may involve the underlying alveolar bone. *Mucogingival surgery is* defined as "periodontal surgical procedures designed to correct defects in the morphology, position, and/or amount of gingiva" and is described in detail in Chapter 66. The surgical correction of mucogingival deformities may be performed for esthetic reasons, to enhance function, or to facilitate oral hygiene."

Mucogingival Deformities and Conditions on Edentulous Ridges

Mucogingival deformities and conditions on edentulous ridges usually require corrective surgery to restore form and function before the prosthetic replacement of missing teeth or implant placement.17

Occlusal Trauma

The etiology of trauma from occlusion and its effects on the periodontium is discussed in detail in Chapters *24, 25,* and *52.*1

- **Does My Patient with Aggressive Periodontitis Fit the Typical Profile?**
- **Why Do Patients Have Aggressive Periodontitis, and What Puts Them at Risk?**

Although information about the epidemiology of a disease is based on groups of people, whereas clinicians are primarily interested in the individual patient being treated, thoughtful clinicians understand the value of epidemiologic information for the decisions they must make about the philosophy of their practice and the treatment of each patient. Questions that frame the diagnosis of an individual patient include "Is this a rare or common condition? Does my patient fit the profile of people likely to have this disease? Where on the continuum of normality to disease are the signs and symptoms I see in my patient?" Epidemiologic studies identifying risk factors for diseases provide guidance for primary prevention recommendations, and newer molecular epidemiology studies help identify where to intervene in the disease process. Treatment-related questions such as "What is the natural history of the disease that I am treating?" lead to decisions about whether to treat now or continue to evaluate the condition. Similarly, much of our knowledge about the prognosis for an individual patient under a specific treatment comes from epidemiologic studies of treatment outcomes.

The focus of this chapter is on the clinician, which is the reason that many of the topic headings address clinical issues such as abnormality, definition of a case, diagnosis, and risk for new disease and disease progression. A short review of epidemiology and study designs used in

epidemiologic and clinical studies precedes discussion of these clinical issues. (For those who are well versed in these matters, the authors recommend skipping the next section and using it as a reference for the remainder of the chapter.)

WHAT IS EPIDEMIOLOGY?

Epidemiology is "the study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to control health problems."" Epidemiology traditionally has been considered a basic science of public health. What distinguishes public health practice from clinical practice is that public health practice emphasizes the health of population groups, whereas clinical practice is concerned with the health of individual patients. The determinants of disease in an individual patient may be quite different from the determinants of disease in a population. For example, a periodontist may attribute a patient's periodontal disease to the accumulation of plaque and calculus (factors that can be addressed in a practice), whereas a public health practitioner may attribute the high prevalence of periodontal disease in a given population to low socioeconomic status or the lack of access to preventive dental services.

As the definition implies, epidemiology has three purposes: 1) to determine the amount and distribution of a disease in a population, 2) to investigate causes for the disease, and 3) to apply this knowledge to the control of the disease. Perhaps the most basic question in public health and clinical practice is "How much disease is present?" Descriptive studies are used to measure the amount of disease in a population. Disease often is described in terms of the percentage of persons affected and its distribution among subgroups (defined by age, gender, ethnicity, education levels, or other characteristics) in the population. The underlying assumption in epidemiology is that the distribution of disease among members of a population is not random.[32] Some members or subgroups of the population have characteristics that make them more susceptible to disease. These characteristics include the physical, biologic, behavioral, cultural, and social factors that determine health.[a2] Epidemiologists use analytic studies such as case-control or cohort studies to investigate factors associated with a disease. The final purpose of epidemiology is to apply the knowledge gained from studies to "promote, protect, and restore health."[42] Epidemiologic data are the foundation for much of our public health policy. One of the most successful public health interventions has been the fluoridation of public drinking water to prevent dental caries. Epidemiologic data also have been the foundation for much of clinical practice.[32] Diagnostic tests, prognoses, and selection of appropriate therapies are based on studies of groups of people. The practice of evidence-based dentistry requires clinical practitioners to use the best available scientific information in making decisions about the care of individual patients. Much of this scientific information comes from epidemiologic studies and randomized clinical trials in particular.

Epidemiologic Measures of Disease

Prevalence

Prevalence is the proportion of persons in a population who have the disease of interest at a given point or period of time.[33] It is calculated by dividing the number of persons in the population who have the disease by the number of persons in the population.

$$\text{Prevalence} = \frac{\text{Number of persons with the disease}}{\text{Number of persons in the population}}$$

Prevalence, which can be reported as a proportion or percentage, is a measure of the burden of disease in a population. Information about prevalence can be useful for estimating the need for health care resources. For example, prevalence data on dental disease is used for estimating the number of new general dentists and specialists that dental schools should train.

Several factors influence the prevalence of disease. The prevalence of a disease at a given point in time is the result of the dynamic situation between the addition of new cases (incidence), which increases prevalence, and the removal of cases through death or cure, which decreases prevalence.[32] Ironically, the introduction of more sensitive diagnostic tests or new treatments that enhance survival increases prevalence.[32] Also, the prevalence of a nonfatal chronic disease, such as adult periodontitis, tends to increase with increasing age. This increase in prevalence with age, which is simply caused by the accumulation of cases, often is misinterpreted as meaning that older adults are at higher risk for the disease.

Incidence

Incidence-also referred to as risk or *cumulative incidence-is* the average percentage of unaffected persons who will develop the disease of interest during a given period of time.' Incidence can be viewed as the risk or probability that a person will become a case. It is calculated by dividing the number of new cases of disease by the number of persons in the population who are at risk for the disease.

$$\text{Incidence} = \frac{\text{Number of new cases}}{\text{Number of persons at risk}}$$

Whereas prevalence is a measure of the amount of disease existing in a population, incidence is a measure of the occurrence of new disease. The numerator of the incidence equation is the number of persons who transition from a nondiseased state to a diseased state during the period of observation. The denominator in the equation must contain only those persons in the population who are at risk for but do not have the disease at the start of observation. For example, in a study of oral cancer, only individuals who are free of oral cancer at the beginning of the study could be included in the population at risk. In the expression of incidence, specifying the period of observation is necessary. Without a

specified time period, such as per month or per year, incidence has little meaning.

In the study of periodontal disease, rarely, if ever, does *incident periodontal disease* refer strictly to the onset of disease in previously periodontitis-free adults. Instead, it usually refers to the development of new periodontal lesions in people who may have had other periodontal lesions at baseline and to the progression of existing lesions (see later discussion). Incident periodontal disease is typically measured as a change in attachment level over time, and studies rarely differentiate between the development of new lesions and the progression of existing ones.

Epidemiologic Study Designs

To investigate the prevalence and incidence of disease, risk factors associated with disease, and the effectiveness and efficacy of interventions, researchers conduct epidemiologic studies. Most epidemiologic studies are observational. In these studies, the researchers observe natural occurrences in the population. The most common observation studies are cross-sectional, cohort, and case-control studies. In addition to observational studies, epidemiologists also conduct experimental studies in which they manipulate exposures, such as in drug trials when one group of subjects receives the study drug and another group receives a placebo. Experimental studies are useful in studying the efficacy of preventive interventions, treatments, and drugs. Community intervention trials and randomized clinical trials are two types of experimental studies. Because researchers can control the exposures, these studies provide the strongest evidence for cause and effect. For more information of community intervention and clinical trials, the interested reader is referred to texts by Hulley and Cummings, Lilienfeld, and Friedman et al .[30,38,43] Features of the most common observational study designs are reviewed here.

Cross-Sectional Studies

In cross-sectional studies, the presence or absence of disease and characteristics of the members of a population are measured at a point in time. These studies are useful for providing prevalence data on a disease, comparing the characteristics of persons with and without disease, and generating hypotheses regarding the etiology of a disease. Whereas cohort and case-control studies are considered analytic study designs, cross-sectional studies are considered descriptive. Cross-sectional studies also are referred to as *disease frequency surveys* or *prevalence studies.* Depending on the size of the population and the resources available to the researchers, the entire population or a representative sample of the population can be studied. Cross-sectional studies repeated at regular intervals can provide information on trends in disease over time or the effectiveness of prevention or treatment programs.

Cross-sectional studies have two major limitations. First, cross-sectional studies can only identify prevalent cases of disease. Because these studies do not follow a population at risk of the disease over time, incidence cannot be determined. Second, although cross-sectional studies may show that a certain characteristic is associated with having the disease, determining whether the characteristic preceded the disease is not always possible. For example, a cross-sectional study may reveal that people with periodontal disease are more likely to be smokers; however, it cannot always be determined whether the smoking or the disease occurred first. Establishing the temporal relationship between a particular characteristic and the onset of disease is an important criterion for determining whether the characteristic is a cause of the disease. Cohort studies that observe people over time are required to calculate incidence and establish temporality. The advantages of cross-sectional studies are that they are generally less expensive than longitudinal studies and quicker to conduct.

Cohort Studies

Unlike cross-sectional studies, cohort studies follow subjects over time. The purpose of a cohort study is to determine whether an exposure or characteristic is associated with the development of a disease or condition. At the beginning of the study, all subjects must be free of the disease of interest. Subjects are classified into exposed and unexposed groups and then followed over time and monitored for the development of the disease. Incidence can be calculated because new cases of disease are assessed. If the incidence of disease is greater in the exposed group than in the unexposed group, then the study provides evidence that the exposure is a risk factor for the disease. Because a cohort study can demonstrate that an exposure preceded a disease, it provides strong support for an association. The disadvantages of cohort studies are that they can require long periods of follow-up and can be expensive to conduct. Also, if the disease of interest is rare, large numbers of subjects will need to be followed. The preferred study design for investigating rare diseases is the case-control study.

Case-Control Studies

Case-control studies provide an efficient way to investigate the association between an exposure and a disease, especially a rare disease. In a case-control study, persons with the disease (cases) and persons without the disease (controls) are recruited into the study and assessed for the exposure of interest. If an association exists between the exposure and the disease, then the proportion of exposed persons would be expected to be greater among the cases than the controls.

Because case-control studies do not follow subjects through time, they require fewer resources and can be conducted more quickly than cohort studies. For rare diseases such as oral cancer, recruiting existing cases is much more efficient than enrolling a large, cancer-free cohort and observing the subjects over time. The major disadvantage of the case-control study is that the temporal relationship between the exposure and the onset of disease cannot always be determined because the exposure is usually assessed when the disease status is established. Also, the prevalence or incidence of a disease cannot be determined from a case-control study because the subjects are recruited into the study based on their disease status.

More information on the basics of epidemiology can be found in texts by Gordis and Greenberg et al. [32-33]

DIAGNOSIS

Normal versus Abnormal; Health versus Disease

For epidemiologists to study disease in populations or for clinicians to care for individual patients, they have to be able to identify individuals with disease. For some conditions, the distinction between health and disease is apparent. For example, if a teenager has extensive bone loss around the first molars and lower incisors, the clinical diagnosis of localized, aggressive periodontitis (formerly localized juvenile periodontitis) is obvious. Yet for many conditions, a gray area exists between health and disease. Does a patient with a diastolic blood pressure of 90 mm Hg have hypertension? If the tip of a dental explorer "sticks" on the occlusal surface of a molar with no obvious cavitation, is dental caries present? Does a patient with 3 mm of periodontal attachment loss on only one tooth have periodontitis? The consequences of making the wrong decision could be significant. In clinical practice, misdiagnosing diseased and disease-free patients could mean that persons without disease would face the costs and risks of unnecessary treatment while persons with disease go untreated. In epidemiologic studies, the misclassification of subjects would result in the underestimation or overestimation of the prevalence of disease. It also could lead to invalid conclusions about the association between a disease and some exposure or characteristic.

When making diagnoses, clinicians assimilate information from a variety of sources, such as patient interviews, clinical examinations, radiographs, and laboratory data. From this information, the clinician has to distinguish between normal and abnormal findings. One approach for making this distinction is to consider abnormal as unusual.[28] In clinical practice, this refers to the unexpected or infrequent finding or test result. What is unexpected or infrequent is sometimes based on statistically defined thresholds such as two standard deviations from the mean or the 95th percentile (those in the upper 5%). However, thresholds based on statistical considerations are not adequate for all diseases. As Fletcher et al point out, if the same statistical threshold was chosen for all clinical tests, then the prevalence of all diseases would be the same .z[8] Another approach is to establish the threshold using observations associated with an increased risk of disease. For example, 90 mm Hg is chosen as the threshold for hypertension because observations that are above that value are associated with greater risk for developing cardiovascular disease. For a more in-depth discussion of the criteria for abnormality, the interested reader is referred to *Clinical Epidemiology: The Essentials.*[28]

Principles of Diagnostic Testing

Practitioners use diagnostic tests to increase the probability of making correct diagnoses. In dentistry, the diagnosis of periodontal disease is made by the assimilation of clinical and radiographic information, such as bleeding on probing, pocket depth, attachment loss, and bone loss. However, progress is being made in the development of diagnostic tests for periodontal disease. Because periodontal disease is a chronic, infectious disease, microbiologic tests have been developed to detect the presence of specific periodontal pathogens in the gingival sulcus or pockets. These tests are useful for planning treatment for new patients, selecting appropriate recall intervals, monitoring periodontal therapy, determining appropriate antibiotic therapy for patients who do not respond to conventional therapy, and screening patients before extensive restorative or implant therapy.[$°] Also, immunologic and biochemical tests to measure the individual's response to periodontal pathogens are being developed. As more of these tests become available, it will become increasingly important for dental practitioners to understand the principles of diagnostic testing.

Sensitivity and Specificity

When a diagnostic test for a disease or condition gives a positive result, the result can be correct (true positive) or incorrect (false positive). When a test gives a negative result, the result can be true (true negative) or false (false negative) (Table 5-1). The ability of a test to give a correct answer is indicated by its sensitivity and specificity.

The sensitivity of a test is the proportion of subjects with the disease who test positive.

$$\text{Sensitivity} = \frac{\text{Number of subjects who test positive}}{\text{Number of subjects with disease}} = \frac{A}{A + C}$$

A highly sensitive test is unlikely to be negative when someone has the disease (false negative). A clinician should choose a highly sensitive test when the consequences of not identifying a person with a disease could be severe, such as during testing for human immunodeficiency virus (HIV) infection. Another example would be a microbiologic test for active periodontal disease.

TABLE 5-1

Comparison of Diagnostic Test Results with True Disease Status

	TRUE DISEASE STATUS	
Test Result	**Disease**	**No Disease**
Positive	A (true positive)	B (false positive)
Negative	C (false negative)	D (true negative)
Sensitivity	A ÷ (A + C)	
Specificity		D ÷ (B + D)
Positive predictive value	A ÷ (A + B)	
Negative predictive value		D ÷ (C + D)

Although the consequences would not be as potentially severe as in the HIV example, a false-negative result for active periodontal disease could mean that appropriate therapy would not be prescribed. Sensitive tests also are useful when a clinician wants to rule out possible diseases during the early stages of diagnostic work-ups or screen for diseases during routine physical examinations.[28] Because sensitive tests rarely give false-negative results, sensitive tests are most informative when the results are negative.[28] That is, if the results are negative, the clinician can be reasonably sure the person does not have the disease.

The specificity of a test is the proportion of subjects without the disease who test negative.

$$\text{Specificity} = \frac{\text{Number of subjects who test negative}}{\text{Number of subjects without disease}} = \frac{D}{B + D}$$

A highly specific test is unlikely to be positive when a person does not have the disease (false positive). Specific tests are especially indicated when the misdiagnosis of disease in the absence of disease could harm a person either emotionally, physically, or financially.[28] For example, a false-positive screening test for HIV could cause significant emotional stress until more definitive testing could be performed. Although a false-positive microbiologic test for active periodontal disease could mean unnecessary treatment and expense, it also could mean that a person who desires extensive restorative treatment or dental implants would inappropriately be considered as too high-risk for such care. Because highly specific tests rarely give false-positive results, sensitive tests are most informative to clinicians when the results are positive.[28]

Ideally, a diagnostic test would be highly sensitive and specific; however, for most tests, sensitivity comes at the expense of specificity and vice versa. This is because most diagnostic test results take on values distributed over a range of values. In such cases, a threshold, or cut-off point, has to be established to distinguish between positive and negative results. As the threshold is moved higher or lower, the sensitivity and the specificity change in opposite directions. Currently, the threshold for hypertension is a diastolic blood pressure of 90 mm Hg. However, if the threshold for hypertension were increased to 100 mm Hg, the number of false positives would decrease (increased specificity) while the number of false negatives would increase (decreased sensitivity). The decision of where to place a threshold for a test depends on the penalty for making the wrong decision. If the penalty for a false-negative result is higher than the penalty for a false positive, then a threshold that makes the test more sensitive should be selected. But if the penalty for a false positive result is higher, a threshold that makes the test more specific should be selected. Because diagnostic tests are rarely both sensitive and specific, a highly sensitive test is sometimes administered first to rule out people who do not have the disease. Then the people who test positive are given a highly specific test to rule in people who have the disease.

Predictive Value

Sensitivity and specificity are characteristics of a diagnostic test that are useful in choosing an appropriate test. However, once a clinician has received the test result, the most relevant question becomes "Given this test result, what is the probability that it is right?" The answer to this question is the predictive value of the test. The probability that a person with a positive test has the disease is called the *positive predictive value of the test* (A - A + B, as shown in Table 5-1). The probability that a person with a negative test does not have the disease is referred to as the *negative predictive value* (D - C + D). For a given diagnostic test, the predictive values are influenced by the prevalence of the disease in the population tested.[28] As the prevalence of disease in the population decreases, a higher proportion of the positive tests are false. As the prevalence of disease increases, a higher proportion of negative tests are false. This situation is better explained by looking at the extremes of prevalence:

> *Imagine a population in which no one has the disease. In such a group, all positive results, even for a very specific test, will be false positives. Therefore as the prevalence of disease in a population approaches zero, the positive predictive value of a test also approaches zero. Conversely, if everyone in a population tested has the disease, all negative results will be false negatives, even for a very sensitive test. As* ***prevalence approaches*** *100%, negative predictive value approaches zero.*[28]

Because of the influence of prevalence on the predictive values of tests, clinicians have to be aware of the patient's probability of having disease.

RISK VERSUS PROGNOSIS

Risk, Risk Factors, and Risk Assessment

In addition to determining who has a disease at a given point in time, clinicians and epidemiologists are also interested in predicting who will get the disease. The likelihood that a person will get a disease in a specified time period is called *risk*. For any given disease, the risk of developing the disease differs among individuals. The characteristics of individuals that place them at increased risk for getting a disease are called *risk factors.* As the definition implies, exposure to a risk factor must occur before the onset of disease. Exposure to a risk factor may have been at a single point in time, episodic, or continuous. Removal of a risk factor or a reduction in exposure should reduce an individual's risk of getting the disease, but once a person has the disease, removal of the risk factor may not make the disease disappear. And rarely does a single risk factor explain a person's entire risk for a disease. The identification and importance of risk factors for a disease are based on current knowledge, and as knowledge about relationships between factors and disease changes, new factors may become important while previously identified factors become less important or irrelevant.

The process of predicting an individual's probability of disease is called *risk assessment.* Clinicians use risk assessment in several ways. One way is to predict which patients are at risk for disease. For example, people who smoke cigarettes or have diabetes are at a higher risk of developing periodontal disease than nonsmokers or nondiabetics. This information may be important for scheduling the frequency of hygiene appointments. Another way clinicians use risk assessment is to aid in the diagnosis of disease. In adolescent patients with localized bone loss on the lower first molars, the detection of significant numbers of *Actinobacillus actinomycetemcomitans* can help in the diagnosis of early onset periodontitis. Finally, clinicians often use risk assessment to prevent disease by identifying and modifying risk factors. For example, dental providers commonly identify cigarette smokers within their practices and offer smoking cessation services. The amount of disease prevented depends on the success of the intervention in reducing the risk and the number of risk factors associated with the disease.

Prognosis, Prognostic Factors, and Prognosis Assessment

Once disease is identified, the patient's and clinician's attentions usually turn to the course of disease. Unlike risk, which deals with the prediction of new disease, prognosis is the prediction of the course or outcome of the disease. Depending on the disease, important outcomes may include death, survival, or quality of life issues, such as pain and disability. For periodontal disease, important outcomes include tooth loss, recurrent disease, and loss of function. The characteristics or factors that predict the outcome of a disease once disease is present are known as *prognostic factors,* and the process of using prognostic factors to predict the course of a disease is called *prognosis assessment.* In periodontics, factors often considered in the generation of a prognosis include but are not limited to tooth type, furcation involvement, bone loss, pocket depth, tooth mobility, occlusal force, patient's home dental care, presence of systemic disease, and cigarette smoking (see Chapter 32).

As discussed earlier, measures of disease incidence commonly include new periodontal lesions in sites without previous disease and progression of disease in already diseased sites. In reality, the latter event is actually disease progression, not disease incidence. While this distinction may not be extremely important when considering the incidence of disease, the difference between risk factors and prognostic factors should be remembered. Some factors such as smoking may be both risk factors and prognostic factors, while others are either risk factors or prognostic factors. Thus once a person has the disease, two processes must be considered: reducing the risk in healthy sites and increasing the risk for a positive prognosis in the sites with disease.

GINGIVAL DISEASE

Obviously, a gingivitis case involves a person with gingivitis. The more difficult part involves deciding when a person has gingivitis. An early definition of gingivitis simply stated that gingivitis was inflammation of the gingiva." Another definition in the literature states that gingivitis is inflammation of the gingiva in which the junctional epithelium remains attached to the tooth at its original level.31 This definition implies that gingivitis does not exist if the tooth has periodontitis. In other words, if the inflammatory process involves the gingiva and the periodontium and loss of periodontal attachment has occurred, then according to this definition, the condition should be called *periodontitis,* not gingivitis. The presence of plaque-induced gingivitis in a patient with existing but nonprogressing attachment loss has recently been classified (see Box 4-2). Whether the presence or absence of gingivitis is conditional on the presence of attachment loss has important implications for the estimation of the prevalence of gingivitis.

Although the clinical signs of gingivitis are easy to detect, it is not clear how much inflammation a person must have to be considered a gingivitis case. A universally accepted threshold for the amount or severity of gingival inflammation that must be present in an individual does not exist. In studies of gingivitis, a variety of indices have been used. Because different indices have different clinical criteria for establishing the presence or absence of gingivitis, the definition of a gingivitis case varies across studies. In general, however, a gingivitis case is a person with at least mild inflammation in at least one of the gingival units that are assessed. Depending on the study, a gingival unit may be an anatomic structure of the gingiva, such as the interdental papilla, marginal gingiva, or attached gingiva, or it may be a gingival site defined in relation to a tooth, such as the facial, lingual, mesial, or distal gingiva.

How Is Gingivitis Measured?

Gingivitis is measured by gingival indices. Indices are methods for quantifying the amount and severity of diseases or conditions in individuals or populations. Indices are used in clinical practice to assess the gingival status of patients and follow any changes in gingival status over time. Gingival indices are used in epidemiologic studies to compare the prevalence of gingivitis in population groups. In clinical studies, gingival indices are used to test the efficacy of therapeutic agents or devices. The ideal index is simple and quick to use, accurate, reproducible, and quantitative. All gingival indices measure one or more of the following: gingival color, gingival contour, gingival bleeding, extent of gingival involvement, and gingival crevicular fluid flow.24 Most indices assign numbers on an ordinal scale (0, 1, 2, 3, and so on) to represent the extent and severity of the gingival condition. These numbers usually can be summarized to represent the gingival status in an individual or a population. The first quantitative methods for assessing gingivitis appeared around the end of World War II. Many gingival indices have been introduced since that time, and no single index has universal application or acceptance.[45]

TABLE 5-2

Criteria for the Gingival Index

Score	Criteria
0	Normal gingiva
1	Mild inflammation: slight change in color and slight edema. No *bleeding on probing.*
2	Moderate inflammation: redness, edema, and glazing. *Bleeding on probing.*
3	Severe inflammation: marked redness and edema. Ulceration. *Tendency toward spontaneous bleeding.*

From Loe H: The gingival index, the plaque index, and the retention index systems. J Periodontol 1967; 38:610(suppl).

TABLE 5-3

Criteria for the Modified Gingival Index

Score	Criteria
0	Absence of inflammation
1	Mild inflammation: slight change in color, little change in texture of any portion of but not the entire marginal or papillary gingival unit
2	Mild inflammation: criteria as above but involving the entire marginal or papillary gingival unit
3	Moderate inflammation: glazing, redness, edema, and/or hypertrophy of the marginal or papillary gingival unit
4	Severe inflammation: marked redness, edema, and/or hypertrophy of the marginal or papillary gingival unit; spontaneous bleeding, congestion, or ulceration

From Lobene RR, Weatherfor T, Ross NM, et al: A modified gingival index for use in clinical trials. Clin Prevent Dent 1986; 8(1):3.

Gingival Index. The gingival index (GI) was proposed in 1963 as a method for assessing the severity and quantity of gingival inflammation in individual patients or among subjects in large population groups (Table 5-2).[47,49] Only gingival tissues are assessed with the GI. According to this method, each of the four gingival areas of the tooth (facial, mesial, distal, and lingual) is assessed for inflammation and given a score from 0 to 3. The criteria for quantifying the severity of gingival inflammation are shown in Table 5-2. Bleeding is assessed by running a periodontal probe along the soft tissue wall of the gingival crevice. The scores for the four areas of the tooth can be totaled and divided by four to give a tooth score. By adding the tooth scores together and dividing by the number of teeth examined, an individual's GI score can be obtained. The gingival areas of all teeth or selected teeth can be assessed. A GI score of 0.1 to 1.0 indicates mild inflammation, 1.1 to 2.0 indicates moderate inflammation, and 2.1 to 3.0 indicates severe inflammation .[47]

Modified Gingival Index. The modified gingival index (MGI) introduced two important changes to the Gl: 1) elimination of gingival probing to assess the presence or absence of bleeding and 2) redefinition of the scoring system for mild and moderate inflammation (Table 5-3).[46] The developers of the MGI decided to eliminate probing, which could disturb plaque and irritate the gingiva.[41] A noninvasive index would allow for repeated evaluations and permit intracalibration and intercalibration of examiners.[46] Also, the developers wanted an index that would be more sensitive to earlier, more subtle changes in gingival inflammation.[46] To achieve this, they assigned a score of 1 to mild inflammation that involved only a portion of the marginal or papillary gingival unit and a score of 2 to mild inflammation that involved the entire marginal or papillary gingival unit. Scores of 3 and 4 correspond with the original scores of 2 and 3, respectively, of the GI. The scoring criteria for the MGI can be found in Table 5-3. As with the GI, four gingival units per tooth (two marginal, two papillary) are assessed. Either a full or partial mouth assessment can be performed. A mean score for an individual can be calculated by summing the gingival unit scores and dividing by the number of gingival units examined.

The MGI is perhaps the most widely used index in clinical trials of therapeutic agents.[24] Like its predecessors, the MGI does not assess the presence of periodontal pockets or attachment loss. Thus these indices cannot identify gingivitis in the absence of periodontitis.

Gingival Bleeding Indices. Whereas the clinical assessment of gingival color, form, and texture is subjective in nature, gingival bleeding is an objective diagnostic sign of inflammation. Research suggests that bleeding upon the gentle probing of the gingival sulcus may occur before changes in color, form, or texture are apparent.[34,37,s3] Since 1974, numerous indices that measure bleeding only, such as the gingival bleeding index and the Eastman interdental bleeding index, have been published and reviewed elsewhere .[21,23,16] Periodontal probes are used with most indices; however, toothpicks and dental floss are used to elicit bleeding with some indices.[16] Among the indices that require the use of periodontal probes, the type of probe and the angulation, depth, and force of probing vary. Even though gingival bleeding is a sign of inflammation, the bleeding from the gingival sulcus may be associated with other forms of periodontal disease, not just gingivitis. For indices that require insertion of the periodontal probe to the bottom of the gingival sulcus, bleeding may be a sign of periodontitis rather than gingivitis. Gingival bleeding indices are used in clinical practice, surveys of population groups, and clinical trials of antiplaque and antigingivitis agents.

NIDCR Protocol for the Assessment of Gingival Bleeding. In several of its national surveys, such as the NIDR National Survey of Oral Health in U.S. Employed Adults and Seniors (1985-86) and the Third National Health and Nutrition Examination Survey (1988-94), the

National Institute of Dental and Craniofacial Research (NIDCR) has used the presence or absence of gingival bleeding as an indication of gingival health. The gingival assessment is just one of several components of the NIDCR protocol for the assessment of periodontal disease. For this approach, the facial and mesiofacial sites of teeth in two randomly selected quadrants, one maxillary and one mandibular, are assessed for bleeding. A special probe known as the *NIDR probe is* used in these assessments. The NIDR probe is color coded and is graduated at 2, 4, 6, 8, 10, and 12 mm. To begin the assessment, the examiner dries a quadrant of teeth with air. Then, starting with the most posterior tooth in the quadrant (excluding the third molar), the examiner places a periodontal probe 2 mm into the sulcus at the facial site and carefully sweeps the probe into the mesial interproximal area. After probing the sites in the quadrant, the examiner assesses the presence or absence of bleeding at each probed site. The same procedure is repeated for the remaining quadrant. For an individual, the number or percent of teeth or sites with bleeding can be calculated. For population groups, the prevalence of gingival bleeding, usually defined as bleeding at one or more sites, can be determined.

How Much Gingivitis Is Present?

The most recent data on the dental health of the U.S. population come from the third National Health and Nutrition Examination Survey (NHANES III), conducted from 1988 to 1994. The survey was the seventh in a series of national surveys designed to provide estimates of the health status of the U.S. population. This survey used the NIDCR protocol for gingival bleeding, which involves placing the probe in the gingival sulcus at a depth of 2 mm and sweeping the probe from the mesiofacial to the mesial interproximal area. According to data from NHANES III, 54% of the noninstitutionalized civilian U.S. population aged 13 years and older had gingival bleeding in at least one gingival site.75 Gingival bleeding was most prevalent in the 13- to 17-year-old age group (63%) and declined gradually through the 35- to 44-year-old age group (Fig. 5-1). The prevalence increased again at the 45- to 54-year-old age group but remained fairly constant in older age groups. On average per person, 10% of all sites had gingival bleeding; however, among persons with gingival bleeding, an average of 18% of sites had gingival bleeding. The extent of gingival bleeding among persons with gingival bleeding was higher in the younger and older age groups than in the middle age groups (Fig. 5-2).

A study of U.S. school children ages 14 to 17 years reported that the prevalence of gingival bleeding was 61.5%, essentially identical to the prevalence reported among 13- to 17-year-olds in the NHANES III study." Both surveys used the NIDCR gingival sweep method for eliciting gingival bleeding. The prevalence decreased with age from a high of 65% in 14-year-olds to a low of 57% in 17-year-olds. On average per child, 6% of sites measured had gingival bleeding with probing.

In NHANES III, gingival bleeding was assessed at periodontal sites without regard to the periodontal status of the tooth. One definition of gingivitis states that gingivitis is inflammation of the gingiva in which the functional epithelium remains attached to the tooth at its original level.31 If the prevalence of gingival bleeding from NHANES III data is recalculated using only periodontal sites without attachment loss (<1 mm), the prevalence of one or more sites per person with gingival bleeding decreases slightly from 54% to 47%. This indicates that about 7% of the people had bleeding only in sites with attachment loss. The remainder of individuals either did not have any bleeding in sites with

attachment loss or had bleeding in sites with and without attachment loss.

Is More or Less Gingivitis Present Now than Previously?

Although it is generally believed that the prevalence of gingivitis is declining in the U.S., the epidemiologic data needed to make that claim do not exist.' Since *1960,* several national health surveys have assessed periodontal health-the Health Examination Survey (HES) *(1960-62),* NHANES *I (1971-74),* the Health Resources and Services Administration (HRSA) survey of households *(1981),* the National Institute of Dental Research (NIDR) study of employed adults *(1985-86),* and NHANES *III (1988-94).* However, because of differences in populations, sampling methods, and periodontal measurement methods, comparisons of results between these surveys are difficult, if not impossible, to make. Table *5-4* summarizes periodontal findings from studies based on data from these surveys. Even if results from these studies could be compared, they do not support the view that the prevalence of gingivitis is declining.

Does My Patient with Gingivitis Fit the Typical Profile?

Gingivitis is so common that any patient presenting with gingivitis could be considered typical; however, gingivitis is more prevalent among certain groups. Adolescents have a higher prevalence of gingivitis than prepubertal children or adults. The rise of sex hormones during adolescence is suspected to be the cause of the increased prevalence. Studies suggest that the increase in sex hormones during puberty affects the composition of the subgingival microflora.[35,52,54] One study found that increased serum levels of testosterone in boys and estradiol and progesterone in girls was associated with increased levels of the periodontal pathogens *Prevotella intermedia* and *Prevotella nigrescens.*[14] Hormonal effects also may be responsible for the increased prevalence during pregnancy and among women using oral contraceptives. Estimates of the prevalence of gingivitis during pregnancy range from 30% to 100%.z[9]

As shown in Fig. *5-1,* males in all age groups are more likely to have gingivitis than females. The prevalence of gingivitis is especially high for males aged 13 to *17* years. Also, males with gingivitis have more involved sites than females (see Fig. 5-2), especially in the younger age groups. Although the reason for the existence of these gender differences is not known, poorer plaque control among males could likely explain much of their higher prevalence and extent of disease.

Why Do Patients Have Gingivitis, and What Puts Them at Risk?

It is clear from experimental and epidemiologic studies that microbial plaque is the direct cause of gingivitis.[44,50,59,65] The cause and effect relationship between plaque and gingival inflammation was demonstrated in a classic study by Loe et al .5° In that study, *12* individuals *(9* dental students, 1 instructor, and *2* laboratory technicians) were asked to abstain from all measures of oral hygiene. Dental plaque began to form quickly, and the amount of plaque increased with time. All subjects developed gingivitis within 10 to *21* days. The mean GI score increased from *0.27* at baseline to *1.05* at the end of the "no-brushing" period. Gingival inflammation resolved in all subjects within 1 week of resuming hygiene measures. The authors concluded that bacterial plaque was essential in the production of gingival inflammation.

Because bacterial plaque is the cause of the most common form of gingivitis, factors that influence the oral hygiene status of individuals would likely influence the prevalence of gingivitis. The generally poorer oral hygiene status of males may explain the higher prevalence and extent among males.' Poorer oral hygiene also may explain the higher prevalence of gingivitis among adolescents. Even though the increased levels of circulating sex hormones have been implicated in the higher prevalence, the influence of plaque control on gingivitis may be more important than the rising levels of hormones.[74] The conversion of bleeding gingival sites to nonbleeding sites with oral hygiene interventions alone provide string evidence for the role of poor oral hygiene in the etiology of gingivitis.[7,16,22]

Few population-based studies of the association between oral hygiene status and gingivitis have been published. In NHANES I, information on toothbrushing frequency and oral hygiene status were collected. A study that investigated the associations between these factors and the periodontal index (PI) reported that increased toothbrushing frequency and better oral hygiene scores were associated with lower PI scores.[76] These associations remained statistically significant after controlling for age, race, socioeconomic status, alcohol consumption, smoking habits, and dental visits. Although this study was based on the PI, an index of periodontal disease, gingivitis is a component of all but the most severe category. In NHANES III, information on the presence or absence of calculus was collected. However, this study has not reported any association between calculus and gingival health.

Although smoking is one of the most important risk factors for adult periodontitis, its role in gingivitis is unclear. Several studies have indicated that gingival bleeding is reduced among smokers.[14,66] Plaque levels in the smokers were either similar to or greater than plaque levels in nonsmokers. This reduction in gingival bleeding among smokers is perhaps the result of **the vasoconstrictive effects of nicotine in cigarette smoke.** In clinical practice, the smoking status of patients should be considered when gingival bleeding is assessed.

CHRONIC PERIODONTITIS

Periodontitis is inflammation of the periodontium that extends beyond the gingiva and produces destruction of the connective tissue attachment of the teeth .6' No longer considered a single disease, periodontitis is now considered to exist in three primary forms: chronic, aggressive, and as a manifestation of systemic diseases (see Box 4-4). Chronic periodontitis is the most common

TABLE 5-4

U.S. Population–Based Prevalence Studies* of Periodontal Disease

Survey	Year(s) Conducted	Population Sampled	Age at Periodontal Assessment	Method of Periodontal Assessment	Prevalence of Gingivitis	Prevalence of Periodontal Pockets	Prevalence of Attachment Loss
HES[26]	1960–62	Total civilian, non-institutionalized population aged 18 to 79 years	18 to 79 years	Periodontal index; no probing	48.5%	25.4% with pockets Average PI per person: 1.13	Not assessed
HANES I[27]	1971–74	Total civilian, non-institutionalized population aged 1 to 74 years	6 to 74 years	Periodontal index; no probing	25%	4.5% with 1 to 3 pockets 12.1% with ≥4 pockets Average PI per person: 0.83	Not assessed
HRSA[28]	1981	Households (including military personnel and their families)	19 years of age and older	Periodontal index (with modifications) Pocket depth measured in mm at mesial of every permanent erupted tooth	50% with gingivitis without any pockets ≥4 mm	28% with 1 or more teeth with pockets 4 to 6 mm 8% with 1 or more teeth with a pocket ≥6 mm	Not assessed
NIDR[29]	1985–86	Employed persons aged 18 to 64 years	18 to 64 years	Bleeding on probing. Ramfjord probing technique: Measured mesiofacial and midfacial sites in one upper and one lower quadrant (maximum of 28 sites in 14 teeth)	44% with one or more sites with bleeding	13.4% with one or more sites with pockets 4 to 6 mm 0.6% with one or more sites with pockets ≥ 7 mm	43.8% with one or more sites with attachment loss ≥ 3mm
NHANES III[30]	1988–1994	Total civilian, non-institutionalized population aged 2 months and older	13 years and older	Bleeding on probing. Ramfjord probing technique: Measured mesofacial and midfacial sites in one upper and one lower quadrant (maximum of 28 sites in 14 teeth)	54% with one or more sites with bleeding	21.0% with one or more sites with pockets ≥4 mm	38.1% with one or more sites with attachment loss ≥ 3 mm

* References refer to published studies that analyzed data from these surveys. Periodontal findings in any given column are from the study referenced in the second column.

form. Chronic periodontitis progresses slowly and generally becomes clinically significant in adults but may be observed in children. For epidemiologic purposes, a case of chronic periodontitis is a person with the disease. As with gingivitis, methods to measure periodontitis and the amount of disease necessary to consider a person a case vary widely across studies.

How Is Periodontitis Measured?

Periodontal Index. In the early 1950s, gingivitis indices were gaining in popularity; however, no index was available to measure more advanced stages of periodontal disease. Motivated by the lack of valid indices for measuring the prevalence of periodontal disease in population groups, Russell developed the PI (Table 5-5).[69] Use of the PI requires a minimum of equipment-a light source, a mouth mirror, and an explorer. The supporting tissues for each tooth in the mouth are scored according to a progressive scale that gives little weight to gingival inflammation and relatively great weight to advanced periodontal disease.[69] The scoring criteria for the PI are shown in Table 5-5. An individual's score is the sum of the tooth scores divided by the number of teeth examined. The population score is the sum of the individual scores divided by the number of persons examined. Periodontal probing was not recommended because, according to Russell, it "added little and proved to be a troublesome focus of examiner disagreement."[69]

TABLE 5-5

Criteria for the Periodontal Index

Score	Criteria and Scoring for Field Studies
0	Negative: There is neither overt inflammation in the investing tissues nor loss of function due to destruction of supporting tissues.
1	Mild gingivitis: There is an overt area of inflammation in the free gingiva, but this area does not circumscribe the tooth.
2	Gingivitis: Inflammation completely circumscribes the tooth, but there is no apparent break in the epithelial atachment.
6	Gingivitis with pocket formation: The epithelial attachment has been broken, and there is a pocket (not merely a deepened gingival crevice due to swelling in the free gingiva). There is no interference with normal masticatory function, the tooth is firm in its socket, and it has not drifted.
8	Advanced destruction with loss of masticatory function: The tooth may be loose, may have drifted, may sound dull on percussion with a metallic instrument, or may be depressible in its socket.

Modified from Russell AL: A system of classification and scoring for prevalence surveys of periodontal disease. J Dent Res 1954; 35(3):350.

The PI is fast and easy to use. However, one important criticism of the index is that it underestimates the prevalence of disease.[67]

Periodontal Disease Index. As a consultant to the World Health Organization for a 1957 study of periodontal disease in India, Ramfjord was faced with the inadequacies of the available indices for measuring periodontal disease.[67] Taking the most valuable features of existing indices and adding new features to compensate for their shortcomings, Ramfjord developed his own system for measuring periodontal disease.[67] This system became known as the *periodontal disease index (PDI).* One unique aspect of the PDI was the examination of six preselected teeth in the mouth-the maxillary right first molar, maxillary left central incisor, maxillary left first premolar, mandibular left first molar, mandibular right central incisor, and mandibular right first premolar. This selection of teeth became known as the *Ramflord teeth.* Another unique aspect of the PDI was the use of the cementoenamel junction as a fixed landmark for measuring periodontal attachment loss.

To begin an assessment using the PDI, the examiner dries the areas around the six teeth. Next, the examiner assesses the severity of gingival inflammation around the six teeth. Gingival scores for a tooth range from GO for absence of inflammation to G3 for severe gingivitis. At the mesial, facial, distal, and lingual side of each of the six teeth, the distance from the free gingival margin to the cementoenamel junction and the distance from the free gingival margin to the bottom of the gingival sulcus are measured in millimeters with a periodontal probe. If the free gingival margin is on the cementum, its distance from the cementoenamel junction is recorded as a negative number. The distance from the cementoenamel junction to the bottom of the gingival sulcus is the difference between these two measurements. The distance from the cementoenamel junction to the bottom of the gingival sulcus is a measurement of periodontal attachment loss. Ramfjord's method for measuring this distance is commonly referred to as the *indirect method for measuring periodontal attachment loss.* The PDI score for each tooth is based on the assessment of gingival inflammation and the depth of the gingival sulcus in relation to the cementoenamel junction (Table 5-6). If the gingival sulcus does not extend apically to the cementoenamel junction in any of the measured areas, then the PDI score for the tooth is the gingival score. If the gingival sulcus extends below the cementoenamel junction in any of the measured areas by 3 mm or less, then the PDI score is 4. Teeth with sulcus measurements of 3 to 6 mm and greater than 6 mm are given scores of 5 and 6, respectively. The PDI for the individual is the sum of the tooth scores divided by the number of teeth examined. If any of the six preselected teeth are missing, another tooth is not substituted in its place. In addition to the PDI score for periodontal disease, the PDI provides a method for calculating tooth scores for calculus, occlusal attrition, mobility, and proximal contacts.

Although the PDI is rarely used today, two aspects of the index are commonly used: selection of the six Ramfjord teeth and the method for measuring pocket depth

and loss of periodontal attachment. Ramfjord's technique for measuring pocket depth and periodontal attachment loss has been used in national surveys such as the National Health and Nutritional Examination Surveys.

Extent and Severity Index. The PI and the PDI yield scores that represent the severity of periodontal disease in individuals or populations, but these scores do not provide information on the extent of disease. The extent and severity index (ESI) of periodontal disease was developed to provide separate estimates of the extent and severity of periodontal disease in individuals and populations.' Unlike the PI and PDI, the ESI does not assess gingival inflammation. Instead, it estimates the loss of periodontal attachment at the mesiofacial and facial sites of 14 teeth in one maxillary quadrant and 14 teeth in the contralateral mandibular quadrant using the periodontal probing method developed by Ramfjord for the PDL 67 A threshold of disease has to be established to calculate the extent score for an individual. In their initial study of the ESI, Carlos et al considered a site to be diseased when attachment loss exceeded 1 mm.20 (Because the measurements are always rounded down to the next lowest millimeter, greater than 1 mm means >_2 mm.) For an individual, the extent score is the percentage of sites examined that have attachment loss greater than 1 mm. The severity score for an individual is the average loss of attachment per site among the disease sites. The ESI is expressed as a bivariate statistic: ESI = (Extent, Severity). For example, an individual's ESI of (20, 3.0) would be interpreted as 20% of sites examined had disease, and of the diseased sites, the average loss of attachment was 3.0 mm. The ESI for a population would be the average extent and severity scores for the individuals examined.

When ESI scores from two sites per tooth in the whole mouth were compared with an assessment of one upper and one lower quadrant, the developers of the ESI found that little information was lost from the half-mouth assessment.20 However, the ESI has been used for full-mouth examinations on as many as six sites per tooth.

NIDCR Protocol for Periodontal Disease Assessment. The NIDCR periodontal disease assessment, as used in NHANES 111, contains three parts: a periodontal destruction assessment, gingival assessment, and calculus assessment.55 The gingival assessment was previously described in the section on gingivitis. The periodontal destruction examination involves an assessment of loss of periodontal attachment and furcation involvement. Loss of attachment is the distance (in millimeters) from the cementoenamel junction to the bottom of the gingival sulcus. This distance is measured at the facial and mesiofacial sites of teeth in two randomly selected quadrants, one maxillary and one mandibular, using the indirect measurement method developed by Ramfjord.67 Probing is carried out with the use of the NIDCR probe, which is color coded and has markings at 2, 4, 6, 8, 10, and 12 mm. In NHANES III, loss of attachment was reported in millimeters for each site measured. Periodontal pocket depth, which is the distance from the free gingival margin to the bottom of the sulcus, also was reported in millimeters for each site.

Furcation involvement is assessed on eight teeth: the maxillary first and second molars, the maxillary first premolars, and the mandibular first and second molars. The assessment requires the use of a #17 dental explorer for the maxillary teeth and a #3 cowhorn explorer for the mandibular teeth. The extent of furcation involvement is assessed at the mesial, facial, and distal of the maxillary molars, the mesial and distal of the premolars, and the facial and lingual of the mandibular molars. If furcation involvement does not exist, the site is scored as 0.

TABLE 5-6

Criteria for the Periodontal Disease Index

GINGIVAL ASSESSMENT

Score	Criteria
GO	Absence of inflammation
G1	Mild to moderate inflammatory gingival changes not extending all around the tooth
G2	Mild to moderate severe gingivitis extending all around the tooth
G3	Severe gingivitis characterized by marked redness, tendency to bleed, and ulceration

RECORD POCKETS

The distance from the free gingival margin to the cementoenamel junction and the distance from the free gingival margin to the bottom of the gingival crevice or pocket should be recorded for the mesial, facial, distal, and lingual aspects of each tooth examined. The interproximal recording should be secured at the buccal aspect of the interproximal contact areas with the probe pointing in the direction of the long axis of the tooth.

If the gingival margin is on the enamel:

1. Measure from the gum margin to the cementoenamel junction, and record the measurement on the crown of the schematic tooth. If the epithelial attachment is on the crown and the cementoenamel junction cannot be felt by the probe, record the depth of the gingival crevice on the crown.
2. Measure from the gingival margin to the bottom of the pocket when the crevice extends apically to the cementoenamel junction. The measurement should be recorded on the root of the schematic tooth. (The distance from the cementoenamel junction to the bottom of the pocket can then be found by subtracting measurement 1 from measurement 2.)

If the gingival margin is on the cementum:

1. Measure from the cementoenamel junction to the gingival margin. Record as minus value on the root of the schematic tooth.
2. Measure from the cementoenamel junction to the bottom of the gingival crevice. Record value on the root.

Modified from Ramfjord SP: Indices for prevalence and incidence of periodontal disease. I Periodontol 1959; 30:51.

If partial involvement exists but the probe cannot pass through the furcation, the site is scored as 1. If the explorer can pass between the roots (through involvement), the site is scored as 2.

At each site assessed for loss of attachment, the presence or absence of supragingival and subgingival calculus is assessed. Subgingival calculus is detected using the NIDCR probe. A score of 0 is recorded for the site if no calculus is present, a score of 1 is recorded if only supragingival calculus is present, and a score of 2 is recorded if supragingival and subgingival calculus are present.

Radiographic Assessment of Bone Loss. The radiographic assessment of bone loss is an important part of the clinical diagnosis of periodontal disease. However, for the purposes of estimating the prevalence or incidence of periodontitis in population groups, radiographs are rarely used because of ethical and practical considerations. In studies in which radiographic bone loss is used as a measure of periodontitis, bone loss is usually measured from bite-wing radiographs as the distance from the cementoenamel junction to the alveolar crest. Bone loss can be expressed as this distance in millimeters or as a percentage of the root length. Various studies have used bone loss thresholds ranging from > 1 mm tc >3 mm.10 Bone loss measurements from radiographs are highly correlated with measurements of attachment loss taken with periodontal probes.10 The three main sources of error in the assessment of bone loss are 1) variations in projection geometry, 2) variations in film contrast and density, and 3) obstruction of the view by other anatomic structures.10 Computerized programs can detect bone changes as small as 0.5 mm when measuring bone loss from sequential radiographs.40 Also, advanced image-processing techniques such as digital subtraction radiography and computer-assisted densitometric image analysis can enhance the ability to detect bone loss over time.40

How Much Chronic Periodontitis Is Present?

The most recent data for the prevalence of periodontal disease in the U.S. comes from NHANES III (1988-94). Because the assessment of periodontitis in a cross-sectional survey such as NHANES III is a cumulative measure of periodontal destruction, separating chronic periodontitis in adults from other forms is not possible. However, an analysis of NHANES III data for adults aged 30 years and older was recently reported .4 The prevalence of periodontal attachment loss is greatly dependent on the threshold chosen, ranging from a high of 99% for a threshold of > 1 mm to a low of 7% for a threshold of >7 mm (Fig. 5-3). At a threshold of >3 mm, the prevalence of attachment loss in at least one site in the mouth was 53.1%. The prevalence of attachment loss increased steadily with age, from a low of 35.7% for the 30- to 39-year-old age group to a high of 89.2% for the 80- to 90-year-old age group (Fig. 5-4). On average per person, 19.6% of the teeth had attachment loss of >3 mm. Among people with at least one site of attachment loss of >3 mm, an average of 36.6% of the teeth per person were affected. The mean percentage of teeth affected also increased with age (Fig. 5-5). Maxillary molars and mandibular incisors were more likely than other teeth to have attachment loss of >3 mm, whereas maxillary central incisors were the least likely.

As with attachment loss, the prevalence of periodontal pockets is greatly dependent on the threshold chosen (Fig. 5-6). Generally, pockets greater than 3 mm are considered to reflect disease. The prevalence of periodontal pockets >4 mm was 23.1%. The increase in the prevalence of attachment loss with increasing age is not seen with pocket depth (Fig. 5-7). The average extent of pockets >4 mm was 5.2% of teeth per person, and the extent varied little with age (Fig. 5-8).

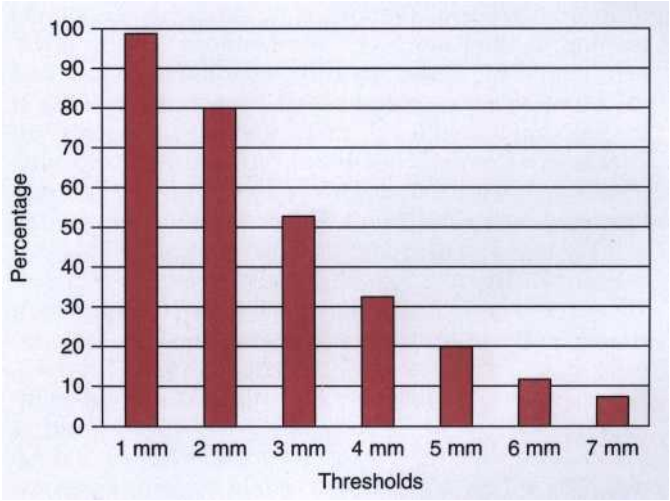

Fig. 5-3 Percentage of persons in the United States with periodontal attachment loss according to different thresholds of attachment loss. (From Albandar JM, Brunelle JA, Kingman A: Destructive periodontal disease in adults 30 years of age and older in the United States, 1988-1994. J Periodontol 1999; 70[1]:13.)

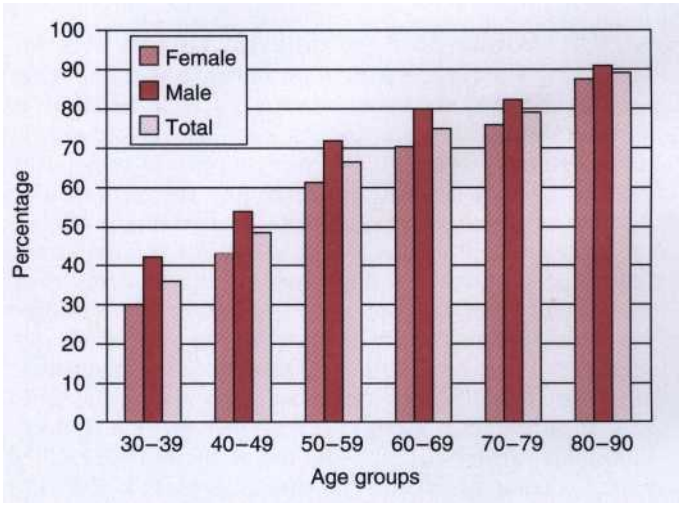

Fig. 5-4 Percentage of persons in the United States with periodontal attachment loss of >3 mm. (From Albandar JM, Brunelle JA, Kingman A: Destructive periodontal disease in adults 30 years of age and older in the United States, 1988-1994. J Periodontol 1999; 70[l]:13.)

The answer to the question "How much adult periodontitis is out there?" must be "It depends on the case definition used."

Is More or Less Chronic Periodontitis Present Now than Previously?

It is frequently stated that the prevalence of periodontal disease has decreased in the U.S. over the past 30 years. However, because of methodologic differences in the national surveys conducted over the years, making any conclusions about changes in the prevalence of periodontal disease is difficult. Drawing any conclusions about trends in the chronic form of periodontitis is even more difficult. A comparison of the methodologies and results from five national surveys conducted in the U.S. can be found in Table 5-4. The first two surveys, the HES (1960-62) and HANES 1 (1971-74), used the PI to measure periodontal disease. The PI relies only on visible signs of inflammation to determine the severity of periodontal disease. The presence of periodontal pockets was estimated by the presence of clinical signs, and clinical attachment loss was not measured. The HRSA survey of U.S. households (1981) was the first national survey to directly measure the depth of periodontal pockets with a periodontal probe; however, periodontal attachment loss was not measured. The last two national surveys, the NIDR survey of employed persons (1985-86) and the

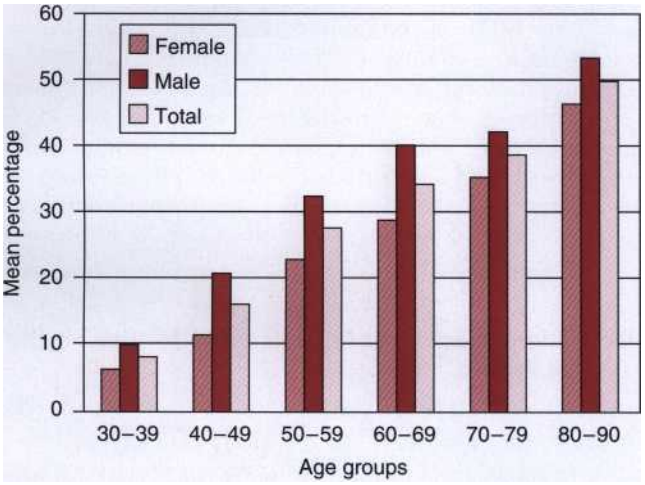

Fig. 5-5 Mean percentage of teeth per person in the United States with attachment loss of >3 mm. (From Albandar JM, Brunelle JA, Kingman A: Destructive periodontal disease in adults 30 years of age and older in the United States, 1988-1994. J Periodontol 1999; 70[1]:13.)

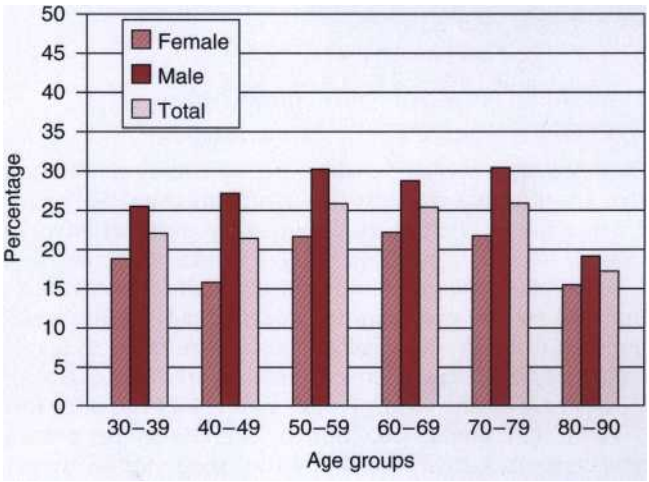

Fig. 5-7 Percentage of persons in the United States with periodontal pockets of >4 mm. (From Albandar JM, Brunelle JA, Kingman A: Destructive periodontal disease in adults 30 years of age and older in the United States, 1988-1994. J Periodontol 1999; 70[11:13.)

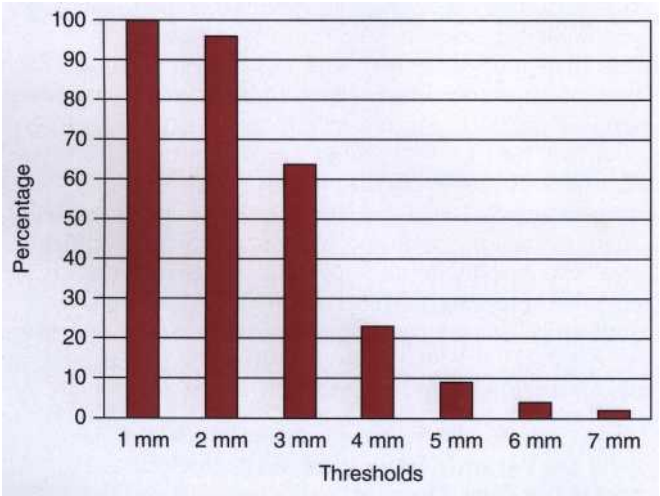

Fig. 5-6 Percentage of persons in the United States with periodontal pockets according to different thresholds of pocket depth. (From Albandar JM, Brunelle JA, Kingman A: Destructive periodontal disease in adults 30 years of age and older in the United States, 1988-1994. J Periodontol 1999; 70[1]:13.)

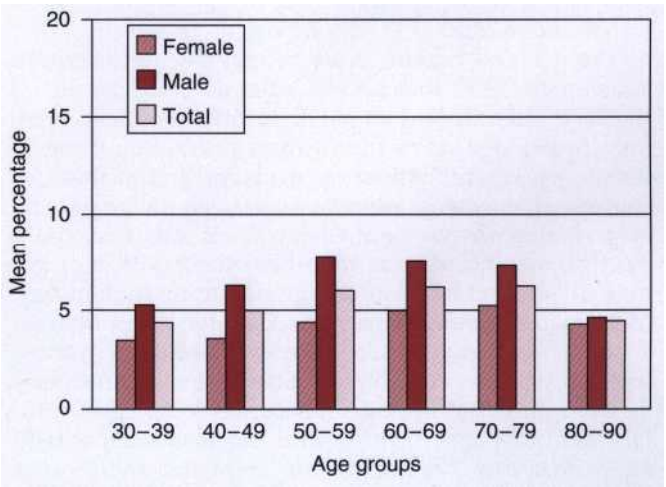

Fig. 5-8 Mean percentage of teeth per person in the United States with pocket depths of >4 mm. (From Albandar JM, Brunelle JA, Kingman A: Destructive periodontal disease in adults 30 years of age and older in the United States, 1988-1994. J Periodontol 1999; 70[l]:13.)

NHANES III (1988-94), used the Ramfjord technique for measuring pocket depth and attachment loss, but the NIDR survey only included employed persons, thereby excluding major groups in the U.S.

Conclusions about trends in periodontal disease will not be available until a series of national surveys that similarly measure periodontal disease are conducted. However, as Douglas and Fox concluded in their study of trends in periodontal disease, "Even if the prevalence and severity of periodontal disease are seen as declining over the next 30 years, it would seem that a substantial proportion of this decline will be counterbalanced by the sizable increase in number of persons and number of teeth per person at risk of disease."" In fact, Douglas and Fox estimated that for U.S. adults who are over the age of 25 years, the number of adults with some manifestation of periodontal disease would increase at least through the year 2010.[26]

How Much New or Progressing Chronic Periodontitis Is Present?

In contrast to prevalence data, no nationally representative longitudinal studies are available in the U.S. The incidence rates must be taken from studies representative of local or regional groups in the U.S. and other countries.

A 10-year follow-up study among Chinese individuals aged 20 to 80 years found that 79.8% of all sites measured (4 sites per tooth) experienced attachment loss." Approximately 48% of the sites measured lost >2 mm, 21.8% of the sites lost >3 mm, and 9% of the sites lost >4 mm. The average attachment level change per person was between 1.45 and 1.86 mm during the follow-up period, corresponding with 0.15 to 0.19 mm per year. Because very little difference in mean attachment loss by age groups existed, the researchers concluded that the influence of age on the rate of periodontal disease progression might be minimal. According to the researchers, the rate of disease progression in this group of Chinese individuals, who had limited access to dental care and poor dental hygiene, was similar to the rate of progression found in other populations around the world.

The Chinese study made no distinction between attachment level changes in sites without disease at the baseline examination and in sites that had existing disease. One study that made a distinction between disease onset and disease progression was a study of community-dwelling older adults (age 65 years and older) living in five contiguous North Carolina counties.[13] The subjects, who were followed for 36 months, were categorized into four groups according to their type of periodontal attachment loss: 1) those who only had attachment loss in previously nondiseased sites, 2) those with only progression of attachment loss in previously diseased sites, 3) those who experienced both types of attachment loss, and 4) those who had no new sites with attachment loss. The researchers considered change to be 3 or more mm of attachment loss over the 3-year period. The researchers found that 40% of the people had no change in their baseline attachment level, 27.5% of the people experienced only new lesions, 11.1% of the people only had attachment loss in sites that had attachment loss at baseline, and 20.1% of the people had both kinds of attachment loss.

Table 5-7 summarizes four other cohort studies-one from Japan, one from the U.S., and two from Sweden. Follow-up times for the four studies ranged from 1 year to 28 years. The two Swedish studies used radiographs to assess changes in alveolar bone height, whereas the studies from the U.S. and Japan used periodontal probing to assess changes in clinical attachment levels. Mean annual loss of bone or attachment loss per person, ranging from approximately 0.03 mm to 0.14 mm, was fairly consistent across the three studies that reported this information. Each study shows that attachment loss or alveolar bone loss progressed in only a small percentage of periodontal sites and subjects. In the study by Ismail et al, 59.3% of the periodontal sites present at baseline showed no change in attachment loss over the 28 years of follow-up. Only 13.3% of the subjects had a mean change in attachment loss of 2 mm or greater. Approximately 90% of the sites followed in the study by Albandar et al showed no change in bone height in the 6 years that passed between baseline and reexamination. In that study, 70% of the subjects had few or no sites with additional bone loss. From the results in these studies, adult periodontitis appears to progress fairly slowly and in only a minority of the adult population.

Does My Patient with Chronic Periodontitis Fit the Typical Profile?

Chronic periodontitis generally becomes clinically significant after age 30.[68] The disease is characterized by a slow progression of attachment loss over time. With 53% of U.S. adults having at least one periodontal site with attachment loss of 3 mm or more, periodontitis is a common disease. Among adults, the prevalence of attachment loss and periodontal pockets are higher in males than females (see Figs. 5-4 and 5-7). Males also are more likely than females to have more teeth with attachment loss and more teeth with pockets (see Figs. 5-5 and 5-8). Typically, the prevalence and extent of periodontal attachment loss increases with age (see Figs. 5-4 and 5-5). This increased prevalence with age is more likely a reflection of the cumulative effect of attachment loss over time as opposed to an increased susceptibility to periodontitis. Unlike attachment loss, the prevalence or extent of periodontal pocketing does not show much variation with age (see Figs. 5-7 and 5-8). The increase in attachment loss with age without a corresponding increase in pocket depth may result from the increasing prevalence of gingival recession with age. In the U.S., the prevalence of > 1 mm of gingival recession increases from 38% in the 30- to 39-year-old age group to 90% in the 80- to 90-year-old age group.[6]

Why Do Patients Have Chronic Periodontitis, and What Puts Them at Risk?

Periodontitis is an infectious disease associated with a group of mainly gram-negative bacteria.[79] The pathogenesis of periodontal disease and the role of microbial factors was extensively reviewed at the 1996 World

TABLE 5-7

Other Studies of Periodontal Disease Progression among Adults

Study	Length	Subjects	Methodology	Results
Haffajee et al.[52]	1 year	Random sample of 271 residents of Ushiku, Japan, ages 20 to 79 years.	Clinical attachment loss measured at six sites on all teeth. Change defined as attachment loss of >_3 mm in 1 year.	27.3% of persons had attachment loss at one or more sites. Older subjects had greater risk of disease progression than younger subjects. Persons with attachment loss at baseline were more likely to have progression.
Ismail et al.[53]	28 years	526 residents of Techumseh, MI, ages 5 to 60, examined at baseline in 1959. 167 reexamined in 1987.	Clinical attachment loss measured at four sites per tooth on all teeth present. Calculated mean attachment loss per person over 28 years.	13.3% of persons had mean loss >_2 mm. 3.0% of persons had mean loss >_3 mm. 1.2% of persons had mean loss >_4 mm. 59.3% of all sites did not change. Mean annual attachment loss per person was 0.04 mm. Only 10.9% of teeth were lost during follow-up.
Albandar et al.[54]	6 years	293 employees of an industrial plant in Oslo, Sweden, examined at baseline (ages 18 to 67 years). 142 were reexamined at 2 and 6 years.	Radiographic alveolar bone height measured from periapical films. Change defined as >_1 mm of bone loss during 2 consecutive exams.	70% of subjects had few or no sites with bone loss. 25% of subjects had moderate progression. 5% had high rates of progression. 90% of all sites did not change. Mean annual bone loss per person ranged by age from 0.03 to 0.05 mm.
Papapanou et al.[55]	10 years	531 Swedes examined at baseline in 1974-76 (ages 25 to 70). 201 Swedes reexamined in 1985-86.	Radiographic alveolar bone height measured at the mesial and distal of each tooth. Reported mean bone loss per person over the 10 years.	17% of persons had mean loss of >_2 mm. Mean annual bone loss per person was 0.07 to 0.14 mm in ages 25 to 65 years (age at baseline), 0.28 mm in 70-year-olds.

Workshop in Periodontics.[17,79] After reviewing the scientific literature, the section members concluded by consensus that sufficient evidence exists to consider three microorganisms as etiologic agents: *A. actinomycetemcomitans, Porphyromonas gingivalis,* and *Bacteriodes forsythus.$* Of these bacteria, *P. gingivalis* and *B. forsythus* often are found in chronic periodontitis, whereas *A. actinomycetemcomitans* often is found in cases of aggressive periodontitis. Evidence suggests that other microorganisms also may be involved in the development of periodontitis.

Although these pathogens are necessary to cause periodontitis, their presence is not sufficient to cause disease. Epidemiologic studies have shown that the presence of microorganisms in the subgingival plaque explains only a small portion of the cases of periodontitis. To explain these findings, periodontal researchers recently have begun to talk about a "new paradigm" for the etiology of adult periodontitis.61 This paradigm indicates that microorganisms are the cause of periodontitis but that the clinical expression of the disease (extent and severity) depends on how the host responds to the extent and virulence of the microbial burden. In response to periodontal pathogens and their endotoxins, immune cells in the periodontium, particularly monocytes, secrete proinflammatory mediators such as prostaglandin E, interleukin 1, and tumor necrosis factor. The body's inflammatory

response is an attempt to protect itself from the pathogens, but at the same time the inflammation can lead to periodontal connective tissue destruction and bone degeneration as the body attempts to rid itself of the infectious tooth. Further understanding of the role of differences in immune response should help in understanding an individual's susceptibility to periodontal disease.

Much epidemiologic research has focused on the identification of environmental and host factors that are involved in the initiation and progression of periodontal disease. Of all the environmental factors known to be associated with periodontitis, cigarette smoking may be the most important. Evidence for the role of smoking in periodontitis includes 1) a higher prevalence of disease among smokers in cross-sectional studies, 2) a higher incidence of periodontitis among smokers in longitudinal studies, 3) a statistically significant association even after controlling for other risk factors, 4) increased prevalence and incidence of disease with increased amounts of smoking, and 5) biologically plausible mechanisms that can explain how smoking is involved in the destruction of periodontal tissues." Cigarette smokers are up to 5 times more likely than nonsmokers to develop severe periodontitis, and the risk of the disease increases with the amount of cigarettes smoked."

Diabetes is another factor that enhances an individual's susceptibility to periodontis. The prevalence and severity of periodontitis is significantly higher in Type 1 (formally called *insulin-dependent* but now called *immune-mediated)* diabetics and Type 2 (formally called *noninsulin-dependent)* diabetics than in nondiabetics. 21,11 Type 1 diabetes typically occurs during childhood or adolescence, whereas Type 2 diabetes usually occurs after age 45. Approximately 9 of 10 individuals with diabetes have Type 2 diabetes. Much of clinicians' understanding of the epidemiologic association between diabetes and periodontitis comes from studies of the Pima Indians of the Gila River Indian Community in Arizona. The Pimas have the highest incidence of Type 2 diabetes ever recorded.41 Among the Pimas, diabetics have a threefold risk of developing periodontitis.27 The effects of diabetes appears to be similar among individuals with Type 1 and Type 2 diabetes as long as the duration of their disease is similar. However, individuals with Type 1 diabetes often have had diabetes longer than Type 2 diabetics and therefore may be at risk of developing more periodontitis.58 In addition to the duration of diabetes, the long-term metabolic control of diabetes is an important factor in periodontitis. Compared with well- and moderately controlled diabetics, the prevalence, severity, and extent of periodontitis are increased among poorly controlled diabetics. 72 The encouraging news is that well-controlled diabetics have similar levels of periodontal disease as nondiabetics, and diabetics treated for moderate to advanced adult periodontitis are able to maintain a healthy periodontium.58,78

Although numerous cross-sectional studies indicate that the prevalence and severity of periodontitis increases with age, the current opinion is that aging does not cause periodontitis. In cross-sectional studies, indicators of periodontitis such as attachment loss and bone loss are cumulative measures of disease over an individual's lifetime. The greater prevalence and severity of periodontitis among older persons in these studies is due to the cumulative effects of the disease over time rather than a greater susceptibility of older people.18 In fact, studies support the view that if a person is susceptible to severe periodontal destruction, the tendency will be seen early.19 Longitudinal studies examining the association between age and periodontitis have been inconclusive. 12 One longitudinal study indicated that when good oral hygiene is maintained throughout a lifetime, periodontal disease progression is negligible .2 In that study, oral hygiene was shown to be the most important predictor for periodontitis, and in all age groups, more than 95% of individuals with good oral hygiene did not have periodontitis. The authors concluded "The effect of age on the progression of periodontitis could therefore be considered negligible when good oral hygiene is maintained."2 Finally, the profitability of continuing the debate of whether age is a risk factor is unclear because whether the risk for periodontal disease is reduced by intervention cannot be tested (i.e., people cannot become younger).

Several other characteristics have been investigated as possible risk factors for adult periodontitis. The following list, adapted from Page and Beck, summarizes many of those characteristics in terms of the current status of the evidence to support their candidacy as risk factors.60

Nutrition: Most information regarding nutrition and periodontal diseases is dated and primarily based on animal studies that involved severe nutritional deficiencies. Minor nutritional deficiencies or imbalances failed to demonstrate an effect on periodontal disease in these animal models. Longitudinal studies that control for possible confounders meeting our stated criteria for evaluation of nutrition as a risk factor are lacking.

Low socioeconomic and educational status: Periodontal disease is more severe in individuals of lower socioeconomic status and poorer education. However, when periodontal status is adjusted for oral hygiene and smoking, the associations between lower socioeconomic and educational status and severe periodontal disease are not seen. Thus socioeconomic and educational statuses do not appear to directly affect the pathogenesis.

Osteoporosis: Longitudinal data are scarce, and multivariate analyses produce inconsistent results.

HIV infection and AIDS: Longitudinal data are scarce. Multivariable analyses generally are lacking. HIV infection and AIDS appear to elevate risk for severe periodontitis.

Infrequent dental visits: Longitudinal data are available. However, multivariate analyses are inconsistent, and risk assessments and intervention studies have not been completed.

Bacteria: Longitudinal data are available. Multivariate analyses implicate certain bacteria, and assessments and some interventions have been completed. Bacteria are generally considered to be causal. However, whether the presence of putative pathogenic species can be used as a strong indicator for future clinical

attachment loss remains controversial. Although some reports claim that the presence of these species is a good predictor, others observed an association with disease progression but found that the presence of putative pathogenic species was unreliable as a predictor for future clinical attachment loss in individual patients and at specific sites. Subject prediction usually is more accurate than site prediction. The absence of any of the group of five to seven putative periodontal pathogens is a reliable indicator for the absence of future clinical attachment loss for most patients.

- Bleeding on probing: Longitudinal data are available. Multivariate analyses implicate bleeding on probing in combination with increasing pocket depth. At present, bleeding on probing is widely used as an indication for needed treatment. However, bleeding on probing alone is not a predictor of elevated risk for future loss of clinical attachment. On the other hand, a lack of bleeding on probing, especially on two or more occasions, is an excellent indicator of periodontal health, with a predictive value of 0.972.
- Previous periodontal disease: Longitudinal data are available. Multivariate analyses implicate past disease. The risk for future periodontal deterioration in a given individual is strongly associated with the presence and severity of existing periodontitis. In other words, individuals with the most advanced existing periodontitis are at greatest risk for future clinical attachment loss. Individuals who are currently free of periodontitis are less likely to experience future clinical attachment loss than those with periodontitis. However, past disease is only a good clinical predictor. It is not likely to be causal, and it is unclear whether past disease is predictive of both incidental attachment loss and progression of current disease.
- Genetic factors: Longitudinal data are available. Multivariate analyses implicate genetic factors. Genetic factors are strongly associated with the aggressive forms and, to a lesser extent, with the chronic form.
- Stress: Most studies involve necrotizing ulcerative gingivitis (NUG). Case control and a few short-term longitudinal studies indicate associations. Multivariate and intervention studies are needed. Biologic mechanisms are known.

AGGRESSIVE PERIODONTITIS

Aggressive periodontitis (formerly known as *early onset periodontitis) is* periodontal destruction that becomes clinically significant around adolescence or early adulthood. The disease has been classified into two types-localized and generalized.[68] Other terms found in the literature that have been used to describe aggressive forms of periodontitis include juvenile, localized juvenile, generalized juvenile, rapidly progressive, severe, and prepubertal periodontitis (see Table 4-3).[68] The distinction between the localized and generalized forms is based on the distribution of the periodontal destruction in the mouth. Localized aggressive periodontitis is characterized by bone loss around the first molars and incisors. As the name implies, generalized aggressive periodontitis is characterized by a more widespread pattern of periodontal destruction.

Although aggressive periodontitis is characterized by age at onset and pattern of periodontal destruction, case definitions for early onset disease or its subtypes have varied across epidemiologic studies. In a national survey of the oral health of U.S. school children, three case definitions were used for aggressive periodontitis, as follows:[48]

- Localized aggressive periodontitis: At least one first molar and at least one incisor or second molar and two or fewer canines or premolars had >3 mm of attachment loss.
- Generalized aggressive periodontitis: Criteria for localized disease were not met, four or more teeth had >3 mm of attachment loss, and at least 2 affected teeth were second molars, canines, or premolars.
- Incidental loss of periodontal attachment: Criteria for localized or generalized were not met, and one or more teeth had >3 mm of attachment loss.

Other studies have based case definitions on various combinations of disease patterns and the extent and severity of pocket depth, attachment loss, and bone loss. A thorough review of studies that have investigated aggressive forms of periodontitis in childhood and adolescence can be found in an article by Papapanou.[62] As our understanding of aggressive periodontitis changes, the nomenclature for the disease and case definitions will likely continue to evolve.

How Much Aggressive Periodontitis Is Present?

Most studies from the U.S. and other countries that have examined localized aggressive periodontitis in adolescents have reported prevalence estimates below 1%.[62] In the U.S., the prevalence of localized and generalized aggressive periodontitis were estimated to be 0.53% and 0.13%, respectively.[48] Another 1.61% of the adolescents had incidental attachment loss-attachment loss that did not fit the study's case definitions for localized or generalized disease.[73] Although these prevalence estimates are small, together they represented almost 300,000 U.S. adolescents at the time of the study (1986-87).[48]

How Much New Aggressive Periodontitis Is Present?

Very few longitudinal studies of aggressive periodontitis have been conducted. One longitudinal study conducted in the United Kingdom followed 167 subjects from ages 14 to 19.[25] Periodontal attachment loss was measured on the mesiofacial surfaces of the first molars, first premolars, and central incisors. During the 5 years of follow-up, the percentage of subjects with attachment loss on one or more of the examined teeth increased dramatically-from 3% to 77% for attachment loss of >1 mm and from 0% to 14% for attachment loss of >2 mm. By age 19, 31% of the sites examined had attachment loss of >1 mm, and 3.1% had attachment loss of >2 mm. The teeth most commonly affected were the maxillary first molars and the mandibular central incisors. In the 19-year-old subjects, 9% of the maxillary molars had

attachment loss of >2 mm. The presence of subgingival calculus and plaque at baseline were significant predictors of loss of attachment at 5 years. Although this study provides useful information on the change in prevalence of aggressive periodontitis, its authors pointed out that the cohort was not a randomly selected group of 14-year-olds, and therefore the results cannot be generalized to the population at large.

Another study that followed a cohort of 14-year-old subjects was conducted among Norwegians.' Of the 2767 subjects examined at baseline (14 years old) in 1984, 215 were reexamined in 1992 (they were also examined in 1986 and 1988). At each examination, the prevalence of radiographic alveolar bone loss was assessed on sets of bite-wing radiographs. Bone loss was measured on the mesial and distal of fully erupted teeth (distal of the canines to the mesial of the second molars) and was defined as the distance from the cemento-enamel junction to the alveolar crest. The distance had to exceed 2 mm for bone loss to be present. At baseline, the prevalence of subjects with one or more lesions was approximately 3.5%. By 1992 the prevalence of subjects with bone loss had doubled. The percentage of subjects with 3 or more sites with bone loss also increased during that time from 2.5% to 33.3%.

A review of the available longitudinal studies of periodontitis in childhood and adolescence concluded that subjects with signs of periodontal disease at a young age are likely to have further periodontal deterioration. Progression is more extensive at initially infected sites and among subjects of low socioeconomic status .62

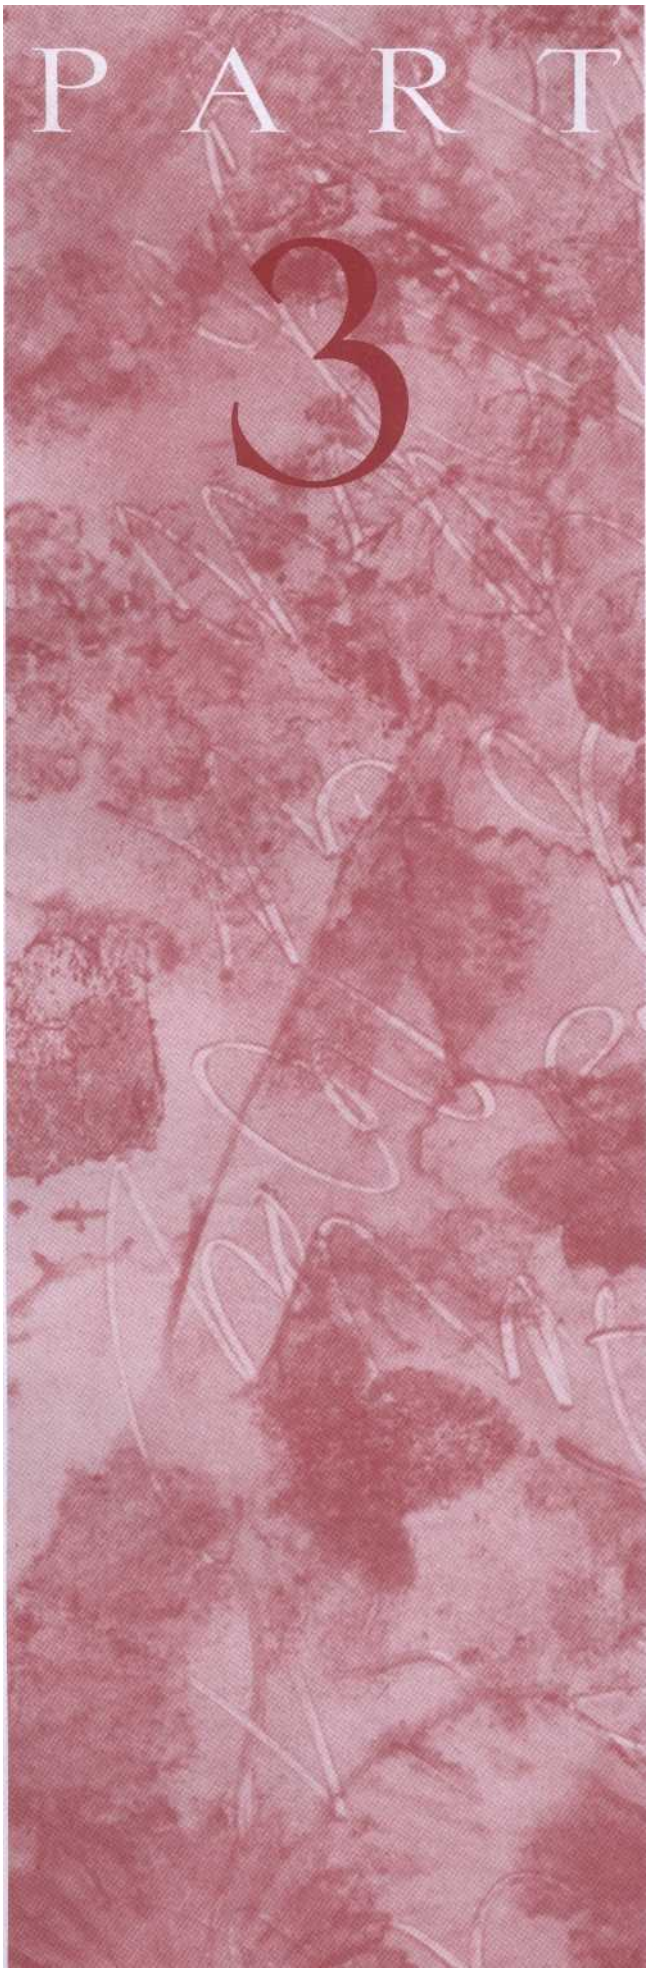
Does My Patient with Aggressive Periodontitis Fit the Typical Profile?

The prevalence of aggressive periodontitis is higher in African-Americans than in whites. In a study of aggressive periodontitis among adolescents in the U.S., it was estimated that 2.05% of African-Americans had localized periodontitis, compared with 0.14% of whites.48 For generalized disease, the prevalence was 0.59% for African-Americans and 0.03% for whites. The prevalence of incidental attachment loss was much higher among African-Americans than whites-4.63% versus 0.91%.

Whether or not the prevalence of aggressive periodontitis differs by gender is unclear. Early case reports and small studies often found the condition to be more prevalent among women; however, findings from larger studies have suggested the distribution of the disease is fairly equal between the genders." The 1986-87 survey of U.S. schoolchildren indicated that males had slightly higher but statistically insignificant prevalence of localized and generalized aggressive periodontitis and incidental attachment loss.48 However, when the distribution of the disease by gender was examined among race groups, differences by gender became much more evident. Among African-Americans, males were 2.9 times more likely than females to have localized disease. Among whites, the association was reversed. White females were 2.5 times more likely than white males to have localized disease.

Why Do Patients Have Aggressive Periodontitis, and What Puts Them at Risk?

The bacterium A. *actinomycetemcomitans is* found in high numbers in localized aggressive periodontal lesions and is the primary pathogen associated with the disease.79 Elimination of the pathogen is associated with clinical improvement.79 The bacterium produces a strong leukotoxin that kills neutrophils, which provide an important defense against periodontal infections. Different strains of A. *actinomycetemcomitans* produce different levels of leukotoxin. Highly toxic strains produce 10 to 20 times the levels of leukotoxin as do minimally toxic strains." Patients with localized aggressive periodontitis are more likely to harbor the highly leukotoxic strains than periodontally healthy persons or persons with chronic periodontitis.81 In a study of 21 families with at least one family member with localized disease, children infected with the highly leukotoxic strains of A. *actinomycetemcomitans* were more likely to develop localized aggressive periodontitis.17 Persons with African backgrounds have been found more likely to be infected with the more virulent strains of A. *actinomycetemcomitans,* which may explain the elevated risk of localized juvenile periodontitis among African-Americans." Although infection with A. *actinomycetemcomitans is* strongly associated with cases of localized disease, not all individuals infected with A. *actinomycetemcomitans* develop localized aggressive periodontitis, and not all individuals with localized disease have detectable levels of A. *actinomycetemcomitans.*



Another factor believed to be involved in the pathogenesis of aggressive periodontitis is defective neutrophil function. Depressed neutrophil chemotaxis is a consistent finding among patients with localized or generalized forms of the disease.77 Studies have shown that 70% to 75% of patients with localized disease have depressed neutrophil chemotaxis.77 Localized aggressive periodontitis tends to occur in families, and this neutrophil chemotaxic abnormality is genetic in origin and may predispose individuals to localized disease." However, not all individuals with localized disease have depressed neutrophil chemotaxis, and not all individuals with depressed neutrophil chemotaxis develop localized disease. Other, currently unidentified host factors are likely involved in the pathogenesis of the disease.

Etiology of Periodontal Diseases

Susan Kinder Haake

The clinical manifestations of periodontal disease result from a complex interplay between the etiologic agents, in this case specific bacteria found in dental plaque, and the host tissues. This part describes the many different factors, locally or systemically, that can influence the course of disease by modifying the processes inherent in the baterial-host interaction.

Inflammation is the central pathologic feature of periodontal disease, and bacterial plaque is the etiologic factor responsible for inducing the host inflammatory processes. In a healthy host, small but variable amounts of bacterial plaque are controlled by the body's defense mechanisms with no net destruction. Specific bacteria in plaque are more likely to be associated with periodontal destruction. Specific strains of a pathogenic species may be more virulent than other strains. Increased plaque accumulation results from ineffective oral hygiene and is further complicated by the presence of local factors such as calculus overhanging dental restorations or crowded and malaligned teeth.

The host response to bacterial plaque is influenced by the individual's genotype, or genetic makeup, and by environmental influences. Genetic variation or mutations that modulate the individual's response to bacterial insult have been identified and in some cases are associated with severe forms of periodontal disease. Individuals who have diabetes or smoke are more susceptible to periodontal destruction than comparable nondiabetic or nonsmoking individuals. Host factors are also critical in the processes of tissue repair inherent in the successful treatment of periodontal diseases. The influence of systemic host factors on periodontal diseases has long been recognized. More recent data indicate that periodontal diseases may have significant impact on systemic conditions such as the occurrence of heart disease, stroke, or preterm, low-birth-weight infants. Thus host factors may act locally in reducing resistance to periodontal tissue destruction as a result of bacterial challenge, and the bacterial challenge may produce local or systemic responses that contribute to a systemic disease.

CRITERIA FOR IDENTIFICATION OF PERIODONTAL PATHOGENS

FUTURE ADVANCES IN PERIODONTAL MICROBIOLOGY

Periodontal disease comprises a group of inflammatory conditions of the supporting tissues of the teeth that are caused by bacteria. Our understanding of the etiology of periodontal diseases has undergone major advances in recent decades.[94,95] In the mid-1900s, all bacterial species found in dental plaque were believed to be equally capable of causing disease, and periodontitis was believed to be the result of cumulative exposure to dental plaque. The association of specific bacterial species with disease came about in the early 1960s, when microscopic examination of plaque revealed that different bacterial morphotypes were found in periodontally healthy versus periodontally diseased sites. In the 1960s and 1970s, technical improvements were made in the procedures used to isolate, cultivate, and identify periodontal microorganisms. This resulted in refinements in bacterial taxonomy (Table 6-1) and clarification of the specific groups of microorganisms present with diseases of the periodontium. In the 1990s, the application of molecular approaches to the identification of microorganisms furthered this process, indicating a substantially greater diversity of species in the periodontal environment than was previously recognized.[46] As our understanding of periodontal microbial ecology continues to advance, so will our understanding of the etiology of periodontal diseases.

The identification of bacterial pathogens in periodontal diseases has been difficult because of a number of factors." The periodontal microbiota is a complex community of microorganisms, many of which are still difficult or impossible to isolate in the laboratory. Currently, it is apparent that multiple species function as pathogens, and species that function as pathogens in one site also may be present in low numbers in healthy sites. The chronic nature of periodontal disease has complicated the search for bacterial pathogens. It was previously thought that periodontal diseases progressed at a slow but steady rate. However, epidemiologic studies have established that the disease progresses at different rates, with alternating episodes of rapid tissue destruction and periods of remission. Identification of the microorganisms found during the different phases of the disease process is technically challenging. Furthermore, the interpretation of microbiologic data is greatly influenced by the clinical classification of disease status, an area that has undergone a number of recent revisions.' Previous and perhaps current classifications involve the grouping of potentially different disease states because of

the difficulties in accurately distinguishing them clinically. It is important to recognize that these types of groupings may obscure microbiologic associations.

Despite the difficulties inherent in characterizing the microbiology of periodontal diseases, a small group of pathogens is recognized because of their association with disease. The properties of these microorganisms that enable them to function as pathogens in the periodontal environment are currently under investigation and promise to provide much information about the basic mechanisms involved in the disease process. Technologic advances in molecular microbiology have improved the ability to detect specific bacteria and their products, which may serve as markers of ongoing disease or predictors of future disease. Some of these technologies have led to commercial products that are currently available for use in clinical therapy. However, although considerable advances have been made toward understanding the bacterial etiology of periodontal diseases, a complete answer to the question "What causes periodontal diseases?" is not known.

DENTAL PLAQUE: A HOST-ASSOCIATED BIOFILM

Dental plaque is a host-associated biofilm. The significance of the biofilm environment has been increasingly recognized in recent years because the environment itself may alter properties of the microorganisms. The biofilm community is initially formed through bacterial interactions with the tooth and then through physical and physiologic interactions among different species within the microbial mass. Furthermore, the bacteria found in the plaque biofilm are strongly influenced by external environmental factors that may be host mediated. Periodontal health can be considered to be a state of balance when the bacterial population coexists with the host and no irreparable damage occurs to either the bacteria or the host tissues. Disruption of this balance causes alterations in both the host and biofilm bacteria and results ultimately in the destruction of the connective tissues of the periodontium.

Macroscopic Structure and Composition of Dental Plaque

Dental plaque can be defined as the soft deposits that form the biofilm adhering to the tooth surface or other hard surfaces in the oral cavity, including removable and fixed restorations.' Plaque is differentiated from other deposits that may be found on the tooth surface such as materia alba and calculus (Color Fig. 6-1). *Materia alba* refers to soft accumulations of bacteria and tissue cells that lack the organized structure of dental plaque and are easily displaced with a water spray. *Calculus is* a hard deposit that forms by mineralization of dental plaque and is generally covered by a layer of unmineralized plaque.

Dental plaque is broadly classified as supragingival or subgingival based on its position on the tooth surface. *Supragingival plaque is* found at or above the gingival margin; the supragingival plaque in direct contact with the gingival margin is referred to as *marginal plaque.*

Subgingival plaque is found below the gingival margin, between the tooth and the gingival sulcular tissue. Morphologic studies indicate a differentiation of tooth-associated and tissue-associated regions of subgingival plaque,[12,69] and in certain cases bacteria are found within the host tissues.[81,82] The different regions of plaque are significant to different processes associated with diseases of the teeth and periodontium. For example, marginal plaque is of prime importance in the development of

gingivitis. Supragingival plaque and tooth-associated subgingival plaque are critical in calculus formation and root caries, whereas tissue-associated subgingival plaque is important in the soft tissue destruction that characterizes different forms of periodontitis.

Dental plaque is composed primarily of microorganisms (Fig. 6-1). One gram of plaque (wet weight) contains approximately 2 x 10 11 bacteria.91 Because 1 g of pure streptococcal cells packed by centrifugation contains 2.3 x 10 11 bacteria, bacteria account for most of the plaque weight.91 Cultivation studies, in which bacteria are isolated and characterized in the laboratory, indicate that more than 500 distinct microbial species are found in dental plaque .6s Recent studies have focused on molecular approaches to bacterial identification, which rely on analysis of ribosomal DNA sequences rather than cultivation. Data using these approaches suggest that as much as 30% of the microorganisms found associated with gingivitis may represent previously uncultivated species .46 Thus it is apparent that substantial numbers of plaque microorganisms are yet to be identified. Nonbacterial microorganisms that are found in plaque include Mycoplasma species, yeasts, protozoa, and viruses. 12 The microorganisms exist within an intercellular matrix that also contains a few host cells such as epithelial cells, macrophages, and leukocytes (Fig. 6-2).

The intercellular matrix, estimated to account for 20% to 30% of the plaque mass, consists of organic and inorganic materials derived from saliva, gingival crevicular fluid, and bacterial products. Organic constituents of the matrix include polysaccharides, proteins, glycoproteins, and lipid material. Glycoproteins from saliva are an important component of the pellicle that initially coats a clean tooth surface (see later discussion), but they also become incorporated into the developing plaque biofilm. Polysaccharides produced by bacteria, of which dextran is the predominant form, contribute to the organic portion of the matrix. Albumin, probably originating from crevicular fluid, has been identified as a component of the plaque matrix. The lipid material consists of debris from the membranes of disrupted bacterial and host cells and possibly food debris.

The inorganic component of plaque is predominately calcium and phosphorus, with trace amounts of other minerals such as sodium, potassium, and fluoride. The source of inorganic constituents of supragingival plaque is primarily saliva; as the mineral content increases, the plaque mass becomes calcified to form calculus. Calculus is frequently found in areas of the dentition adjacent to salivary ducts (e.g., the lingual surface of the mandibular anteriors and the buccal surface of the maxillary first molars), reflecting the high concentration of minerals available from saliva in those regions.

The inorganic component of subgingival plaque is derived from crevicular fluid, which is a serum transudate. Calcification of subgingival plaque also results in calculus formation. Subgingival calculus is typically dark green or dark brown, probably reflecting the presence of subgingival matrix components distinct from those of supragingival calculus (e.g., blood products associated with subgingival hemorrhage). The fluoride component of plaque is largely derived from external sources such as fluoridated toothpastes and rinses. Fluoride is used therapeutically to aid in remineralization of tooth structure, prevention of demineralization of tooth structure, and inhibition of the growth of many plaque microorganisms .79

Studies using traditional histologic methods suggested a relatively uniform dense structure to dental plaque. However, these approaches are subject to artifacts from the processes of dehydration, fixation, embedding, and staining. Recent studies using newly developed microscopic techniques have enabled examination of plaque structure without these processing requirements. In contrast with earlier findings, studies using these newer microscopy techniques reveal that plaque is actually heterogeneous in structure, with clear evidence of open fluid-filled channels running through the plaque mass.13,14,107 (Fig. 6-3). These channels may provide for circulation within plaque to facilitate movement of soluble molecules such as nutrients or waste products. The bacteria exist and proliferate within the intercellular matrix through which the channels course. This matrix confers a specialized environment, which distinguishes bacteria that exist within the biofilm from those that are free-floating in solutions such as saliva or crevicular fluid. For example, the biofilm matrix functions as a barrier. Substances produced by bacteria within the biofilm are retained and essentially concentrated, which fosters metabolic interactions among the different bacteria (see later discussion of physiologic properties).

Formation of Dental Plaque

Dental plaque may be readily visualized on teeth after 1 to 2 days with no oral hygiene measures. Plaque is white, grayish, or yellow and has a globular appearance. Movement of tissues and food materials over the teeth results in mechanical removal of plaque; such removal is particularly effective on the coronal two thirds of the tooth surface. Thus plaque is typically observed on the gingival third of the tooth surface, where it accumulates without disruption by the movement of food and tissues over the tooth surface during mastication. Plaque deposits also form preferentially in cracks, pits, and fissures in the tooth structure; under overhanging restorations; and around malaligned teeth. The location and rate of plaque formation vary among individuals, and determining factors include oral hygiene as well as host factors such as diet or salivary composition and flow rate .60

Small amounts of plaque that are not discernible on the tooth surface may be detected by running a periodontal probe or explorer along the gingival third of the tooth. Another common method of detecting small amounts of plaque is the use of disclosing solutions (see Color Fig. 6-1). Interproximal plaque formation is less evident visually but also may be monitored with an explorer or probe.

In the absence of oral hygiene measures, plaque continues to accumulate until a balance is reached between the forces of plaque removal and those of plaque formation. The formation of dental plaque at the microscopic level represents a highly ordered and predictable ecologic succession. The process of plaque formation can be

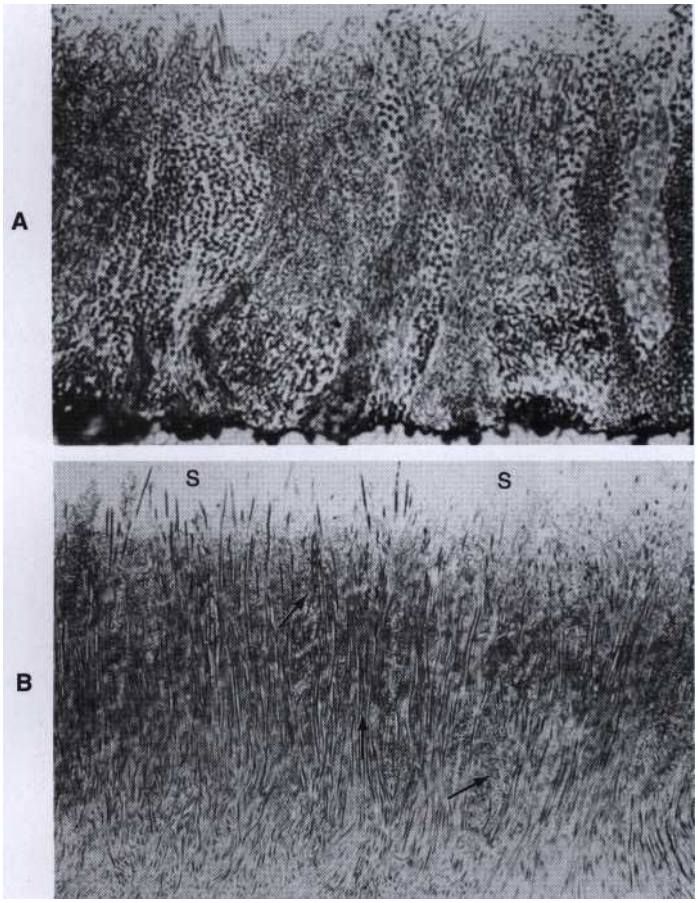

Fig. 6-1 A, One-day-old plaque. Microcolonies of plaque bacteria extend perpendicularly away from tooth surfaces. divided into three phases: formation of the pellicle coating on the tooth surface, initial colonization by bacteria, and secondary colonization and plaque maturation.

Formation of the Dental Pellicle. Formation of the dental pellicle on the tooth surface is the initial phase of plaque development. All surfaces of the oral cavity, including all tissue surfaces as well as surfaces of teeth and fixed and removable restorations, are coated with a glycoprotein pellicle. This pellicle is derived from components of saliva and crevicular fluid as well as bacterial and host tissue cell products and debris.

The specific components of pellicles on different surfaces vary in composition. Studies of early (2-hour) enamel pellicle reveal that its amino acid composition differs from that of saliva,83 indicating that the pellicle forms by *selective adsorption o f the environmental macromolecules.* The mechanisms involved in enamel pellicle formation include electrostatic, van der Waals, and hydrophobic forces. The hydroxyapatite surface has a predominance of negatively charged phosphate groups that interact directly or indirectly with positively charged components of salivary and crevicular fluid macromolecules.'"

Pellicles function as a protective barrier, providing lubrication for the surfaces and preventing tissue desiccation. However, they also provide a substrate to which bacteria in the environment attach. Because the epithelial tissue cells are continually sloughed, the bacterial population on the tissue surfaces is continually disrupted. In contrast, pellicle on the nonshedding hard surfaces provides a substrate on which bacteria progressively accumulate to form dental plaque.

Initial Colonization of the Tooth Surface. Within a few hours, bacteria are found on the dental pellicle.

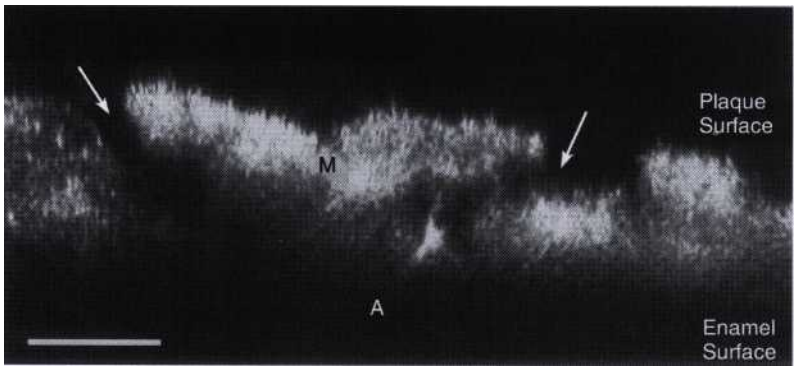

Fig. 6-3 Vertical section through a 4-day human plaque sample. An intraoral device designed for in vivo generation of plaque biofilms on enamel was used. Confocal microscopy enabled visualization of the section of plaque without the dehydration steps used in conventional histologic preparations. (From Wood et al: Architecture of intact natural human plaque biofilms studied by confocal laser scanning microscopy. J Dent Res 2000; 79:21. Courtesy Dr. Simon Wood, Leeds, England.)**

The initial bacteria colonizing the pellicle-coated tooth surface are predominantly gram-positive facultative microorganisms such as *Actinomyces viscosus* and *Streptococcus sanguis*. These initial colonizers adhere to the pellicle[21,24,63] through specific molecules, termed *adhesins,* on the bacterial surface that interact with receptors in the dental pellicle. For example, cells of *A. viscosus* possess fibrous protein structures called *fimbriae* that extend from the bacterial cell surface. Protein adhesins on these fimbriae specifically bind to proline-rich proteins that are found in dental pellicle,[63] resulting in the attachment of the bacterial cell to the pellicle-coated tooth surface.

The plaque mass then matures through the growth of attached species, as well as the colonization and growth of additional species. *In this ecologic succession of the biofilm, there is a transition from the early aerobic environment characterized by gram positive facultative species to a highly oxygen-deprived environment in which gram-negative anaerobic microorganisms predominate.*

Secondary Colonization and Plaque Maturation.

Secondary colonizers are the microorganisms that do not initially colonize clean tooth surfaces, including *Prevotella intermedia, Prevotella loescheii, Capnocytophaga spp., Fusobacterium nucleatum,* and *Porphyromonas gingivalis.*[39] These microorganisms adhere to cells of bacteria already in the plaque mass. Extensive laboratory studies have documented the ability of different species and genera of plaque microorganisms to adhere to one another, a process known as *coaggregation.* This process occurs primarily through the highly specific stereochemical interaction of protein and carbohydrate molecules located on the bacterial cell surfaces",' in addition to the less specific interactions resulting from hydrophobic, electrostatic, and van der Waals forces. [18-25]

The significance of coaggregation in oral colonization has been documented in studies of biofilm formation in vitro' as well as in animal model studies.[62] Well-characterized interactions of secondary colonizers with early colonizers include the coaggregation of *F. nucleatum* with S. *sanguis,*[35] *P. loescheii* with *A. viscosus,*[103,104] and *Capnocytophaga ochracea* with *A. viscosus.*[105] Most studies of coaggregation have focused on interactions among different gram-positive species and between gram-positive and gram-negative species. In the latter stages of plaque formation, coaggregation between different gram-negative species is likely to predominate. Examples of these types of interactions are the coaggregation of *F. nucleatum* with P. *gingivalis*[36-38] or *Treponema denticola.*[40]

Microscopic Structure and Physiologic Properties of Dental Plaque

A high degree of specificity is found in the interactions between bacteria in dental plaque, as demonstrated by the studies of coaggregation. This is further evident from light and electron microscopic studies of the structure of

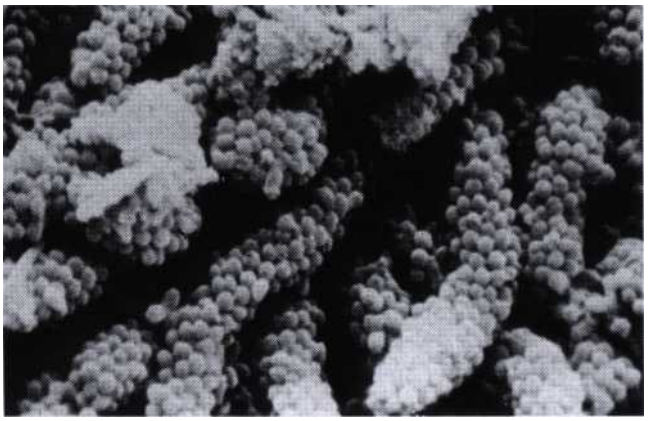

Fig. 6-5 Long-standing supragingival plaque near the gingival margin demonstrates "corncob" arrangement. A central gram-negative filamentous core supports the outer coccal cells, which are firmly attached by interbacterial adherence or coaggregation.

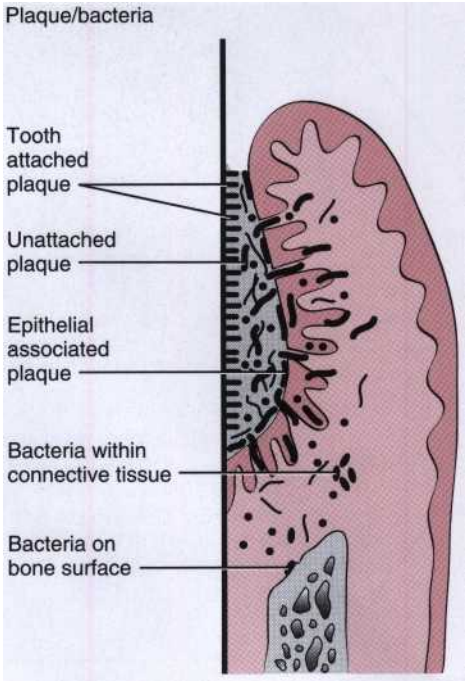

Fig. 6-6 Diagram depicting the plaque-bacteria association with tooth surface and periodontal tissues.

dental plaque formed in vivo.[52] Supragingival plaque typically demonstrates a stratified organization of the bacterial morphotypes. Gram-positive cocci and short rods predominate at the tooth surface (Fig. 6-4), whereas gram-negative rods and filaments (see Fig. 6-1) as well as spirochetes predominate in the outer surface of the mature plaque mass. Highly specific cell-to-cell interactions are also evident from the "corncob" structures" often observed (Fig. 6-5). Corncob formations have been observed between rod-shaped bacterial cells (e.g., *Bacterionema matruchotii* or *F. nucleatum)* that form the inner core of the structure and coccal cells (e.g., streptococci or *P. gingivalis)* that attach along the surface of the rod-shaped cell .[37,48]

The environmental parameters of the subgingival region differ from those of the supragingival region. The gingival crevice or pocket is bathed by the flow of crevicular fluid, which contains many substances that the bacteria may use as nutrients (see later discussion). Host inflammatory cells and mediators are likely to have considerable influence on the establishment and growth of bacteria in this region. Morphologic and microbiologic studies of subgingival plaque reveal distinctions between the tooth-associated and tissue-associated regions of subgingival plaque (Figs. 6-6 and 6-7).

The tooth-associated (attached) plaque (Figs. 6-8 and 6-9) is characterized by gram-positive rods and cocci, including *Streptococcus mitis, S. sanguis, A. viscosus, Actinomyces naeslundii,* and *Eubacterium spp. The apical border o f the plaque mass is separated from the junctional epithelium by a layer o f host leukocytes, and the bacteria o f this apical tooth-associated region show an increased concentration o f gram-negative rods.* The portion of plaque adjacent to the tissue surfaces (Figs. 6-10 and 6-11) is more loosely organized than the very dense tooth-associated region. It contains primarily gram-negative rods and cocci, as well as large numbers of filaments, flagellated rods, and spirochetes. Host tissue cells (e.g., white blood cells and epithelial cells) also may be found in this region. Studies of tissue-associated plaque indicate a predominance of species such as S. *oralis, S. intermedius, P. micros, P. gingivalis, P. intermedia, Bacteroides forsythus,* and *F. nucleatum*.[16,21] Bacteria found in tissue-associated plaque (e.g., *P. gingivalis)* also have been found in host tissues .[52] Thus the physical proximity of these bacteria to the host tissues in the plaque mass may be important in **the process of tissue invasion (see Chapter 8).**

The transition from gram-positive to gram-negative microorganisms observed in the structural development of dental plaque is paralleled by a physiologic transition in the developing plaque. The early colonizers (e.g., streptococci and *Actinomyces* species) use oxygen and lower the reduction-oxidation potential of the environment, which then favors the growth of anaerobic species.[15,102] Gram-positive species use sugars as an energy source and saliva as a carbon source. The bacteria that predominate in mature plaque are anaerobic and asaccharolytic, and use amino acids and small peptides as energy sources .[56]

Laboratory studies have demonstrated many physiologic interactions among the different bacteria found in dental plaque (Fig. 6-12). Lactate and formate are byproducts of the metabolism of streptococci and *Actinomyces* species and may be used in the metabolism of other plaque microorganisms. The growth of P. *gingivalis* is enhanced by metabolic byproducts produced by other microorganisms, such as succinate from C. *ochracea* and protoheme from *Campylobacter rectus.*[27-28,61]

The host also functions as an important source of nutrients. For example, the bacterial enzymes that degrade host proteins result in the release of ammonia, which may be used by bacteria as a nitrogen source .[7] Hemin iron from the breakdown of host hemoglobin may be im-

portant in the metabolism of P. *gingivalis.*[5] Increases in steroid hormones are associated with significant increases in the proportions of P. *intermedia* found in subgingival plaque.[42] Physiologic interactions occur both between different microorganisms in plaque and between the host and plaque microorganisms. These nutritional interdependencies are probably critical to the growth and survival of microorganisms in dental plaque and may partly explain the evolution of highly specific structural interactions observed among bacteria in plaque.

Significance of the Biofilm Environment

Studies of oral microbial communities as biofilms in vitro further highlight the significance of structural and physiologic interactions between bacterial species in plaque. For example, the presence of *F. nucleatum* in experimental mixed biofilm communities is critical to the survival of high numbers of the anaerobic species P. *nigrescens* and P. *gingivalis.* The ability of *F. nucleatum* to coaggregate with both the facultative and anaerobic species may facilitate the survival of the anaerobes.[4] In addition, *F. nucleatum* can reduce the reduction-oxidation potential of its environment so that it may function to provide a protective econiche for other anaerobic species.[15] Similar effects have been observed in other biofilm model systems using different combinations of anaerobic and facultative species.[74] Recent analyses of more than 13,000 plaque samples of 40 subgingival microorganisms using a DNA-hybridization methodology was used to define "complexes" of periodontal microorganisms. The composition of the different complexes is based on the frequency with which microorganisms are recovered together.[96] Interestingly, the early colonizers are either independent of defined complexes (A. *naeslundii, A. viscosus)* or members of the yellow *(Streptococcus spp.)* or purple

complexes (A. *odontolyticus)* (Fig. 6-13). The microorganisms primarily considered secondary colonizers fell into the green, orange or red complexes. The green complex includes E. *corrodens, Actinobacillus actinomycetemcomitans* serotype a, and *Capnocytophaga spp.* The orange complex includes *Fusobacterium, Prevotella,* and *Campylobacter spp.* The green and orange complexes include species recognized as pathogens in periodontal and nonperiodontal infections. The red complex consists of P. *gingivalis, B.* forsythus, and T. *denticola.* The red complex is of particular interest because it is associated with bleeding on probing, which is an important clinical parameter of destructive periodontal diseases.[96] The existence of complexes of species in plaque is another reflection of bacterial interdependency in the biofilm environment.

It has been recognized for some time that bacteria growing in microbial communities adherent to a surface do not "behave" the same as bacteria growing suspended in a liquid environment. For example, the resistance of bacteria to antimicrobial agents is significantly increased in the biofilm environment.[1,14,31,14] The resistance to antimicrobials inherent to biofilm bacteria may relate to limited diffusion of substances into the biofilm matrix,

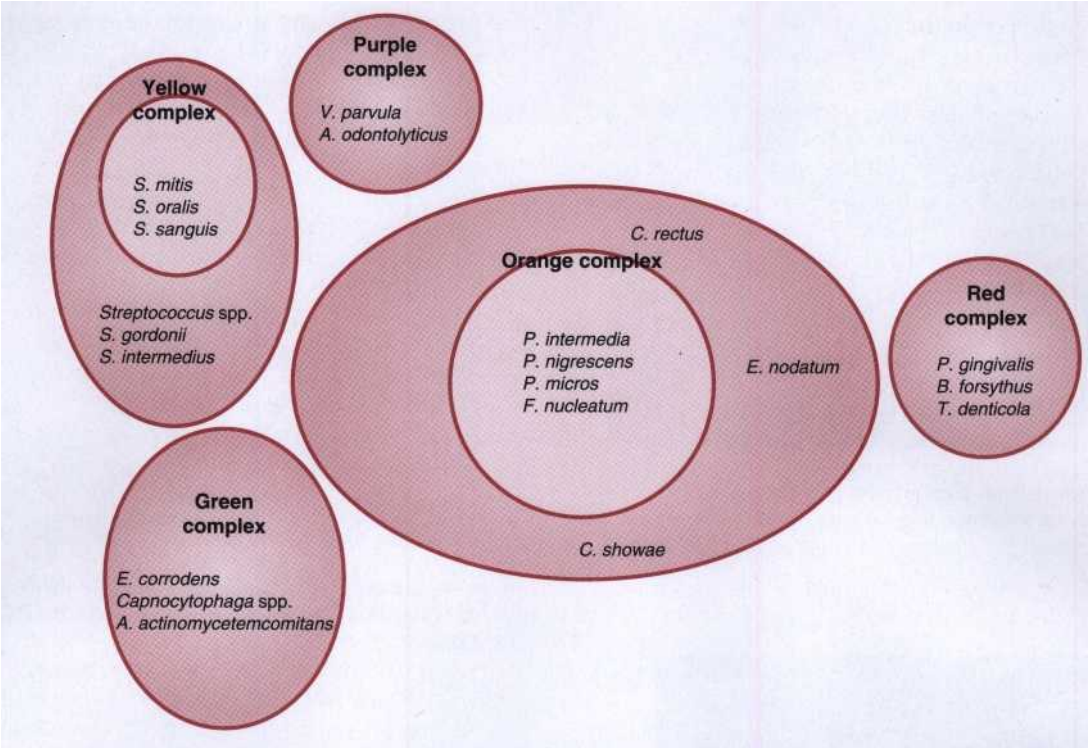

Fig. 6-13 Diagrammatic representation of selected species in the microbial complexes identified in the subgingival microbiota. Each defined grouping i5 identified by a color. The red complex species, as a group and individually, are found more often in periodontal sites demonstrating bleeding on probing. (Adapted from Socransky et al: Microbial complexes in subgingival plaque. J Clin Periodontol 1998; 25:134.)

the slow rate of cell growth in the biofilm environment, and possibly to altered properties of bacteria in response to growth on a surface.[14] This is a critical issue in the use of antimicrobials to manage periodontal infections or other biofilm associated infections, and it is currently a very active area of research.

ASSOCIATION OF PLAQUE MICROORGANISMS WITH PERIODONTAL DISEASES

Microbial Specificity of Periodontal Diseases

In the mid-1900s, periodontal disease was believed to result from an accumulation of plaque over time in conjunction with a diminished host response and increased host susceptibility with age. This thinking was supported by epidemiologic studies that correlated both age and the amount of plaque with evidence of periodontitiS.[59,80,84] Periodontal disease was clearly associated with plaque, and all plaque was thought to be alike and equally capable of causing disease.

However, several observations contradicted these conclusions. First, some individuals with considerable amounts of plaque and calculus, as well as gingivitis, never developed destructive periodontitis. Furthermore, individuals who did present with periodontitis demonstrated considerable site specificity in the pattern of disease. Some sites were unaffected, whereas advanced disease was found in adjacent sites. In the presence of a uniform host response, these findings were inconsistent with the concept that all plaque was equally pathogenic. Recognition of the differences in plaque at sites of different clinical status (i.e., disease versus health)[54,89,91] led to a renewed search for specific pathogens in periodontal diseases and a conceptual transition from the nonspecific to the specific plaque hypothesis.

Nonspecific Plaque Hypothesis

The nonspecific and specific plaque hypotheses were delineated in 1976 by Walter Loesche, a researcher at the University of Michigan. The nonspecific plaque hypothesis maintains that periodontal disease results from the "elaboration of noxious products by the entire plaque flora."[57] According to this thinking, when only small amounts of plaque are present, the noxious products are neutralized by the host. Similarly, large amounts of plaque would produce large amounts of noxious products, which would essentially overwhelm the host's defenses. Inherent in the nonspecific plaque hypothesis is the concept that control of periodontal disease depends on control of the amount of plaque accumulation. Treatment of periodontitis by debridement (nonsurgical or surgical) and oral hygiene measures focuses on the removal of plaque and its products and is founded in the nonspecific plaque hypothesis. Thus although the nonspecific plaque hypothesis has been discarded in favor of the specific plaque hypothesis, much clinical treatment is still based on the nonspecific plaque hypothesis.

Specific Plaque Hypothesis

The specific plaque hypothesis states that only certain plaque is pathogenic, and its pathogenicity depends on the presence of or increase in specific microorganisms.[57] This concept predicts that plaque harboring specific bacterial pathogens results in periodontal disease because these organisms produce substances that mediate the destruction of host tissues.

At about the same time that Loesche proposed the specific plaque hypothesis, major advances were made in techniques used to isolate and identify periodontal microorganisms. These included improvements in procedures to sample subgingival plaque, handling of samples to prevent killing the bacteria, and media used to grow the bacteria in the laboratory.[94] The result was a tremendous increase in the ability to isolate periodontal microorganisms and considerable refinement in bacterial taxonomy. Acceptance of the specific plaque hypothesis was spurred by the recognition of *A. actinomycetemcomitans* as a pathogen in localized aggressive periodontitis.[7,89] These advances led to a series of association studies focused on identifying specific periodontal pathogens by examining the microbiota associated with states of health and disease in cross-sectional and longitudinal studies.

Microorganisms Associated with Specific Periodontal Diseases

The microbiota associated with periodontal health and disease has been studied with a wide variety of techniques for sampling, cultivation, and/or detection of bacteria by DNA hybridization.[11,20,58,68,71,96,97,111] Further, the classification of periodontal diseases has undergone a number of changes during the time that association studies have been conducted.[1,75] The following material is discussed in the context of the recently revised classification system[2] with reference to earlier classification schemes as necessitated by the population studied. These evolving variables make direct comparisons of the association studies difficult. However, comparisons do reveal the general characteristics of the microbial populations found in the presence of different clinical states and implicate a discrete group of bacteria that function as periodontal pathogens.

Early studies that used appropriate microbiologic procedures clearly demonstrated that the number and proportions of different subgingival bacterial groups varied in periodontal health when compared with the disease state.[53,119,91] The total number of bacteria, determined by microscopic counts per gram of plaque, are twice as high in periodontally diseased sites than in healthy sites.[91] Because considerably more plaque is found at diseased sites, this suggests that the total bacterial load is much greater than that at healthy sites.

The differences between periodontal health and disease also are evident when the morphotypes of the bacteria from healthy and diseased sites are examined. Fewer coccal cells and more motile rods and spirochetes are found in diseased sites than in healthy sites (Fig. 6-14).[53] The bacteria cultivated from periodontally healthy sites[89] consist predominantly of gram-positive facultative rods and cocci (approximately 75%). The recovery of this group of microorganisms is decreased proportionally in gingivitis (44%) and periodontitis (10% to 13%). These decreases are accompanied by increases in the proportions of gram-negative rods, from 13% in health to 40% in gingivitis and 74% in advanced periodontitis (Fig. 6-15).

Periodontal Health. The recovery of microorganisms from periodontally healthy sites is meager when compared with that from diseased sites. The bacteria associated with periodontal health are primarily gram-positive facultative species and members of the genera *Streptococcus* and *Actinomyces (e.g., S. sanguis, S. mitis, A. viscosus,* and *A. naeslundii).* Small proportions of gram-negative species are also found, most frequently *P. intermedia, F. nucleatum,* and *Capnocytophaga, Neisseria,* and *Veillonella spp.* Microscopic studies indicate that a few spirochetes and motile rods also may be found.

Certain bacterial species have been proposed to be protective or beneficial to the host, including S. *sanguis, Veillonella parvula,* and C. *ochracea.* They are typically found in high numbers at periodontal sites that do not demonstrate attachment loss (inactive sites) but in low numbers at sites where active periodontal destruction occurs.[19,94] These species probably function in preventing the colonization or proliferation of pathogenic microorganisms. One example of a mechanism by which this may occur is the production of H_2O_2 by *S. sanguis;* H_2O_2 is known to be lethal to cells of *A. actinomycetemcomitans.* Clinical studies have shown that sites with high levels of *C. ochracea* and *S. sanguis* are associated with a greater gain of attachment level after therapy,[94] further supporting this concept. A better understanding of plaque ecology and the interactions between bacteria and their products in plaque will undoubtedly reveal many other examples.

Gingivitis. The development of gingivitis has been extensively studied in a model system referred to as *ex-*

perimental gingivitis and initially described by Harald Loe and coworkers.[54,98] Periodontal health is first established in human subjects by cleaning and rigorous oral hygiene measures, followed by abstinence from oral hygiene for 21 days. After 8 hours without oral hygiene, bacteria may be found at concentrations of 10^3 to 10^4 per square millimeter of tooth surface and will increase in number by a factor of 100 to 1000 in the next 24-hour period.[92]

The initial microbiota of experimental gingivitis consists of gram-positive rods, gram-positive cocci, and gram-negative cocci. The transition to gingivitis is evident by inflammatory changes observed in the gingival tissues and is accompanied first by the appearance of gram-negative rods and filaments (Fig. 6-16), then by spirochetal and motile microorganisms.[98]

The bacteria found in naturally occurring *dental plaque-induced gingivitis (chronic gingivitis)* consist of roughly equal proportions of gram-positive (56%) and gram-negative (44%) species, as well as facultative (59%) and anaerobic (41%) microorganisms (see Fig. 6-15).[89] Predominant gram-positive species include *S. sanguis, S. mitis, S. intermedius, S. oralis, A. viscosus, A. naeslundii,* and *Peptostreptococcus micros.* The gram-negative microorganisms are predominantly *F. nucleatum, P. intermedia, V. parvula,* as well as *Hemophilus, Capnocytophaga* and *Campylobacter spp.*[65,68,89]

Pregnancy-associated gingivitis is an acute inflammation of the gingival tissues associated with pregnancy. This condition is accompanied by increases in steroid hormones in crevicular fluid and dramatic increases in the levels of *P. intermedia,* which use the steroids as growth factors.[42]

Studies of gingivitis support the conclusion that disease development is associated with selected alterations in the microbial composition of dental plaque and are not simply the result of an accumulation of plaque. Gingivitis is generally believed to precede the development of chronic periodontitis; however, many individuals demonstrate long-standing gingivitis that never advances to destruction of the periodontal attachment.[6,55]

Chronic Periodontitis. The hallmark of periodontitis is the loss of connective tissue attachment to the tooth. Numerous forms of periodontal disease are found in adult populations; these forms are characterized by different rates of progression (Fig. 6-17) and different responses to therapy.[2] Studies in which untreated populations were examined over long time intervals indicate disease progression at mean rates ranging from 0.05 to 0.3 mm of attachment loss per year (i.e., the gradual model).[1] When populations are examined over short time intervals, individual sites demonstrated short phases of attachment destruction interposed by periods of no disease activity (i.e., the burst model).[26] It is unclear from recent studies whether the gradual or burst

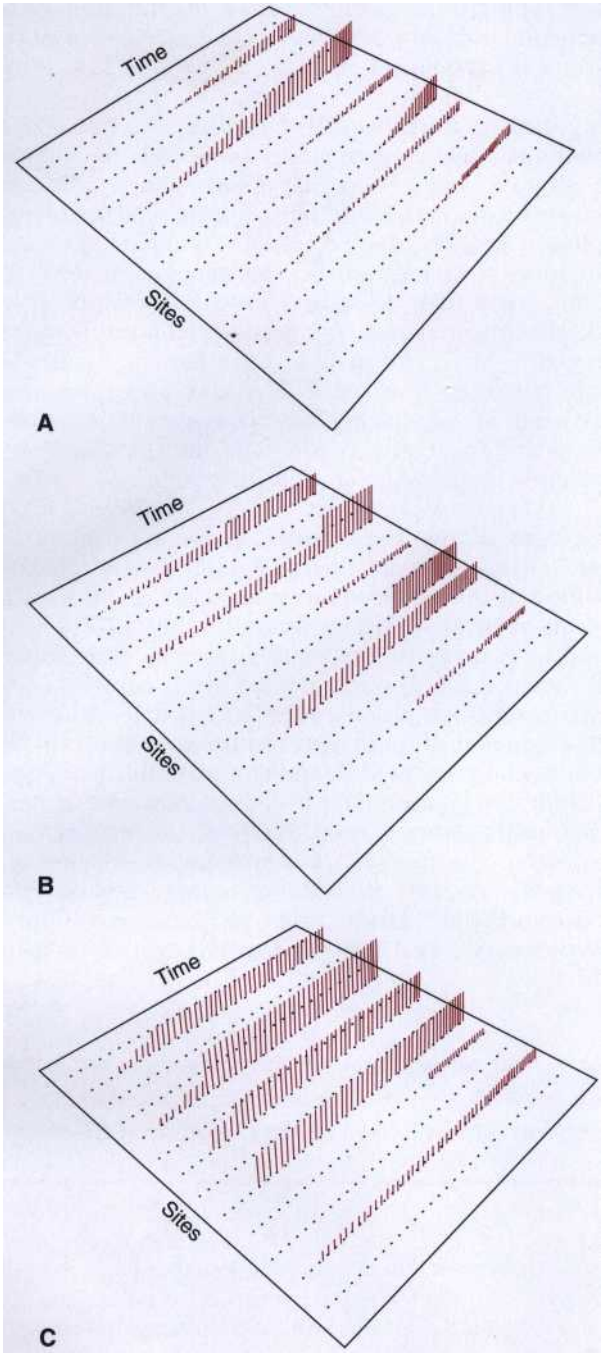

Fig. 6-17 Diagrammatic representation of different possible modes of progression of chronic destructive periodontal disease. Sites on the x-axis are plotted against time on the y-axis, and activity is shown on the z-axis. A, Some sites show progressive loss of attachment over time, whereas others show no destruction. The time of onset and the extent of destruction vary among sites. B, Random burst model. Activity occurs at random at any site. Some sites show no activity, whereas others show one or several bursts of activity. The cumulative extent of destruction varies among sites. C, Asynchronous multiple burst model. Several sites show bursts of activity over a finite period, followed by prolonged periods of inactivity. Occasional bursts may occur infrequently at certain sites at later periods. Other sites show no periodontal disease activity at any time. The difference from the model shown in B is that in C, the majority of destructive disease activity takes place within a few years of the individual's life. (Courtesy Drs. S. Socransky, A. Haffajee, M. Goodson, and J. Lindhe, Boston, Mass., and Goteborg, Sweden.)

model of disease progression, or some other model, is correct.[6]

Microbiologic examinations of chronic periodontitis have been carried out in both cross-sectional and longitudinal studies; the latter have been conducted with and without treatment. These studies support the concept that chronic periodontitis is associated with specific bacterial agents. Microscopic examination of plaque from sites with chronic periodontitis have consistently revealed elevated proportions of spirochetes (see Fig. 6-14).[53,51] Cultivation of plaque microorganisms from sites of chronic periodontitis reveals high percentages of anaerobic (90%) gram-negative (75%) bacterial species (see Fig. 6-15).[18,19]

In *chronic periodontitis,* the bacteria most often cultivated at high levels include P. *gingivalis, B. forsythus, P. intermedia, C. rectus, Eikenella corrodens, F. nucleatum, A. actinomycetemcomitans, P. micros,* and *Treponema* and *Eubacterium*[spp.41,47,56,68,89,93,94,97] When periodontally active sites (i.e., with recent attachment loss) were examined in comparison with inactive sites (i.e., with no recent attachment loss), C. *rectus, P. gingivalis, P. intermedia, E. nucleatum,* and *B. forsythus* were found to be elevated in the active sites.[20] Furthermore, detectable levels of P. *gingivalis, P. intermedia, B. forsythus, C. rectus,* and *A. actinomycetemcomitans* are associated with disease progression,[20,106] and elimination of specific bacterial pathogens with therapy is associated with an improved clinical response.[10,29,90] Both P. *gingivalis* and *A. actinomycetemcomitans* have been shown to invade host tissue cells, which may be significant in aggressive forms of adult periodontitis.[8,9,82] Recent studies have documented an association between chronic periodontitis and viral microorganisms of the herpesviruses group, most notably Epstein-Barr Virus-1 (EBV-1) and human cytomegalovirus (HCMV).[12] Further, the presence of subgingival EBV-1 and HCMV are associated with high levels of putative bacterial pathogens, including P. *gingivalis, B. forsythus, P. intermedia,* and T. *denticola.* These data support the hypothesis that viral infection may contribute to periodontal pathogenesis, but the potential role of viral agents remains to be determined.

Localized Aggressive Periodontitis. Several forms of periodontitis are characterized by rapid and severe attachment loss occurring in individuals during or before puberty. Localized aggressive periodontitis (previously referred to as *localized juvenile periodontitis [LIP])* (see Chapter 28) develops around the time of puberty, is observed in females more often than in males, and typically affects the permanent molars and incisors. This condition is almost uniformly seen in individuals who demonstrate some systemic defect in immune regulation, and most affected individuals demonstrate defective neutrophil function.

The microbiota associated with localized aggressive periodontitis is predominantly composed of gram-negative, capnophilic, and anaerobic rods.[70,71,89] Microbiologic studies indicate that almost all LJP sites harbor A. *actinomycetemcomitans,* which may comprise as much as 90% of the total cultivable microbiota.[43,67] Other organisms found in significant levels include P. *gingivalis, E. corrodens, C. rectus, E nucleatum, B. capillus, Eubacterium brachy,*

and *Capnocytophaga spp.* and spirochetes.[43,64,66,67] Herpesviruses, including EBV-1 and HCMV, also have been associated with localized aggressive periodontitis.[12,64,99]

A. actinomycetemcomitans is generally accepted as the primary etiologic agent in most, but not all, cases of localized aggressive periodontitis (see discussion of virulence factors in Chapter 8).[44,94] Studies of therapy indicate that both mechanical debridement and systemic antibiotic treatment are necessary to control the levels of *A. actinomycetemcomitans* in this disease.[43,76,77] The failure of mechanical therapy alone may relate to the ability of this organism to invade host tissues.[8,9,82]

Periodontitis as a Manifestation of Systemic Disease. Previous classification schemes delineated "prepubertal periodontitis" as a rare form of periodontitis found to affect the primary dentition. This group has now been reclassified under the heading of periodontitis as a manifestation of systemic disease because most children with severe periodontal destruction also demonstrate profound immunologic abnormalities. The underlying immune deficiency may vary and includes neutrophil defects and leukocyte adhesion defects, for example.[17,34] Recent studies have demonstrated that some cases of severe periodontal destruction are associated with a mutation in the cathepsin C gene in afflicted children (see Chapter 10, "Genetic Factors Associated with Periodontal Disease"). Studies of patients with "prepubertal periodontitis" indicate that subgingival bacteria associated with other forms of periodontal disease also are found in these patients.[68,73] This is consistent with the concept that the occurrence of severe destruction at an early age is a reflection of an increased host susceptibility, in this case resulting from systemic disease. Identification of severe periodontal destruction in a child may be one of the first signs of systemic disease.

Necrotizing Periodontal Diseases. Necrotizing periodontal diseases present as acute inflammation of the gingival and periodontal tissues characterized by necrosis of the marginal gingival tissue and interdental papillae. Clinically, these conditions often are associated with stress or human immunodeficiency virus (HIV) infection. They may be accompanied by malodor, pain, and possibly systemic symptoms including lymphadenopathy, fever, and malaise. Microbiologic studies indicate that high levels of P. *intertnedia* and spirochetes are found in necrotizing ulcerative gingivitis lesions. Spirochetes are found to penetrate necrotic tissue and apparently unaffected connective tissue.[49,50]

Abscesses of the Periodontium. Periodontal abscesses are acute lesions that may result in very rapid destruction of the periodontal tissues. They often occur in patients with untreated periodontitis but also may be found in patients during maintenance or after scaling and root planing. Periodontal abscesses also may occur in the absence of periodontitis; for example, associated with impaction of a foreign object (e.g., a popcorn kernel or dental floss) or with endodontic problems.[33] Typical clinical symptoms of periodontal abscesses include pain, swelling, suppuration, bleeding on probing, and mobility of the involved tooth. Signs of systemic involvement may be present, including cervical lymphadenopathy and an elevated white blood cell count.[32] Investigations reveal that bacteria recognized as peri-

TABLE 6-2

Evidence Supporting a Role for A. actinomycetemcomitans and P. gingivalis as Pathogens in Periodontal Disease: Socransky's Criteria

Criterion	A. actinomycetemcomitans	P. gingivalis
Association	Increased in localized aggressive periodontitis (LAP) lesions	Increased in periodontitis lesions
	Increased in some chronic periodontitis lesions	Found associated with crevicular epithelium
	Detected in the tissues of LAP lesions	
Elimination	Suppressed or eliminated in successful therapy	Suppressed or eliminated in successful therapy
	Found in recurrent lesions	Found in recurrent lesions
Host response	Increased serum and local antibody levels in LAP	Increased systemic and local antibody levels in periodontitis
Animal studies	Capable of inducing disease in gnotobiotic rats	Found to be important in experimental mixed infections and in periodontitis in the cynomolgus monkey
Virulence factors	Host tissue cell invasion, leukotoxin, collagenase, endotoxin (LPS), epitheliotoxin, fibroblast inhibiting factor, bone resorption-inducing factor	Host tissue cell adherence and invasion, collagenase, trypsin-like enzyme, fibrinolysin, phospholipase A, phosphatases, endotoxin (LPS), H_2S, NH_3, fatty acids, factors that affect PIVIN function

Adapted from Socransky SS, Haffajee AD: The bacterial etiology of destructive periodontal disease: Current concepts. j Periodontol 1992; 63:322.

odontal pathogens are commonly found in significant numbers in periodontal abscesses. These microorganisms include F. *nucleatum*, *P. intermedia, P. gingivalis, P. micros,* and B. *forsythus.*[30,32,72]

Conclusions from Studies of the Association of Microorganisms with Periodontal Diseases

Studies examining the microbiota associated with periodontal diseases versus the healthy state suggest that a discrete number of microorganisms may function as pathogens in the disease processes. However, conclusions based on these studies must be considered in light of several limitations. One limitation is our inability to identify and isolate a substantial proportion of the microorganisms found in the subgingival environment. Even with improvements in cultivation, the relative occurrence of the newly described species in health and disease needs to be addressed. For example, little information is available on the newly described spirochetal microorganisms *(Treponema spp.,* Table 6-2). Another limitation is that association, although important, is only one aspect of demonstrating an etiologic role for a particular bacterium (see following discussion). The periodontal microbiota is a very complex ecologic system with many structural and physiologic interactions among the resident bacteria and between the bacteria and the host. It is clearly possible that levels of a particular species may be elevated as a result of environmental changes produced by the disease process and may not be a causative agent. A possible example of this comes from studies on the development of gingivitis in humans at the time of puberty. It was found that the proportions of *Capnocytophaga spp.* increased before the development of gingivitis, whereas P. *intermedia* was recovered after the onset of gingivitis.[65] This suggests a causative role for the *Capnocytophaga spp.,* in contrast to the emergence of P. *intermedia* associated with environmental changes upon the development of gingivitis. Similarly, recent studies have demonstrated an association of herpesviruses with periodontal diseases, but the possible role of these microorganisms in the disease process is yet to be determined. Thus association studies represent an important, but only a first, step in critically identifying pathogens in periodontal diseases.

CRITERIA FOR IDENTIFICATION OF PERIODONTAL PATHOGENS

In the 1870s, Robert Koch developed the **classic criteria by which a microorganism can** be judged to be a causative agent in human infections. These criteria, known as *Koch's postulates,* stipulate that the causative agent must:

1. Be routinely isolated from diseased individuals
2. Be grown in pure culture in the laboratory
3. Produce a similar disease when inoculated into susceptible laboratory animals
4. Be recovered from lesions in a diseased laboratory animal

Streptococcus mutans, for example, has been shown to fulfill Koch's postulates as an etiologic agent of dental caries. However, difficulties exist in the application of these criteria to other types of diseases, and the applicability of Koch's postulates has been increasingly challenged in recent years. In the case of periodontitis, three primary problems are the inability to culture all the organisms that have been associated with disease (e.g., many of the oral spirochetes), the difficulties inherent in defining and culturing sites of active disease, and the lack of a good animal model system for the study of periodontitis.[94]

Sigmund Socransky, a researcher at the Forsyth Dental Center in Boston, proposed criteria by which periodontal microorganisms may be judged to be potential pathogens.[94] According to these criteria, a potential pathogen must:

1. Be associated with disease, as evident by increases in the number of organisms at diseased sites
2. Be eliminated or decreased in sites that demonstrate clinical resolution of disease with treatment
3. Demonstrate a host response, in the form of an alteration in the host cellular or humoral immune response
4. Be capable of causing disease in experimental animal models
5. Demonstrate virulence factors responsible for enabling the microorganism to cause destruction of the periodontal tissues

Data supporting the role of A. *actinomycetemcomitans* and P. *gingivalis* as periodontal pathogens, based on these criteria, are presented in Table 6-2. The association and elimination criteria are discussed in the preceding sections. The latter three criteria focus on the host parasite interaction, which is discussed in Chapter 8 (Microbial Interactions with the Host in Periodontal Diseases).

FUTURE ADVANCES IN PERIODONTAL MICROBIOLOGY

Scientific progress at the end of the 20th century, particularly in the field of molecular biology, has led to advances in our approach to the study of periodontal microbiology. DNA-based methodology for the identification and detection of specific bacteria and viruses represents a remarkable advantage in time and cost as compared with cultivation techniques. This has led to a dramatic increase in the number of samples that can be examined and the number of microorganisms enumerated. Perhaps even more profound, the ability to detect microorganisms that cannot be cultivated has underscored the limitations of our knowledge of this complex ecologic niche. The use of these approaches to continue the study of the periodontal region will undoubtedly refine our current understanding of the microbial ecology and etiology of diseases.

SPECIFIC IMMUNE RESPONSES
T-CELL RESPONSES
B-CELL RESPONSES AND ANTIBODIES
SUMMARY

m re common periodontal diseases found in hu-
ans are gingivitis and periodontitis. These are in-
flammatory responses in the periodontal tissues induced by microorganisms in dental plaque, which may lead to tissue destruction. This chapter focuses on the role of the immune system in inflammation. The immune system is a network designed for the homeostasis of large molecules (oligomers) and cells based on specific recognition processes. Recognition of the structural features of an oligomer by receptors on immune cells is an important component of the specificity of the immune system.

Immune responses are categorized as either innate or adaptive. Innate immune responses do not adapt with repeated exposure to the same pathogen. An example of innate immunity is phagocytic cells (i.e., monocytes, macrophages, and neutrophils), which possess a number of inherently antimicrobial peptides and proteins that kill many different, rather than one specific, pathogen. In contrast, the specific adaptive immune responses will increase after exposure to a pathogen. Lymphocytes (e.g., T-cells and 13-cells) are important in the fundamental form of specific adaptive immunity referred to as the specific immune response. The ability of T-cells and B-cells to recognize specific oligomeric structures on a pathogen and generate progeny that also recognize the structure enables the immune system to respond more rapidly and effectively when exposed to that pathogen again.

Inflammation is an observable alteration in tissues associated with changes in vascular permeability and dilation, often with the infiltration of leukocytes into affected tissues. These changes result in the erythema, edema, heat, pain, and loss of function that are the "cardinal signs" of inflammation. Typically, inflammation can progress through three stages: immediate, acute, and chronic. Leukocytes, the white blood cells, control all three stages of inflammation (Table 7-1, Fig. 7-1).

Leukocytes originate in the bone marrow and exit from the blood by transendothelial migration under normal conditions, accounting for the resident leukocytes (or nonelicited leukocytes) found in tissues. Among the most important resident leukocytes are mast cells, peripheral dendritic cells (DC, and monocyte-derivatives such as dermal dendrocytes (histiocytes). These resident leukocytes transmit information that

TABLE 7-1

Cells of the Immune System

Leukocyte	Normal Blood Levels (per mm)	Notable Properties (Cell Diameter in Blood)	Key Receptors in Interactions with Antigen*	Important Functions in Inflammation
Myeloid Cells				
Neutrophil	4000 to 8000	Terminally differentiated in blood, granular cytoplasm (9 to 10 Am)	CRI, CR3 (Mac-1) CR4 FcyRll C5aR(CD88)	Phagocytic killing of microorganisms
Monocyte	200 to 800	Immature in blood (9 to 10 Am)	CRI, CR3 (Mac-1) CR4, CD1 FcyRI, FcyRll MHC Class II C5aR (CD88)	Can differentiate to macrophages with diameters > 20 Am Functions in phagocytosis and antigen processing and presentation
Peripheral dendritic cell	N/A	Immature in blood (9 to 10 Am)	ICAM-1, LFA-1 MHC Class II CD1	Resident in parabasilar epithelium Function in processing and presentation of antigen
Eosinophil	50 to 300	Terminally differentiated in blood, granular cytoplasm (9 to 10 Am)	FCeRII (low affinity) FcyRll C5aR (CD88) CRI, CR3 (Mac-1) CR4	Antiparasitic and antihelminthic activity, mediated by IgE
Basophil	0 to 100	Terminally differentiated in blood, granular cytoplasm (9 to 10 Am)	FcERI (high affinity) CRI, CR3, CR4 C5aR (CD88)	Receptor profile suggests that cells may respond to bacterial and parasitic infections
Mast cell	N/A	N/A	FcERI (high affinity) C3aR C5aR (CD88) CR4, no CR3	Resident in perivascular connective tissue Anaphylactic effects in response to C3a and C5a Antigen recognized by IgE
Lymphoid Cells				
CD4+ cells	400 to 1600	(8 to 10 Am)	TCR, CD4	Scanning antigen presented by professional antigen-presenting cells In inflammation, this may result in clonal expansion of B-cells and T -cells
CD8+ cells	200 to 800	(8 to 10 Am)	TCR, CD8	Scanning antigen presented by all cells In inflammation, this may result in clonal expansion and killing of the cell presenting antigen
B-cell	200 to 800	(8 to 10 Am)	BCR MHC Class II	Binding soluble antigen, antigen processing and presentation In inflammation, this may result in clonal expansion and antibody secretion
NK-cell	100 to 500	(8 to 15 Am)	KIR, KAR	Scanning cell antigens, target cell killing if KAR scans antigen, no killing if KIR scans antigen

N/A, Not applicable.

* **All cells present self-derived antigens using MHC Class I molecules. See text for explanation of receptor designations.**

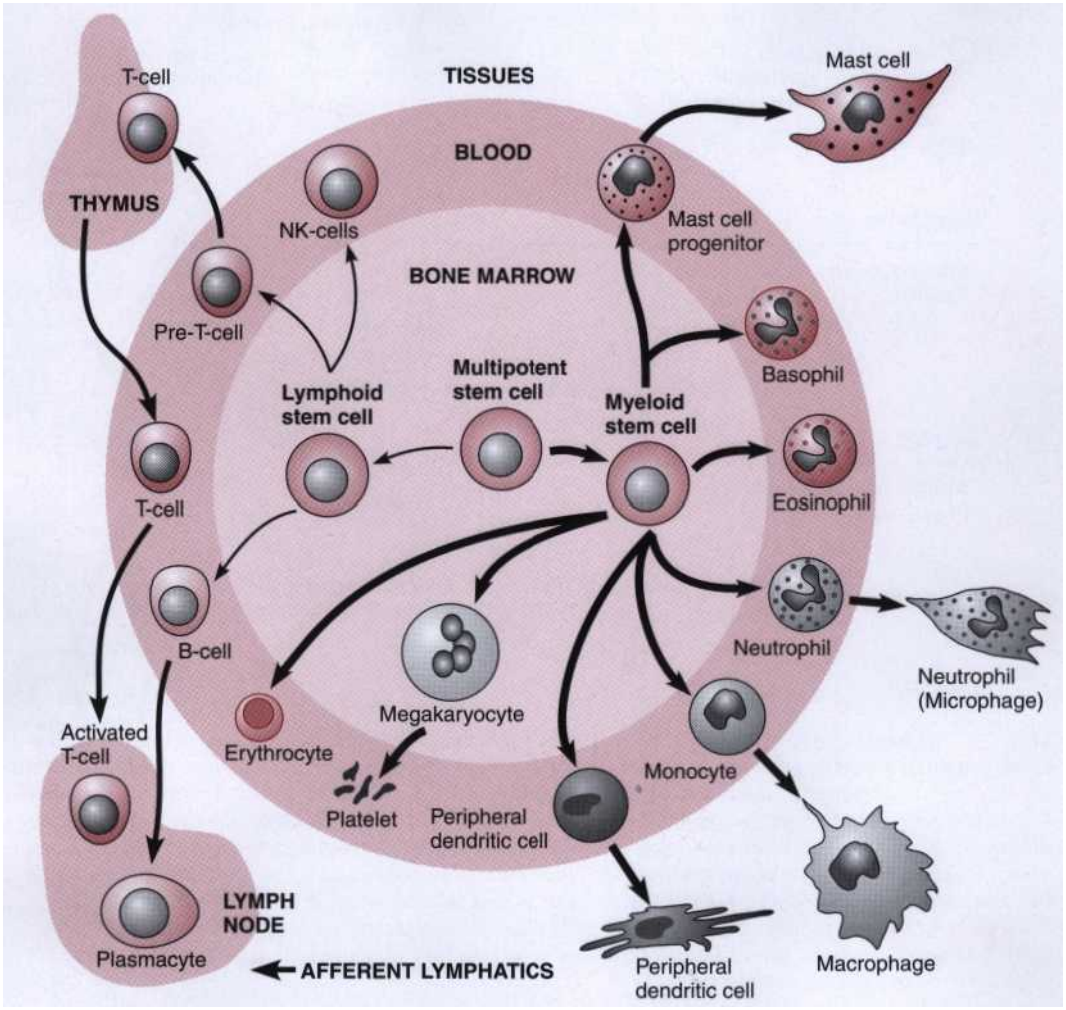

Fig. 7-1 The main cells of the immune system are derived from the lymphoid and myeloid arms of the hematopoietic system. In the bone marrow, the myeloid arm gives rise to peripheral dendritic cells, phagocytes (neutrophils and monocytes), mast cell precursors, basophils, eosinophils, platelets, and erythrocytes. In the tissues, peripheral dendritic cells, monocytes, and mast cell precursors further differentiate. The monocyte can become a macrophage. In the bone marrow, the lymphoid arm gives rise to NK-cells, B-cells, and pre-T-cells. The pre-T-cells differentiate to T-cells in the thymus. Secondary lymphoid organs, including lymph nodes and the spleen, are areas where antigen presenting cells, B-cells, and dendritic cells, present antigen to T-cells. Terminal differentiation of B- and T-cells also occurs in these organs.

initiates the processes of immediate inflammation (Fig. 7-2). Immediate inflammation is followed within minutes by a short-lived period (up to several hours) of acute inflammation that is characterized by an influx of neutrophils to the area after they exit the blood. If the problem is not resolved, acute inflammation gives way to a potentially unending period of chronic inflammation dominated by the migration of lymphocytes and macrophages to the local tissues. The leukocytes recruited into tissues in acute and chronic inflammation are termed inflammatory leukocytes.

CELLS OF IMMUNITY AND INFLAMMATION

Cells of the immune system that are important in inflammation and host defenses include in mast cells, dermal dendrocytes (histiocytes), peripheral dendritic cells, neutrophils, monocytes/macrophages, T-cells, B-cells, and NK-cells (see Table 7-1, Fig. 7-1). Other hematopoietic leukocytes (i.e., basophils, eosinophils, erythrocytes, and platelets) also participate in certain forms of inflammation or immune function but will not be described here.

Cells possess receptors, which are molecules on the cell surfaces that enable the cell to interact with other molecules or cells. Receptors reflect and dictate the function of cells. Historically, the names given to receptors often related to function. In addition to these common names, a systematic nomenclature known as the CD (cluster of differentiation) system has been developed. Under this system, receptors are identified as CD1, CD2, and so on. In this chapter, multiple designations are provided for specific receptors when the different designations have been commonly used.

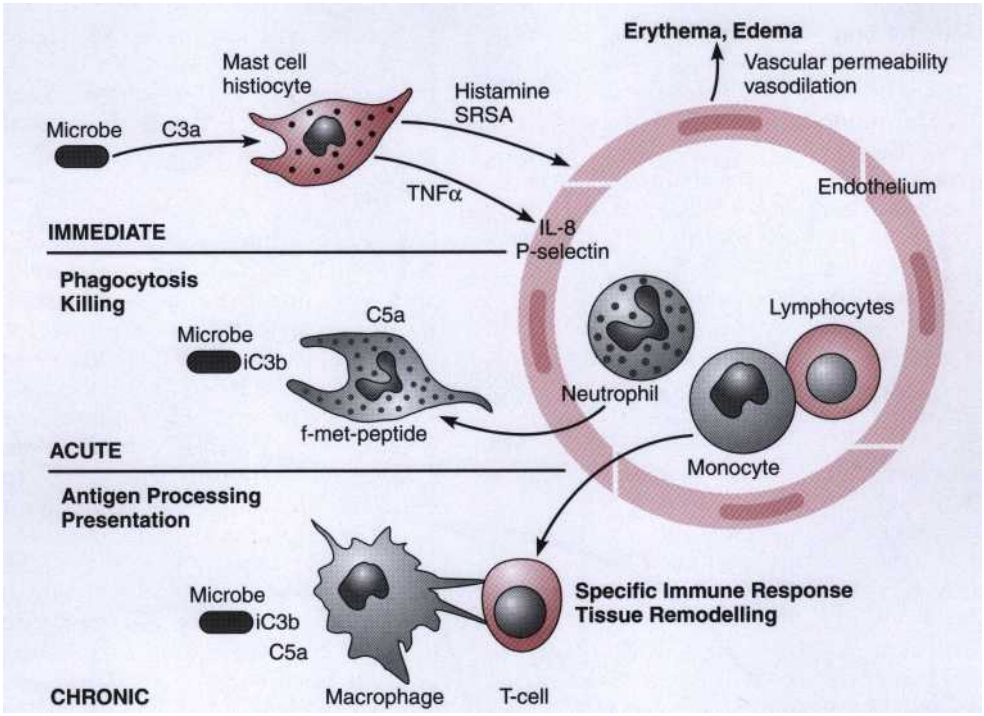

Fig. 7-2 The natural history of inflammation actually starts before an irritant exists, with the transendothelial migration of resident leukocytes, especially the mast cell. Mast cells are among the most effective cells in alerting the endothelium of a local problen. Mast cell interaction with the vascular system leads to erythema and edema, which are two of the five cardinal signs of inflammation. Mast cells also signal the endothelial cells to recruit inflammatory leukocytes. The inflammatory leukocytes are active in phagocytosis, killing, antigen processing and presentation, specific immune responses, and tissue remodeling. They cause the infiltrated area to lose function (the fifth cardinal sign of inflammation) as a side effect of their intense focus on resolving the problem and remodeling the tissue. Also depicted are the complement metabolites, iC3b, C3a, and C5a. These molecules are important in allowing the immune system to "see" substances for which they do not possess receptors.

Mast Cells

Mast cells are important in immediate inflammation (see Table 7-1 and Fig. 7-1). They possess receptors for complement components (C3a and C5a) as well as receptors for the Fc portion of the antibody molecules IgE and IgG (FccR and FcyR, respectively). The stimulation of these receptors can result in activation and secretion of vasoactive substances that increase vascular permeability and dilation, two important signs of anaphylaxis. Anaphylaxis can be life threatening if it is widespread (systemic), but it is usually localized and is important in initiating inflammatory responses against local microbial invasion." Mast cells feature prominent cytoplasmic granules, termed lysosomes, which store inflammatory mediators such as histamine, eosinophil chemotactic factor, neutrophil chemotactic factor, and heparin. Mast cells can synthesize, **de novo,** other inflammatory mediators, such as the slow-reacting substances of anaphylaxis (SRS-A), tumor necrosis factor-a (TNF-a), and leukotriene C4.

Dermal Dendrocytes

Dermal dendrocytes (histiocytes) are widely distributed and form a large system of collagen-associated dendritic cells of myeloid origin. These cells are distributed near blood vessels and possess receptors for the complement component C3a, by which they participate in immediate inflammation. They express the major histocompatibility complex (MHC; see discussion below) Class II molecules.32

Peripheral Dendritic Cells

Peripheral dendritic cells (DC) are leukocytes with cytoplasmic projections, or dendrites (see Table 7-1).a Langerhans cells are DCs that reside in the suprabasilar portions of squamous epithelium. DCs ingest antigen locally and transport the antigen to the lymph nodes through the afferent lymphatics. DCs express high levels of MHC Class 11 molecules and CD1 as well as cell adhesion molecules (intercellular adhesion molecule-1 [ICAM-1]; leukocyte function associated antigen-3 [LFA-3]), and costimulatory factors (B7-1, B7-2; discussed below).

Neutrophils and Monocytes/Macrophages

Neutrophils and monocytes are closely related phagocytic leukocytes. The fundamental difference between these two cells is that neutrophils differentiate almost

completely within the bone marrow (14 days), whereas monocytes exit the bone marrow after 2 days in a relatively immature state and may differentiate in the tissues. Neutrophils and monocytes are the same size (10-gm diameter) in the blood.

Neutrophils (also known as *polymorphonuclear leukocytes, or PMNs)* are the predominant leukocyte in blood, accounting for about two thirds of all blood leukocytes (4000 to 8000 cells/mm3; see Table 7-1). They possess many lysosomes within their cytoplasm. Because neutrophils do not need to differentiate substantially to function, they are suited for rapid responses. When neutrophils leave the blood, they always retain their small size and hence were once called *microphages.* Neutrophils possess receptors for metabolites of the complement molecule C3, designated complement receptor 1, 3, and 4 (CR1, CR3, CR4); and CS (C5aR). They also possess receptors for IgG antibody (FcyR). These receptors enable neutrophils to participate in the inflammatory response and to ingest foreign molecules and cells in the process of phagocytosis.

By convention, monocytes are referred to as *macrophages* when they leave the blood. They complete their differentiation in the local tissues and may become greater than 22 gm diameter; hence the macrophage designation (see Table 7-1). Because macrophages differentiate and live in the local tissues, they are suited for communicating with lymphocytes and other surrounding cells. Macrophages live long enough to present antigen to Tcells. Together, macrophages and lymphocytes (discussed below) orchestrate the chronic immune response. Monocytes/macrophages possess CRl, CR3, CR4, C5aR receptors, several classes of Fcy receptors (FcyRI, FcyRII, FcyRIII), and molecules important in antigen presentation (MHC Class II receptor, CD1).

Lymphocytes

The three main types of lymphocytes are distinguished on the basis of their receptors for antigens: T and B-lymphocytes and natural killer (NK) cells. In the blood, B-cells and T-cells are inactive and exhibit a fairly small size (8 to 10 gym). NK-cells may differentiate extensively in the bone marrow and appear in blood as a large, granular lymphocyte. With a diameter of 15 um or greater, these cells are larger than any other leukocyte in the blood.

T-Cells

Tcells recognize diverse antigens using a low-affinity transmembranous complex, the T -cell antigen receptor (TCR). Antigens are recognized by Tcells in association with either MHC Class I or Class II molecules on the surface of the antigen presenting cell. T-cells are subdivided based on whether they possess the coreceptors CD4 or CD8. The CD4 coreceptor reversibly binds (scans for) MHC Class II molecules (HLA-DR, HLA-DP, HLA-DQ) that are found on dendritic cells, macrophages, and B-cells. CD4+ Tcells initiate and help with immune responses by providing proliferative and differentiative signals. The CD8 coreceptor scans for MHC Class I molecules, which are found on all cells. The CD8+ T-cells are predominantly cytotoxic T-cells involved in controlling intracellular antigens (e.g., certain bacteria, hyphal fungi, viruses).

B-Cells

B-cells help control extracellular antigens such as bacteria, fungal yeast, and virions. B-cells recognize diverse antigens using the B-cell antigen receptor (BCR), which is a high-affinity antigen receptor. The high-affinity interaction between BCR and antigen enables the B-cell to bind and ingest the antigen without antigen presentation. The antigen is tightly bound, not scanned. Ingested antigen is degraded and presented to T-cells.

Before antigen exposure, B-cells express IgM as part of the BCR. After antigen exposure, some B-cells differentiate to form plasma cells dedicated to the production and secretion of antibodies of the IgM isotype. Others in the presence of Tcells may differentiate along the memory pathway, forming memory B-cells. Memory B-cells give rise to plasma cells upon secondary exposure to antigen and produce high-affinity antibodies of the appropriate isotype.

Natural Killer (NK) Cells

NK-cells recognize and kill certain tumor and virally infected cells. The NK-cells possess several classes of antigen receptors, including killer inhibitory receptors (KIR) and killer activating receptors (KAR). These receptors will recognize antigens associated with MHC Class I molecules, MHC Class I molecules themselves, or certain other surface glycoproteins. Normal cells possess MHC Class I molecules that present antigens recognized as "self"; these interact with KIR and protect the cells from NK-cell mediated killing. Alterations in antigens presented by the MHC Class I molecules, occurring in tumor- and virally infected cells, may result in NK-cell activation because the KIR do not detect sufficient self antigens. Additionally, cells can present self-antigens in response to stress or other alteration, which are recognized by the KAR. KAR activation can override KIR inhibition and cause the NK-cell to kill the target cell.

COMPLEMENT

Complement (C) is an interacting network of about 30 membrane-associated cell receptors and soluble serum glycoproteins (Table 7-2). Soluble components of this system account for about 5% (3 to 4 mg/mL) of the total serum protein. Most soluble components are synthesized in the liver, but many also may be produced by macrophages (C1, C2, C3, C4, CS, Factor B, Cl-INA, Factor D, and Factor H). The soluble components of the complement system were first observed to cause bacteriolysis and cytolysis in association with antibody (a "complement" of antibody), and later in the absence of antibody. These lytic effects are famous but represent only one function of complement.

The complement system is a central component of inflammation that enables endothelium and leukocytes to recognize and bind foreign substances for which they lack receptors. Complement promotes inflammation by generating the following:

A vasoactive substance, termed *kinin-like,* C2a, which induces pain, increases vascular permeability and dilation
Molecules, termed *anaphylatoxins,* C3a and C5a, which produce anaphylaxis by inducing mast cell secretion
A chemotaxin, C5a, which attracts leukocytes and stimulates phagocyte secretion
An opsonin, iC3b, covalently bound to molecular aggregates, particles, or cells, which enables phagocytes to ingest them

C3 is the most important component of complement (Fig. 7-3, A). It also is the predominant component, accounting for about one third of the total complement (1.6 mg/mL). A sequestered, internal thioester bond is the essential feature of C3, and it shares this feature with

TABLE 7-2

Complement Components

Component	Molecular Weight (kd)	Serum Concentration (μg/ml)*
Classical Pathway Initiators		
C1q†	410	150 to 180
C1r	85	50
C1s	85	100
Mannose-binding lectin (MBL)	400	1.5 to 1.8
MASP1	93 (proform)	1.5 to 12
MASP2	90 (proform)	Undetermined
C3 Convertase and C3/C5 Convertase Formation		
C2	110	30
C3	195	1200 to 1300
C4	210	400 to 450
Factor B	93	200 to 225
Factor D	25	1.5
Membrane Attach Complex Formation		
C5	205	80
C6	128	75
C7	121	55
C8	155	80
C9	79	200
C1-INA	109	180
Factor I	88 to 93	25 to 35
Anaphylatoxin inactivator	310	30
Soluble Regulators of Complement Activation		
Factor H	150	500 to 520
C4BP	570	200
Membrane Regulators of Complement Activation		
		Location
MCP (CD46)	45 to 70	All cells
DAF (CD55)	75 to 80	All cells
CR1 (CD35)	250	Phagocytes, B-cells, erythrocytes
CR2 (CD21)	140	B-cells
Opsonic Receptors of iC3b		
CR3 (Mac-1; CD11b/CD18)	165/95‡	Phagocytes, dendritic cells
CR4 (p150/95; CD11c/CD18)	150/95‡	Phagocytes

the related molecule, C4. Splitting of C3 forms C3a and C3b and exposes the internal thioester bond residing within the C3b fragment. Two main pathways result in the splitting of C3, the alternative and the classical pathways (Fig. 7-3, B). The outcome of C3b generation is dictated by the presence or absence of the regulators of complement activation (discussed below).

Both the alternative pathway and classical pathway lead to inflammation and phagocytosis through an enzyme that is designated a bound C3 convertase. The alternative pathway is initiated without provocation by a spontaneous hydrolysis of the internal thioester bond of C3 by water. This pathway leads to the hydrolysis of C3b by larger structures (designated R), including the hydroxyls and amines on macromolecules and bacterial cell surfaces. The resulting covalent structure, C3b-R, leads to the bound C3 convertase (R-C3bBb).

The classical pathway is initiated in response to the presence of some irritant. Irritants include antibody-antigen complexes, certain membranes, or suspicious polymers (e.g., mannans). This pathway involves the activation of a serine protease (e.g., Clgrs) which has attached to an irritant. The protease serves as a C4/C2 convertase and leads to formation of a C3 convertase covalently bound to R (R-C4bC2b), with release of the vasoactive kinin-like substance C2a. The classical pathway also may be activated in the absence of such irritants, but this is controlled by an inactivator, Cl-Inactivator (Cl-INA). A deficiency of C1-INA (often occurring secondary to infection) can result in swollen lips or eyelids (angioedema) due to such spontaneous activation of the classical pathway.

Two main processes can occur with the formation of bound C3 convertase in the absence of regulators, such as in the presence of bacterial cells (Fig. 7-4). First, amplification occurs; second, the membrane attack complex is formed. Amplification is an exponential increase in the formation of C3b. This results because the bound C3 convertase (either R-C3bBb or R-C4bC2b) forms more C3b, and the resultant C3b may form more C3 convertases (R-C3bBb). Formation of C3b also is associated with the production of the anaphylatoxin C3a.

Formation of the membrane attack complex is initiated after approximately 100 molecules of C3b are formed, when the thioester of one C3b is hydrolyzed by the C3 convertase (R-C3bBb or R-C4bC2b) itself at a specific site on the C3b (or Cob) subunit of the convertae.20 This results in the formation of the structure R-C3b-C3bBb or R-C3b-C4bC2b. These new complexes can bind and cleave both C3 and C5; thus they are called C3/C5 convertases. The CS convertase activity is monumentally slow (in fact, one of the slowest enzymatic activities in the known universe); at best, one CS is converted every four minutes by one CS convertae." Nonetheless, the cleavage of C5 produces two important fragments, C5a and C5b. The C5a fragment is the main leukocyte chemoattractant derived from complement and is an important anaphylatoxin. The C5b component associates with C6, C7, C8, and C9, forming a membrane attack complex that can lyse certain bacteria and cells by forming a large pore in the target cell membrane.

The six regulators of complement activation are encoded in a tight cluster on chromosome 1: Factor H, membrane cofactor protein (MCP), complement receptor 1 (CR1), complement receptor 2 (CR2), decay accelerating factor (DAF), and C4-binding protein (C4BP). Four of these regulators are cofactors working with the proteolytic soluble enzyme, Factor 1, including Factor H, MCP, CR1, and C4bp.

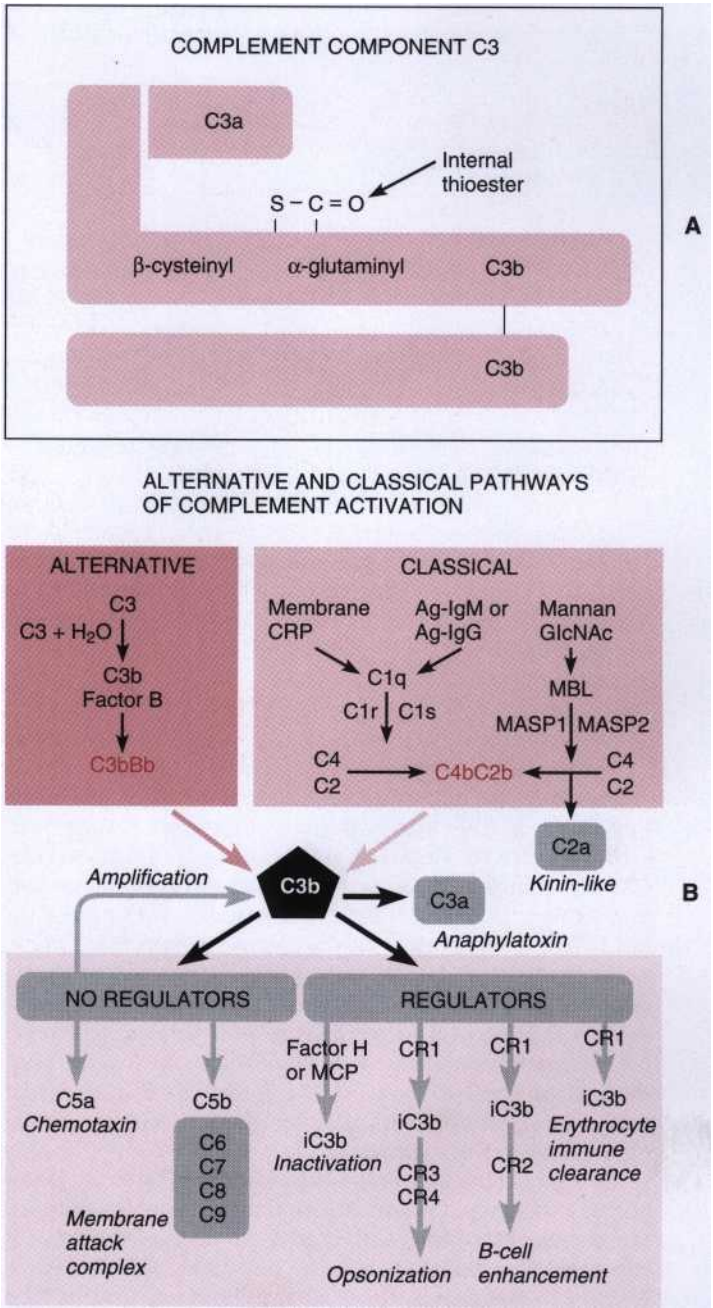

Fig. 7-3 A, The central component of complement is C3. See the text for details of the importance and function of C3. B, The central goal of the complement system is the formation of C3b. Both the alternative and classical pathways lead to formation of 0 convertase enzymes (C3bBb, C4bC2b) and the generation of C3b. The biologic consequences of C3b formation depend on the presence or absence of regulators. See the text for details of the complement pathways.

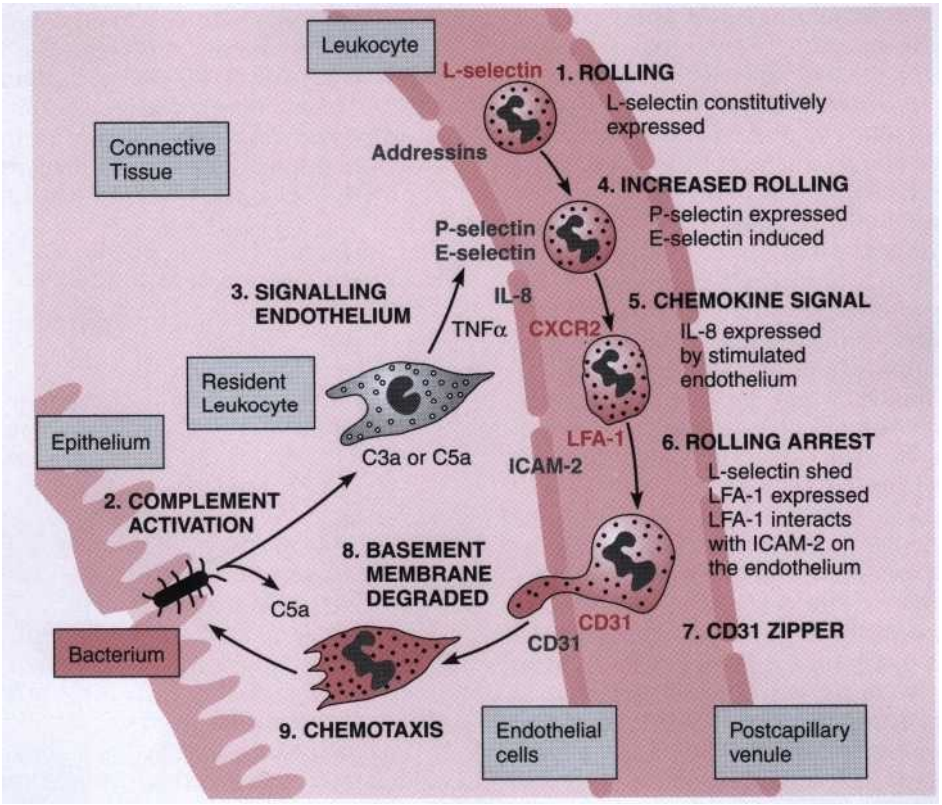

Fig. 7-4 Inflammation is a result of the interaction between complement, resident leukocytes, endothelium, and the recruited inflammatory leukocytes. Endothelial components are indicated in gray type; leukocyte components are indicated in red type. See the text for a discussion of the events involved in transendothelial migration.

Factor H and C4BP are serum cofactors that are most important in the inactivation of fluid phase C3b and Cob respectively. Factor H enables Factor I to inactivate C3b by clipping out a small piece, forming inactivated C3b (iC3b). The iC3b is inactive because it no longer can bind Factor G and thus can no longer generate C3 convertases. MCP and DAF are widely distributed on host cells and are mainly designed to protect the host cell against C3b and C3 convertase, respectively, which have bound to the same host cell. MCP binds to R-C3b, and enables Factor I to convert the R-C3b to R-iC3b. This halts further amplification. Eventually, iC3b is further metabolized and destroyed.

CRl is a transmembrane molecule expressed by phagocytes (neutrophils and macrophages), B-cells, and red blood cells. CRl binds C3b that is attached covalently to the surface of another particle, and it attracts Factor I, leading to the inactivation of amplification by the formation of iC3b. Phagocytes possess receptors for iC3b and will efficiently ingest the iC3b-bound cell or particle in a process known as opsonic phagocytosis (discussed further below), with subsequent destruction of the ingested material. Thus whereas MCP protects host cells, CR1 targets foreign or altered cells or molecules in the area for destruction.

In summary, the complement system is important in identifying and neutralizing substances for which the host does not possess specific receptors. **Complement can be considered to be the** fire of **the** immune system. When this fire ignites, it radiates the local area with molecules (C2a, C3a, and C5a) that enhance the inflammatory response and enable the endothelium and leukocytes to "see" and "find" the problem. The complement system additionally facilitates phagocytosis and destruction of foreign substances or direct destruction of cells or microorganisms via the membrane attack complex.

TRANSENDOTHELIAL MIGRATION

The directed movement of leukocytes from **the** blood into the local tissues is central to inflammation. Transendothelial migration is a selective interaction between leukocytes and endothelium that results in the leukocyte pushing its way between endothelial cells to exit the blood and enter the tissues. Defects in transendothelial migration are associated with aggressive periodontitis; reflecting the importance of this process in periodontal diseases.

Neutrophils and monocytes spend less than 12 hours in circulation. B-cells and T-cells stay in the blood for

only about 30 minutes at a time. B-cells and T-cells require the additional influence of lymphoid organs (lymph nodes, spleen, tonsils, Peyer's patches, adenoids) to function properly. Thus they constantly exit the blood, pass through lymphatic' and secondary lymphoid organs, and re-enter the blood in a perpetual process known as lymphocyte recirculation. The blood contains only 2% of all lymphocytes at any given time, and lymphocytes are estimated to recirculate as much as 50 times a day.[30]

In a local inflammatory response, transendothelial migration occurs in the following sequential phases: rolling (Step 1), an insult to local tissue (Step 2), signaling the endothelium (Step 3), increased rolling (Step 4), signal for rolling arrest (Step 5), strong adhesion (arrested rolling) (Step 6), and the zipper phase (Step 7). These processes are illustrated in Figure 7-4 and discussed below.

Leukocytes use the lectin (a nonenzymatic carbohydrate-binding protein), designated L-selectin, to interact with carbohydrate molecules known as *vascular addressins (e.g.,* sialomucin CD34)[4] on the lumenal surface of endothelial cells (Step 1, Fig. 7-4). This brief interaction manifests itself as the rolling of the leukocyte along the lumenal surface of the endothelium, a process whereby the leukocyte essentially pauses to inspect the endothelium.

A local insult (Step 2, Fig. 7-4) triggers the release of a variety of inflammatory signals (such as interleukin-1ß [IL-1ß], tumor necrosis factor a [TNF-a]) from cells in the tissue, especially from resident leukocytes such as mast cells.[33] Mast cells are crucial in initiating neutrophil recruitment against bacteria[22] and respond to anaphylatoxins such as C3a and C5a (Step 3, Fig. 7-4).

IL-1ß, TNF-a, CSa, and lipopolysaccharides can stimulate endothelial cells to express P-selectin and E-selectin on their lumenal surfaces.[14,14] Either of these selectin' can bind carbohydrate molecules found on the leukocyte,[5] resulting in an increase in the time the leukocyte remains associated with the endothelium. This appears microscopically as an increase in number of leukocytes attached to the lumenal surface of the endothelium, or increased rolling. Notice that endothelial cells, not inflammatory leukocytes, initially respond to local inflammatory signals from the resident leukocytes.

The stimulated endothelium also releases chemokines. Chemokines are small peptide cytokines, first recognized for their chemoattractant activities, which play a fundamental role as selective signals for leukocytes to exit the blood (Step 5, Fig. 7-4). Chemokines function as a signal for rolling arrest. As illustrated in Fig. 7-4, the interaction of a chemokine, interleukin-8 (IL-8), with the leukocyte receptor, CXCR2 causes the leukocyte to shed L-selectin and upregulate the integrin, leukocyte function-associated antigen-1 (LFA-1).[17] Integrins are transmembrane adhesins, some of which have been adapted for use by the immune system. LFA-1 binds intercellular adhesion molecule-2 (ICAM-2), which is expressed constitutively by endothelium (Step 6, Fig. 7-4). This results in rolling arrest because the phagocyte becomes firmly associated with the endothelium. Prolonged or severe disturbances of the endothelium can upregulate ICAM-1, which is a more efficient ligand for LFA-l.

Because leukocytes differ with respect to their chemokine receptors, the chemokine' dictate which leukocytes (e.g., neutrophils, macrophages, lymphocytes, eosinophils, basophils) dominate the leukocyte infiltrate. Different stimuli (e.g., cytokines, tissue injury, viral or microbial insults) can lead to expression of different chemokines.[11,13,21] For example, hypoxia, a condition in which only neutrophils can function successfully, favors endothelial release of IL-8,[19] a chemokine to which neutrophils are responsive. The integrin phase of transendothelial migration (i.e., the interaction of LFA-1 with ICAM-2) also can be somewhat selective. Thus chronic inflammatory leukocytes (monocytes and lymphocytes) possess integrins that are not expressed by neutrophils. One such integrin, "very late antigen-4 (VLA-4)," binds endothelial vascular cell adhesion molecule-1 (VCAM-1). Endothelium expresses VCAM-1 after prolonged inflammation, thus providing a mechanism for the selection of chronic inflammatory cells.

CD31 (Platelet-Endothelial Cell Adhesion Molecule-1) is a 130-kd transmembrane glycoprotein present at the intercellular borders of endothelial cells facing into lumen and on all leukocytes. CD31 is a homophilic adhesion molecule because CD31 molecules bind to one another. The binding of CD31 on endothelium with CD31 on leukocytes guides leukocytes to the boundaries between endothelial cells (Step 7, Fig. 7-4). Once the leukocyte locates the interendothelial junction, it uses its own CD31 like a zipper (CD31 zipper) with the CD31 of the endothelial cells.' This zipper effect has been proposed as a mechanism of minimizing the leakage of fluid. As the endothelium unzips its CD31, the leukocyte rapidly "zips" between the endothelial cells.

Leukocytes accumulate briefly between the basement membrane and the endothelial cell. This pause may reflect a period of secretion of proteases to degrade the basement membrane (Step 8, Fig. 7-4). Leukocytes possess several proteases, including urokinase plasminogen activator receptor (uPAR). The uPAR leads to the activation of collagenase, which then may degrade the basement membrane and enable the leukocyte to enter the connective tissues.

LEUKOCYTE FUNCTIONS

Chemotaxis

Once the leukocyte enters the connective tissue, it must be able to locate and migrate to the site of insult. This is accomplished by chemotaxis, which depends on the leukocyte's ability to sense a chemical gradient across its cell body and migrate in the direction of increasing concentration (Step 9, Fig. 7-4). The phagocyte senses only a limited number of chemicals -chemotaxins for which it has receptors, or chemotaxin receptors. Table 7-3 lists some molecules that can serve as chemotaxins and their sources. The receptors for chemotaxis belong to a family called the *G-protein coupled family* (Fig. 7-5, A). This family of receptors also includes the various light receptors

in our retinas; thus in some ways, leukocytes "see" a chemotactic gradient much as we see light. The only class of Chemotaxins derived directly from bacteria are formyl-methionyl peptides.

To migrate toward a target, leukocytes assume an asymmetric or polarized shape rather than the rounded morphology evident in blood (Fig. 7-5, B). Even under ideal experimental conditions, neutrophil migration has been observed to be primarily random until the neutrophil is 1 to 2 body lengths (10 to 20 /-tm) away from a recognizable target particle. [16]

Phagocytosis

Phagocytosis is the process by which cells ingest particles of a size visible to light microscopy. Neutrophils and monocytes/macrophages are the only cells efficient enough at phagocytosis to be considered "professional phagocytes." Phagocytosis results in the eventual containment of a pathogen within a membrane-delimited structure, the phagosome (Figs. 7-6 and 7-7, A). The immune system has evolved mechanisms of coating the pathogen with a few recognizable ligands, which enable the phagocyte to bind and ingest the pathogen. This is referred to as opsonization. A selected list of opsonins and the molecules with which they interact is presented in Table 7-4.

Once a microbe has been ingested, it may be killed. Phagocytes kill bacteria by two broad categories of killing mechanisms. One category is based on the reduction of oxygen and is referred to as *oxidative.* Oxidative mechanisms require 1) the presence of oxygen and 2) an oxidation-reduction potential, Eh, at or above -160 mV. Both variables may be suboptimal within the gingival crevice. Neutrophils do not require oxygen for energy and can function under anaerobic conditions. Thus phagocytes also must possess the second category of killing mechanisms, the nonoxidative mechanisms.

Nonoxidative killing requires phagosome-lysosome fusion. This process involves the movement toward and subsequent membrane fusion of the lysosome with the phagosome, forming a phagolysosome. This results in the secretion of lysosomal components into the phagolysosome. Each neutrophil possesses two main types of lysosomes, or granules: specific granules, designed for both extracellular and intraphagolysosomal secretion, and azurophil granules, designed mainly for intraphagolysosomal secretion. Less than 30 seconds after phagocy-

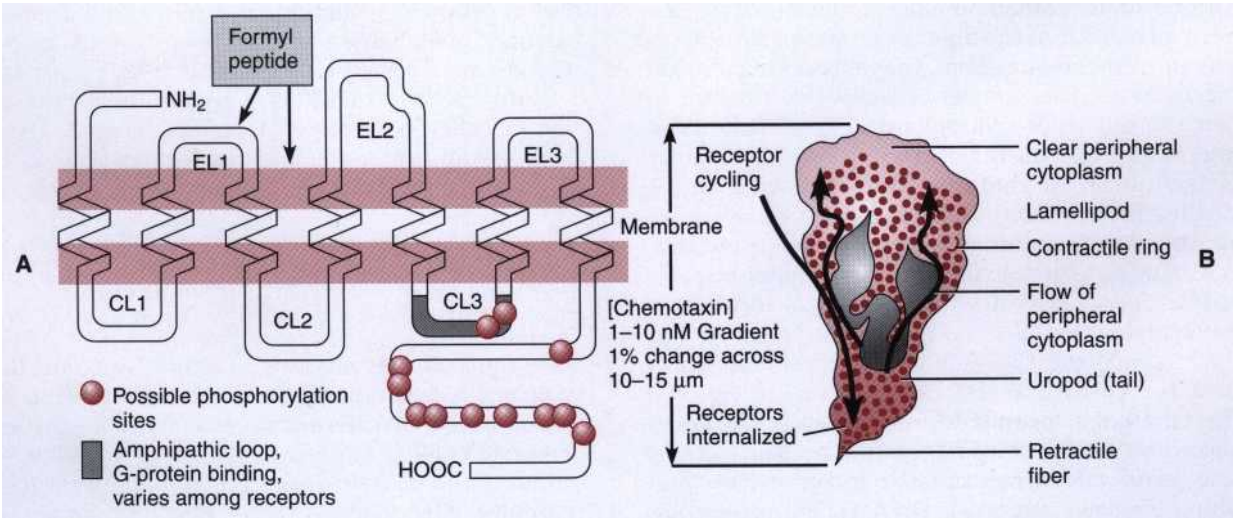

Fig. 7-5 Leukocytes can "hone in" on various irritants, such as a microorganism, by chemotaxis. This requires a chemotaxin receptor (A). The chemotaxin receptors are members of the G-protein coupled family. Seven transmembranous domains, three extracellular loops (ELl-3), and three cytosolic loops (CL1-3) characterize this family of molecules. B, Neutrophils polarize, forming an anterior lamellipod and a posterior uropod. Cytoplasm appears to squirt through a contractile ring. Neutrophils exhibit strikingly sensitive chemotaxis and can detect a 1 % gradient over the length of its cell body at nanomolar concentrations.

tosis, neutrophils secrete specific granule components into the phagolysosome. Specific granules contain several microbiocidal components including lysozyme and lactoferrin. Lysozyme is an enzyme that possesses enzyme-dependent bactericidal activity and enzyme-independent bactericidal and fungicidal activity. Lactoferrin is a bacteriostatic compound that contains a bactericidal peptide domain, lactoferricin. Neutrophils secrete azurophil granule components into the phagolysosome minutes after the secretion of the specific granules. Among the microbicidal compounds are small antimicrobial peptides known as a-defensins (e.g., HNP-1, HNP-2, HNP-3, and HNP-4), serprocidins (elastase, proteinase 3, azurocidin), cathepsin G, and lysozyme. These nonoxidative mechanisms of neutrophil killing may be of particular importance in periodontal diseases because of the highly anaerobic conditions in the subgingival environment.

In the presence of oxygen, phagocytes additionally possess mechanisms of oxidative killing. In particular, neutrophils exert intense microbicidal activity by forming toxic, reduced oxygen metabolites such as superoxide anion (O2) using the NADPH oxidase system. The superoxide anion also contributes to the formation of hydrogen peroxide (H_2O_2), which is capable of diffusing across membranes. Inside a target cell, H_2O_2 may be further reduced to the hydroxyl radical, which can cause DNA damage. More importantly, H202 is a substrate for myeloperoxidase (WO). In the presence of H_2O_2 and chloride, MPO catalyzes the formation of hypochlorous acid (HOCI). This molecule is the acidic form of the laundry bleach salt, sodium hypochlorite (NaOCl), which also is used as an antimicrobialcleansing irrigant in endodontics. Deficiencies in the NADPH oxidase system result in chronic granulomatous disease, a severe, recurrent, focal infection by organisms which do not release H_2O_2 on their own. Chronic granulomatous disease has been associated inconsistently with aggressive periodontal disease, suggesting that oxidative microbicidal mechanisms are of some importance in periodontal infections.

In summary, phagocytosis is of primary importance in the ability of a host to resist or combat infection. Once a pathogenic microorganism is ingested, several mechanisms of killing are possible. Because of the highly anaerobic conditions in the periodontal environment, nonoxidative mechanisms of killing are of particular importance.

Antigen Processing and Presentation

The major bistocompatibility complex (MHC) is a locus on the short arm of chromosome 6 (6p21.3) that encodes a number of molecules, including MHC Classes 1, II, and III molecules, which are involved with antigen uptake, processing, and presentation. All cells process and present self-derived antigens (intracellular antigens) in association with MHC Class I molecules. MHC Class I molecules are used to present intracellular antigens to CD8+ T-cells and NK-cells. MHC Class III molecules include complement factors B, C2, and C4.

Antigens derived from extracellular sources are presented by professional antigen-presenting cells (APC) in association with MHC Class II molecules. The three main professional APC are peripheral dendritic cells, monocyte-derivatives, and B-cells. These cells are

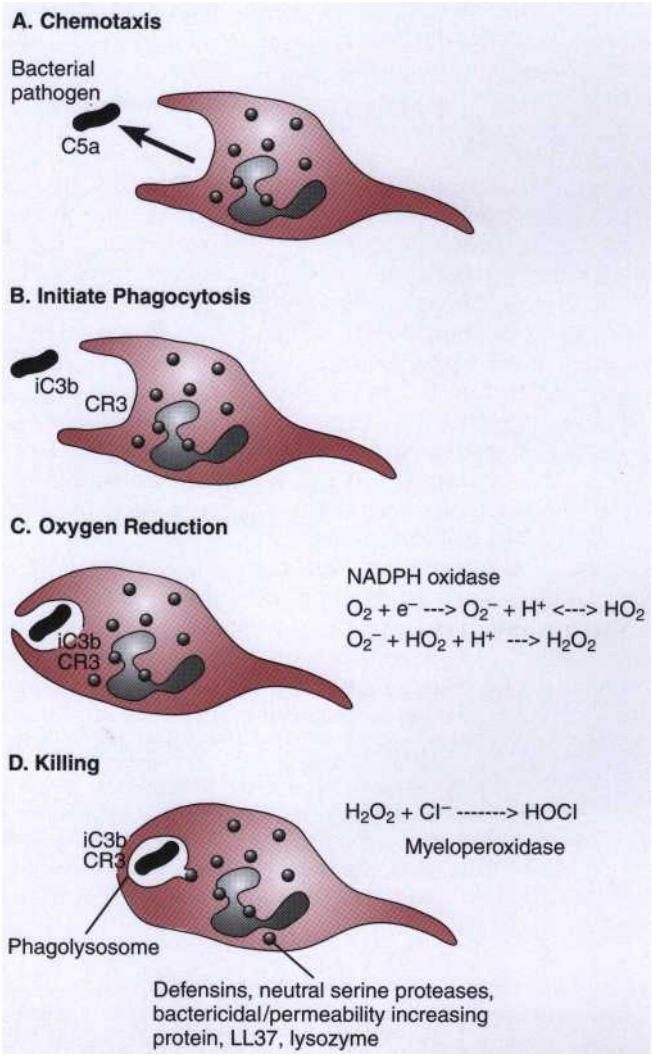

Fig. 7-6 After neutrophils exit the blood, they must kill the offending pathogens. This process consists of overlapping steps, which are illustrated in this diagram. A, *Chemotaxis* **refers to directed motility that enables the leukocyte to locate its target. C5a is a chemotaxin, which may be generated by any target that activates complement. B, Phagocytosis also requires the interaction of receptors with a few ligands. The diagram illustrates the important interaction between the opsonin iC3b, which will coat an offending particle or cell, and the opsonic receptor CR3. C, Oxygen reduction requires the presence of oxygen and a certain redox potential, both of which can vary in the gingival crevice. The formation of several oxygen metabolites can kill some bacteria. D, "Killing" involves several processes. First, phagocytosis traps the microorganism in the stringent environment of the phagosome. Second, the phagosome and lysosomes (granules) fuse to form the phagolysosome. In this step, all the toxic compounds of the lysosome (e.g., defensins, neutral serine proteases) are dumped into the phagolysosome. Third, myeloperoxidase in the phagolysosome can convert hydrogen peroxide to hypochlorous acid.**

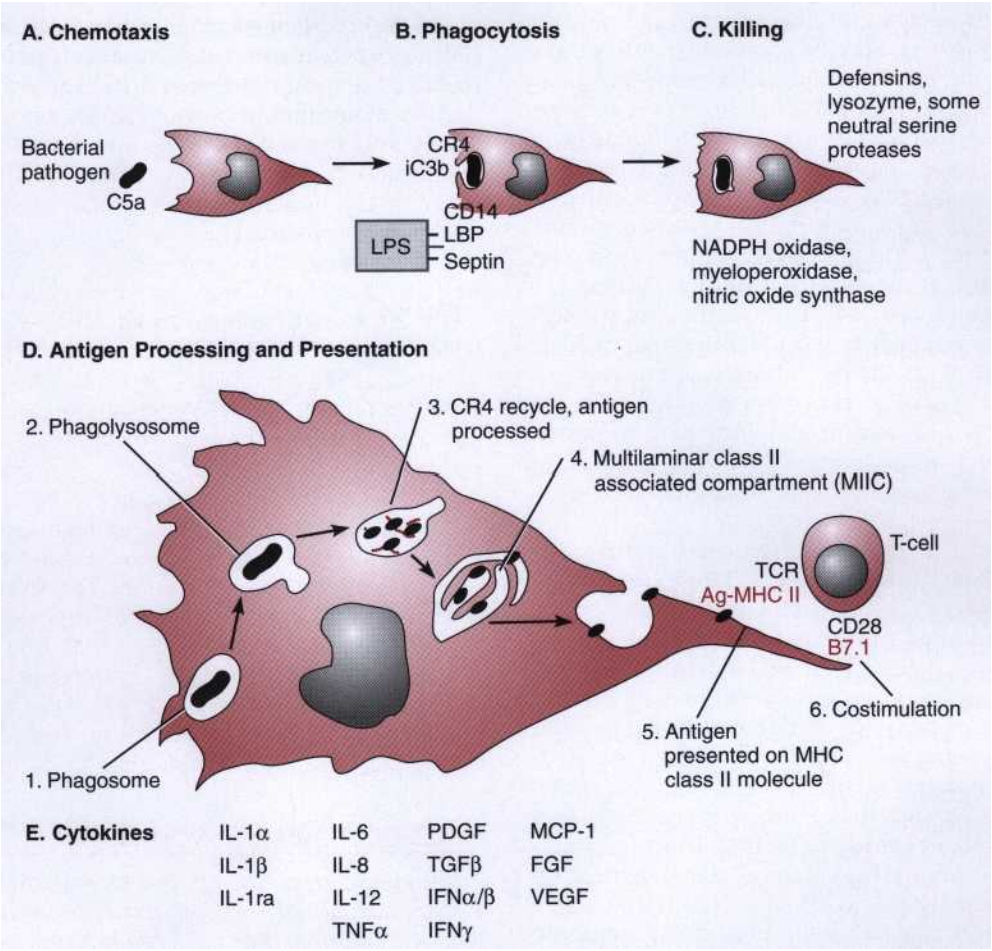

Fig. 7-7 Mononuclear phagocytes (monocytes in blood, macrophages in tissues) are closely related to neutrophils. Their activities are similar, and they exhibit chemotaxis (A), phagocytosis (B), and killing (C), similar to neutrophils. Mononuclear phagocytes are particularly adept at processing and presenting antigen to T-cells (D), a process that may require more than 20 hours. Note that antigen is presented in association with MHC Class II molecules along with a costimulatory signal (B7-1). Mononuclear phagocytes also release cytokines (E) that direct lymphocyte differentiation. See the text for details of the interactions illustrated.

TABLE 7-4

Opsonins and Opsonic Receptors

Target	Opsonin	Opsonic Receptor	Cell Possessing Opsonic Receptor
Gram-negative bacteria	LPS-binding protein (LBP) or septin	CD14	Macrophages Neutrophils (if primed with TNFa)
Any particle or cell	iC3b	CR3 (MacI)	Neutrophils Macrophages
		CR4	Macrophages
Any particle or cell	IgGI, IgG2, IgG3	FcyRI	Macrophages
		FcyRII	Macrophages Neutrophils

See text for explanation of abbreviations.

specialized to present antigen to CD4+ T-cells, which recognize antigen in association with the MHC Class II molecule. This is important because CD4+ Tcells control the proliferation of other T- and B-cells.

The professional APC express MHC Class II molecules (i.e., HLA-DP, HLA-DQ, HLA-DR) constitutively. Externally derived antigens are processed by phagocytosis, and the resulting peptide molecules associate with the MHC Class II molecules on the cell surface. As shown in Fig. 7-7, *D,* antigen associates with the MHC Class II molecule within the multilaminar Class II-associated compartment (MIIC). Oligomeric peptide fragments derived from extracellular polymers are bound by as many as four specificity pockets found in the MHC Class II molecule. Because the binding specificity is not for the entire peptide sequence, MHC Class II molecules are somewhat promiscuous and may bind to many different peptides.

Members of MHC Class I, II, and III molecules are among the most pleomorphic molecules in man. Pleomorphism refers to stable variations among individuals within a species, based on the occurrence of variants of certain genes. Pleomorphism in the MHC is particularly high near the specificity pockets. This means that the antigens bound by one person's MHC Class I or II molecules may not bind exactly the same peptides as those from a different individual. The existence of such pleomorphism may be important in species survival (as opposed to individual survival) and has become a significant consideration in transplantation (hence the term *histocompatibility).* If the donor tissue is not well matched in the MHC, it will present a multitude of new antigens that are recognized as foreign, and the donor tissue will be rejected by the resulting immune response.

The interaction between two cells permits a high level of sophistication unattainable by the simple interaction of two molecules, enabling the APC to present antigen to the Tcell with a second signal. The most important second signal is called *costimulation.* Costimulation reaffirms to the Tcell that it has recognized an undesirable antigen. In the absence of costimulation, T-cells may become unresponsive or apoptotic and die. Costimulation is mediated by a variety of transmembrane molecules of the tumor necrosis factor superfamily (Table 7-5), a family of molecules that deals with issues of cellular life and death. Costimulation does three things: 1) it makes the T -cell resistant to apoptosis (a programmed cell death); 2) it upregulates growth factor receptors on the T-cell, thereby stimulating its proliferation; and 3) it decreases the amount of time needed to trigger the Tcell (also referred to as *amplification).*[7,18]

Increases in the expression of costimulatory molecules occur in the presence of certain environmental stimuli. Macrophages increase the expression of costimulatory molecules if they are exposed to bacterial LPS[31,36] as well as particulate and occasionally soluble antigen. B-cells exposed to antigen to which they are specific, to selected bacterial membrane components (e.g., specific proteins, LPS), or to a B-cell activator molecule produced by T-cells (Gp39), respond by increasing the expression of the costimulatory molecules B7-1, B7-2, or both.[10-35] In addition, viral infection or certain chemical irritants can upregulate B7-1 or B7-3 on nonprofessional APCs.[12] A receptor molecule named Toll, first identified in fruit flies *(Drosophila spp.),* was shown to be important in certain responses to injury or infection. The human Toll-like receptors (TLRs) are stimulated by highly conserved bacterial components such as LPS.[26] The IL-1 receptor also is a TLR. TLRs cause APCs to upregulate the costimulatory B7 molecules.[23,24] Although T-cells may constantly interact with antigen, costimulation enables this interaction to progress to T-cell proliferation.

SPECIFIC IMMUNE RESPONSES

Chronic inflammation, if protracted, can result in an adaptation called the *specific immune response.* The specific immune response requires lymphocytes, which use two types of receptors to generate specific immune responses, the B-cell antigen receptor (BCR) and the Tcell antigen receptor (TCR). Four phases are involved in the generation of specific immunity: 1) clonal selection, the selection of lymphocytes that bear receptors (BCRs or TCRs) recognizing the specific antigen; 2) clonal expansion, the proliferation of those lymphocytes; 3) clonal contraction, the death of "effector" lymphocytes; and 4) memory, the maintenance of an expanded clone of cells that bears the specific receptors (BCRs or TCRs) recognizing the antigen (Fig. 7-8). As long as a sufficient number of lymphocytes are maintained to provide protection against a specific antigen, the individual is said to be immune.

TABLE 7-5

Selected TNF Superfamily Molecules Involved in Costimulation

Stimulating Cell (Antigen Presentor)	Costimulatory Factor	Stimulated Cell	Costimulatory Receptor on Stimulated Cell
APC	B7-2 (CD86)	CD4+ and CD8+ Tcells	CD28
APC	B7-2 (CD80)	Activated Tcells	CD28
Nonprofessional APC	B7-3	T-cells	CD28
Stimulated B-cells	CD70 (TNFSF7)	CD4+ T-cells	CD27

See text for explanation of abbreviations.

T-cells are selected when their TCR interacts with antigen presented by MHC Class I or II molecules. B-cell clonal selection requires only the multivalent binding of antigen by the BCR. A proliferation of the antigen-specific cells occurs after this clonal selection. This process is called *clonal expansion* and results in a 100- to 5000-fold increase in these cells.' In B-cell responses, some antigen-specific receptors are produced as soluble antibodies. The increase in antibody concentration and the strength of antibody binding is referred to as an increase in titer. Titer is operationally defined as the reciprocal dilution of antibody required to detect a standardized amount of antigen. Clonal contraction occurs by apoptosis at a rate equal to that of clonal expansion. More than 95% of antigen-specific Tcells are lost during the contraction phase,' usually occurring over several weeks. After clonal contraction, an increased population of memory Tcells or B-cells are maintained; this is the essence of the specific immune response.

The increase in antibody titer or antigen-specific Tcells resulting from the exposure of a host to an antigen for the first time is referred to as the primary response. The secondary response develops after a subsequent exposure to that same antigen. Because of the generation of memory (i.e., the expanded pool of cells recognizing antigen), the secondary response 1) is more rapid in onset, 2) is longer in duration, 3) is greater in strength due to higher titers, and 4) for B-cells, may have greater specificity against the antigen compared to the primary response. The expanded pool of memory cells provides a reservoir of cells that is sustained for years by constant stimulation of antigen maintained by follicular dendritic cells (nonhematopoetic cells found in the lymphoid tissues). The primary response takes slightly more than 1 week (8 to 14 days) to become measurable and biologically or clinically useful. Secondary responses are measurable within 1 to 3 days and are so effective that an individual may not be aware of the infection. Vaccination is the development of immunity, or resistance to infection, after a secondary response (the booster) that is adequate to consider the individual immune to a subsequent infection.

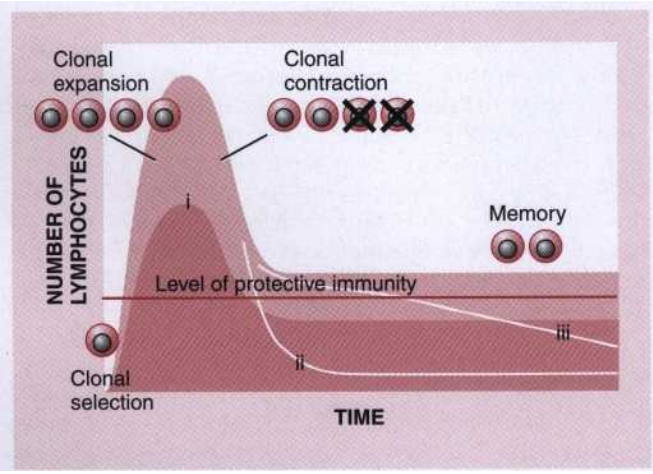

Fig. 7-8 Schematic illustration of the four phases of the specific immune response in relation to the occurrence of protective immunity. See the text for details of the four phases: clonal selection, clonal expansion, clonal contraction, and memory. Protective immunity i5 achieved if an adequate number of the lymphocytes are maintained in the memory phase, and the individual is said to be "immune". However, this does not always happen, a5 an individual may i) not undergo sufficient clonal expansion, ii) undergo excessive clonal contraction, or iii) be unable to maintain memory. (Adapted from Ahmed R, Gray D: Immunological memory and protective immunity: Understanding their relation. Science 1996; 272:54.)

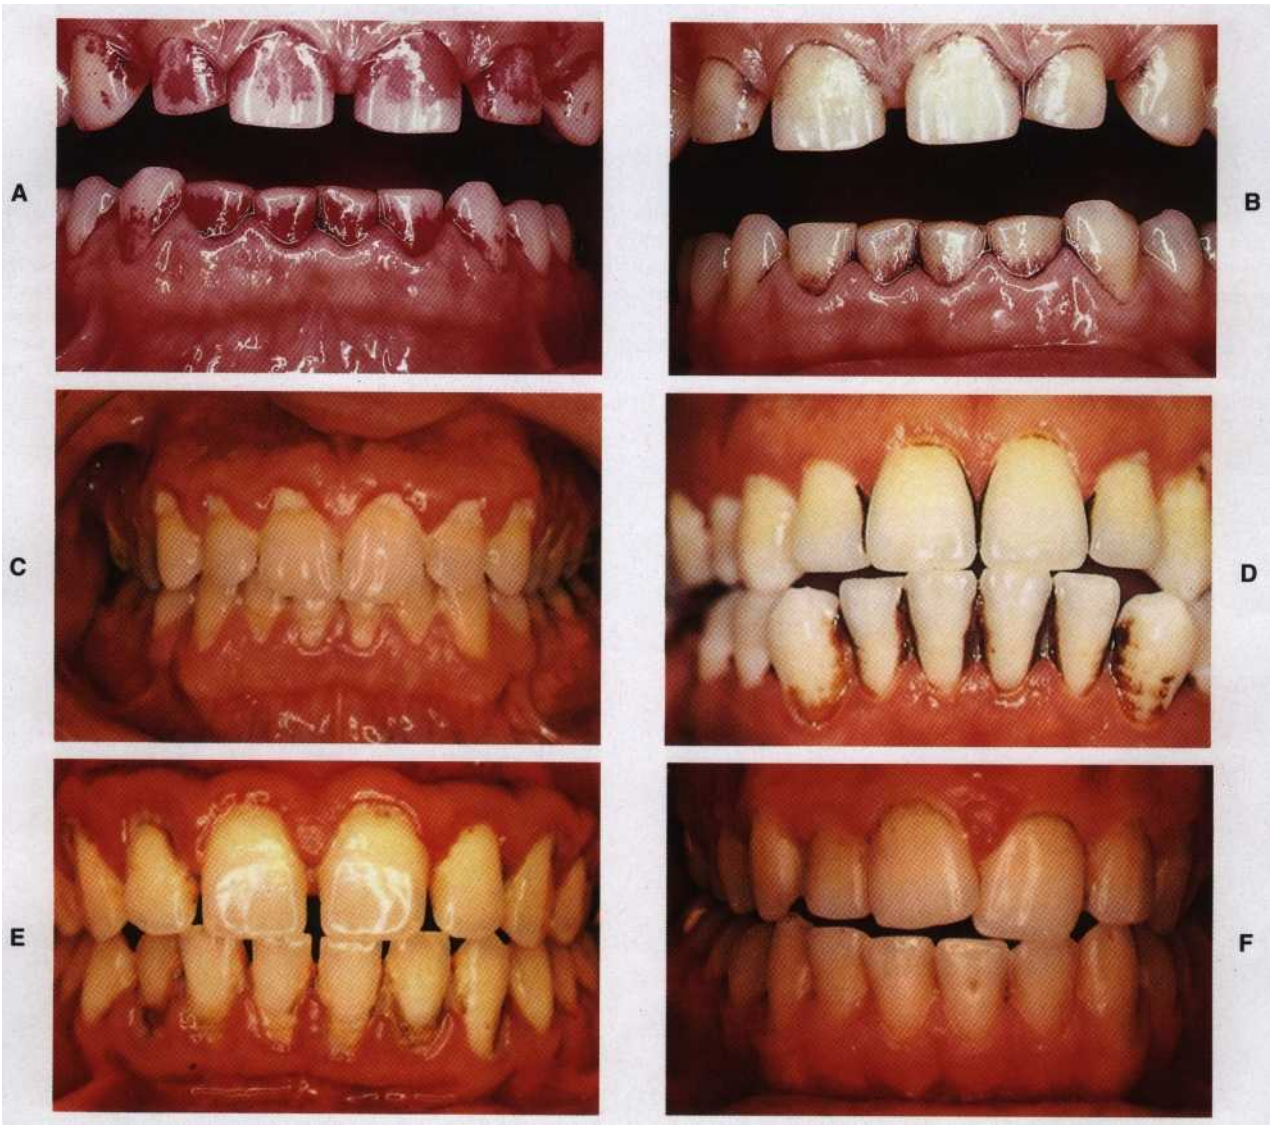
T-CELL RESPONSES

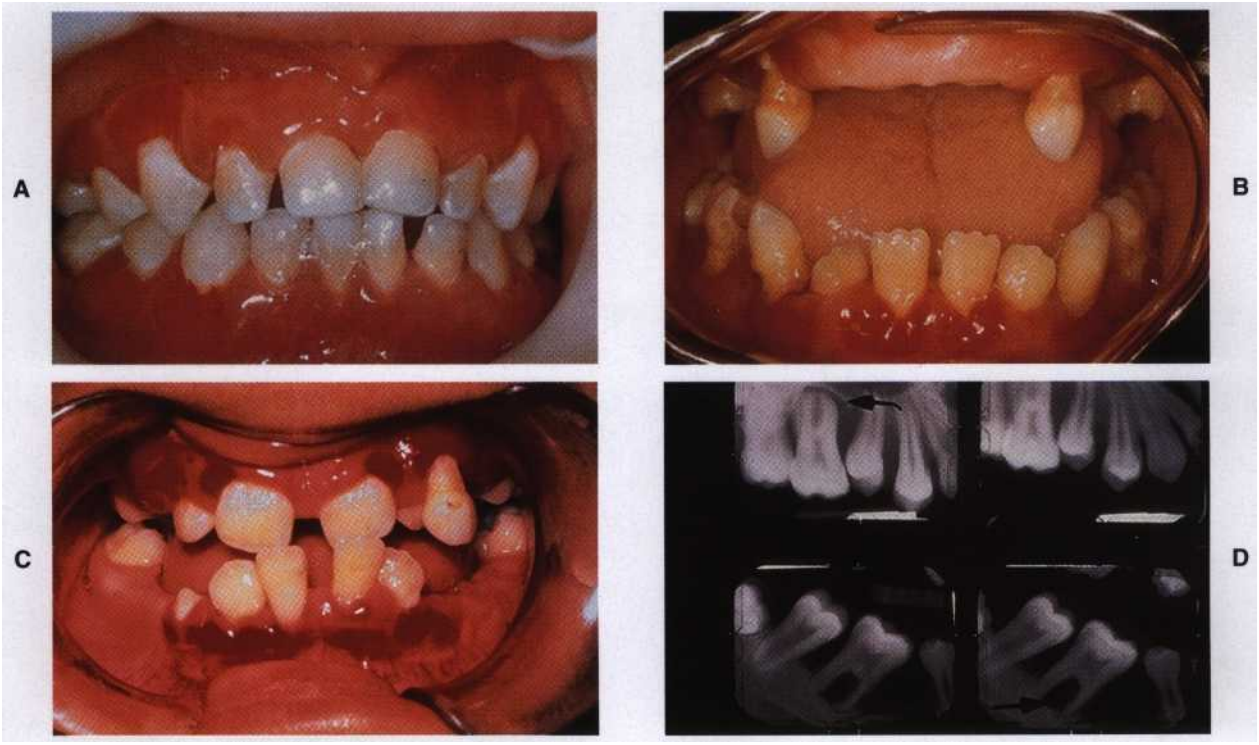
To obtain a specific immune response, the T -cell must interact with the antigen-presenting cell (APC). This is a complex process requiring that the T-cell recognize the antigen on the APC, receive costimulation, activate growth cytokine receptors, and produce cytokines, which signal and support growth and differentiation. Once activated, the T-cell undergoes proliferation and differentiation, leading to one of several possible mature T-cell phenotypes.

T-cell antigen recognition is a function of the Tcell antigen receptor, a low-affinity receptor of the immunoglobulin superfamily. T-cells may express 3000 to 50,000 TCRs on their surface. Antigens are presented to the TCR by MHC Class I or II molecules on the APC. CD1 is a related antigen-presenting molecule that presents specific antigens to NKTcells, a unique subpopulation of CD4- and CD8- T-cells. The TCR recognizes and binds the MHC-peptide complex.28 Antigen (Ag) is contacted by the TCR using variable domains found at the N-terminus of the TCR *a* and 6 subunits. TCR-peptide binding is more specific than that of the MHC-peptide, which is based on recognition of a smaller number of discontinuous amino acids. Thus the T-cell may recognize fewer antigens than those presented by the MHC.

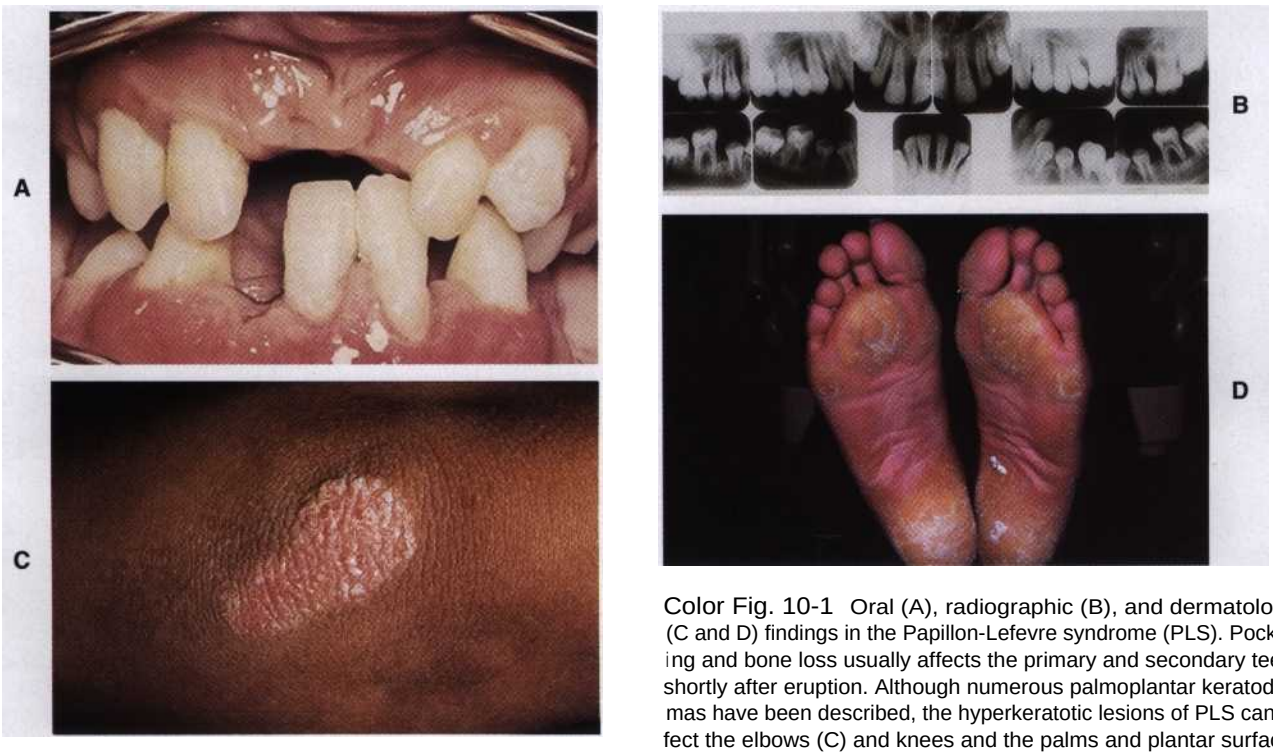


The TCR consists of a number of components in addition to those that bind antigen. These include components that form the CD3 transductory apparatus (TCR-CD3), which is important in the activation of the TCR and the eventual transmission or transduction of the signal into the cell. CD8 and CD4 are T-cell coreceptors whose recognition of MHC Class I and II molecules, respectively, on APC is essential for T-cell function and subsequent TCR activation. Activation of these coreceptors 1) increases the excitability of the TCR and 2) increases the binding between the T-cell and the antigen-presenting cell.

The low affinity of the TCR enables the T-cell to bind antigen presenting cells in a reversible manner, which occurs between multiple TCRs and one or a few antigens over time. This time-dependent interaction of many TCRs with a few antigens is referred to as scanning. Scanning that leads to T-cell activation is called serial triggering. To fully activate T-cells, multiple TCR engagement must be sustained for 2 to 20 hours.



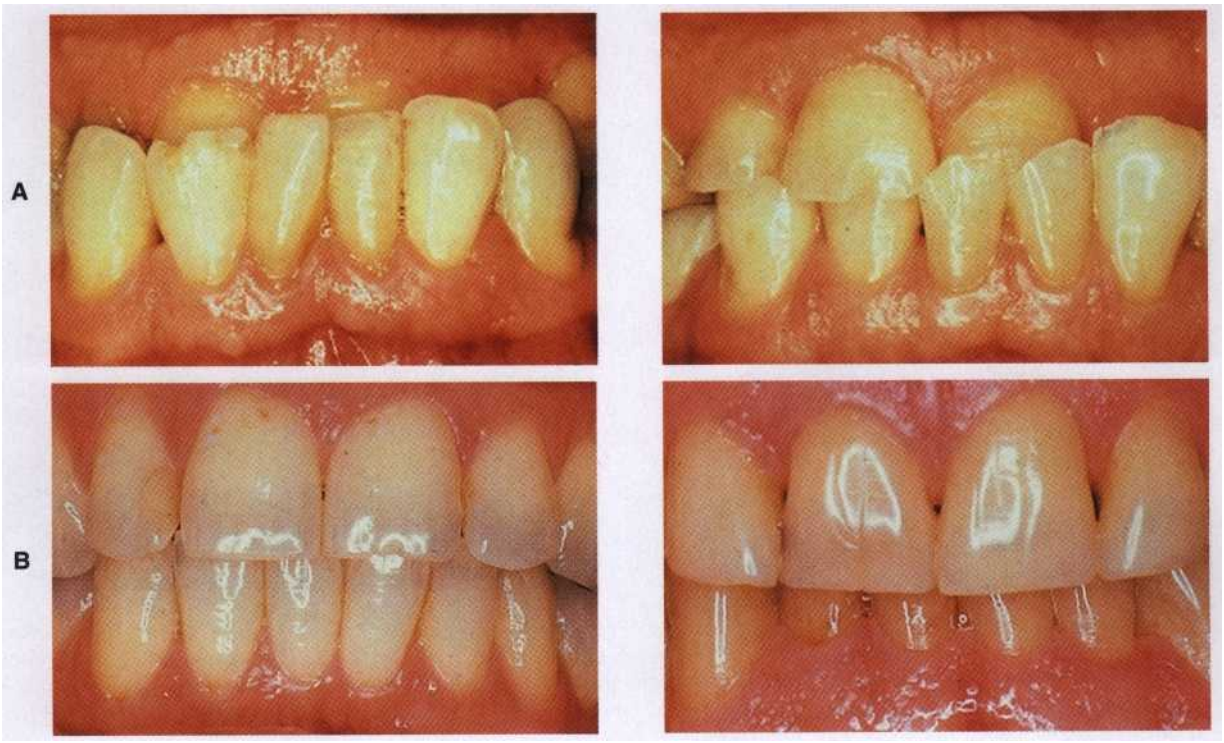
Activation of T-cells leads to proliferative differentiation. This process begins with activation of the protein tyrosine kinases lck, fyn and ZAP, which activate the TCR, phospholipase C (PLC), and CD28 respectively (Fig. 7-9). Activation of CD28 prepares the T-cell to receive the costimulatory signals, which are important in T-cell survival and function. Activation of phospholipase C



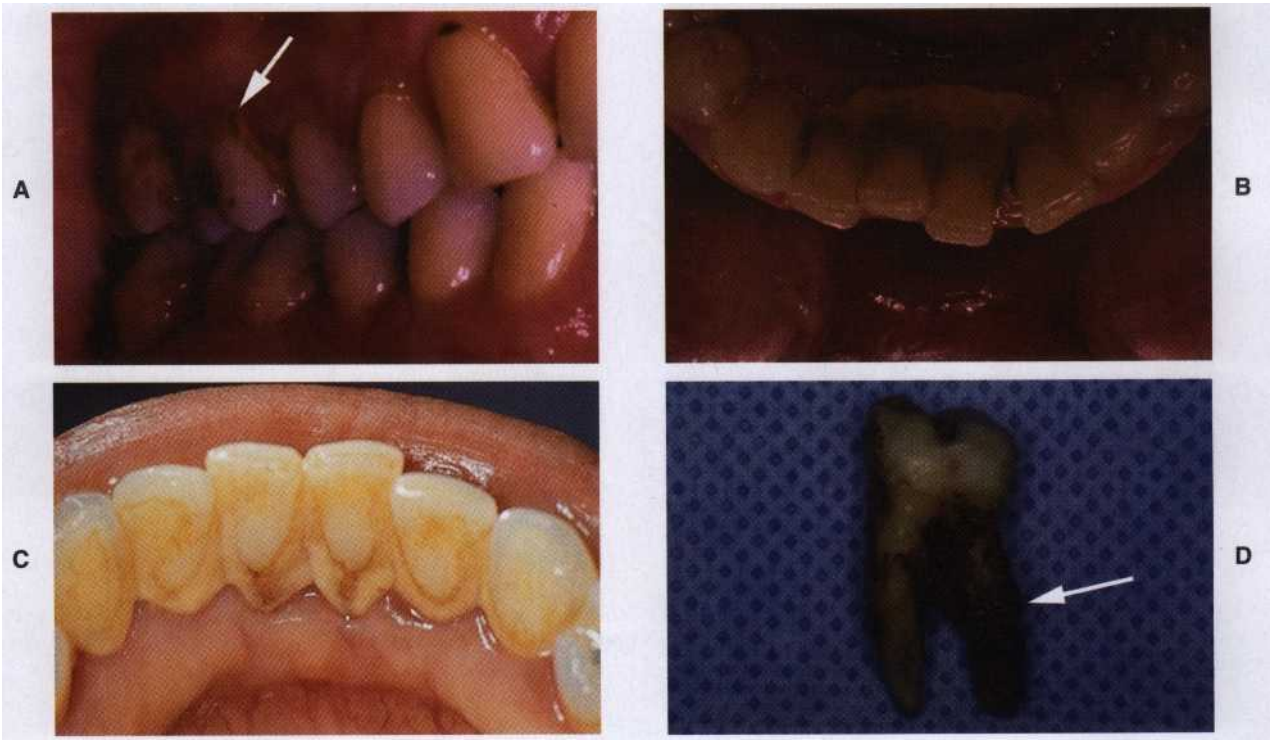
Color Fig. 1-1 Left, Clinically normal gingiva in a young adult. *Right,* **Heavily pigmented (melanotic) gingiva in a middle-aged adult.** (From Glickman I, Smulow JB: Periodontal Disease: Clinical, Radiographic, and Histopathologic Features. Philadelphia, Saunders, 1974.)

Color Fig. 6-1 A, Disclosed supragingival plaque covering one half to two thirds of the clinical crowns. B, Same patient as in A. Supragingival plaque disclosed with an oxidation-reduction dye that indicates reduced (anaerobic) areas of plaque. The supragingival anaerobic areas (purple stain) are located interproximally and along the gingival margin. C, *Materia alba* generalized throughout the mouth, with heaviest accumulation near the gingiva. Note the gingiva present. D, Teeth stained by several weeks of mouthrinses with alexidine. This stain can be easily removed. E, Supragingival calculus in a patient with gingival inflammation. F, Green stain on anterior teeth. Note the inflamed, enlarged interdental papilla between the maxillary central incisors. (A and B, courtesy Dr. S. Socransky, Boston, Mass.)

Color Fig. 8-1 Periodontal manifestations of disorders affecting neutrophil function. A and B, Clinical appearance of patients with cyclic neutropenia, a condition that involves reduction in the number of circulating neutrophils (blood neutrophil levels <1500/mm3). A, 5-year-old boy with cyclic neutropenia. Note the aggressive and extensive inflammation in the gingival tissues. B, A 7-year-old boy with cyclic neutropenia demonstrating acute and extensive gingival inflammation and advanced attachment loss with recession evident. C and D, Clinical and radiographic appearances of patients with leukocyte adhesion deficiency (LAD type 1). This **disorder involves defects in neutrophil transendothelial migration, resulting in a lack of extravascular neutrophils in periodontal lesions. However, dense infiltrates of mononuclear leukocytes are found in the periodontal lesions**.[171] Note the tissue inflammation evident clinically (C) and the extensive bone loss seen in these patients (D, arrows). For additional information, see text and Table 8-5. (Courtesy Dr. Max Listgarten [A and B] and Dr. D. C. Anderson [C and D]).



Color Fig. 10-1 Oral (A), radiographic (B), and dermatologic (C and D) findings in the Papillon-Lefevre syndrome (PLS). Pocketing and bone loss usually affects the primary and secondary teeth shortly after eruption. Although numerous palmoplantar keratodermas have been described, the hyperkeratotic lesions of PLS can affect the elbows (C) and knees and the palms and plantar surfaces of the feet (D). (Courtesy Dr. Robert J. Gorlin.)



Color Fig. 10-2 Oral (A) and radiographic (B) appearance of a patient with leukocyte adhesion deficiency (LAD). The child was deficient in CD18 (i.e., LAD type I), which results in absent or severely reduced levels of the 13-2 integrin molecule. The patient suffered from recurrent infections of the middle ear, tongue, and perirectal areas as well a5 the periodontium. (From Majorana A, Notarangelo LID, Savoldi E, et al: Leukocyte adhesion deficiency in a child with severe oral involvement. Oral Surg Oral Med Oral Pathol Oral Radiol Endod 1999; 87:691.)

Color Fig. 10-3 Reared-apart twin pairs. A, 37-year-old female identical twins. Note the similarity in tooth and arch forms in the twins. B, 40-year-old male fraternal twins. (From Pihlstrom B, Michalowicz B: Genetic risk for periodontal disease: A clinical perspective. Journal de Paradontologie d'Implantologie Orale 1998; 17:123.)

Color Fig. 10-4 Reared-together twin pairs. A, 70-year-old male identical twins. B, 67-year-old male fraternal twins. (From Pihlstrom B, Michalowicz B: Genetic risk for periodontal disease: A clinical perspective. journal de Paradontologie d'Implantologie Orale 1998; 17:123.)

Color Fig. 11-1 A, Supragingival calculus is depicted on the buccal surfaces of maxillary molars adjacent to orifice for Stenson's duct. B and C, Extensive supragingival calculus is present on the lingual surfaces of lower anterior teeth. D, Dark pigmented deposits of subgingival calculus are shown on the distal root of an extracted lower molar.

K, Easily bleeding, marginal erythema with a diffuse erythematous area between the upper left lateral incisor and canine. Marginal edematous changes are seen, as well as easily bleeding around lower anterior teeth. The patient is 7 months pregnant. (A and B, courtesy Dr. Joan Otomo-Corgel; C-F, courtesy Dr. T. N. Sims; K, courtesy Dr. Philip Melnick.)

results in the generation of diacylglycerol (DAG) and 1,4,5-inositol triphosphate (IP3). DAG signals the activation of a transcription activating cofactor, NF-ATn. IP3 stimulates the release of Call, which results in the activation of a calmodulin-calcineurin A/B phosphatase. This phosphatase dephosphorylates NF-ATc and enables it to enter the nucleus, where it combines with NF-ATn to form active NF-AT (nuclear factor of activated T-cells). NF-AT then upregulates transcription of genes, such as those for IL-2 and IL-Ma, which support T -cell growth and differentiation. The latent cytoplasmic transcription factor NF-K0 also is activated and is important in delaying apoptosis. One of the most important proliferative differentiation signals is the cytokine interleukin-2. The activated transcription factors are required for the T-cell to express one of the subunits of the heterotrimeric receptor for IL-2 and the IL-2Ra and also produce IL-2.9 Thus IL-2 produced by the activated T-cell interacts

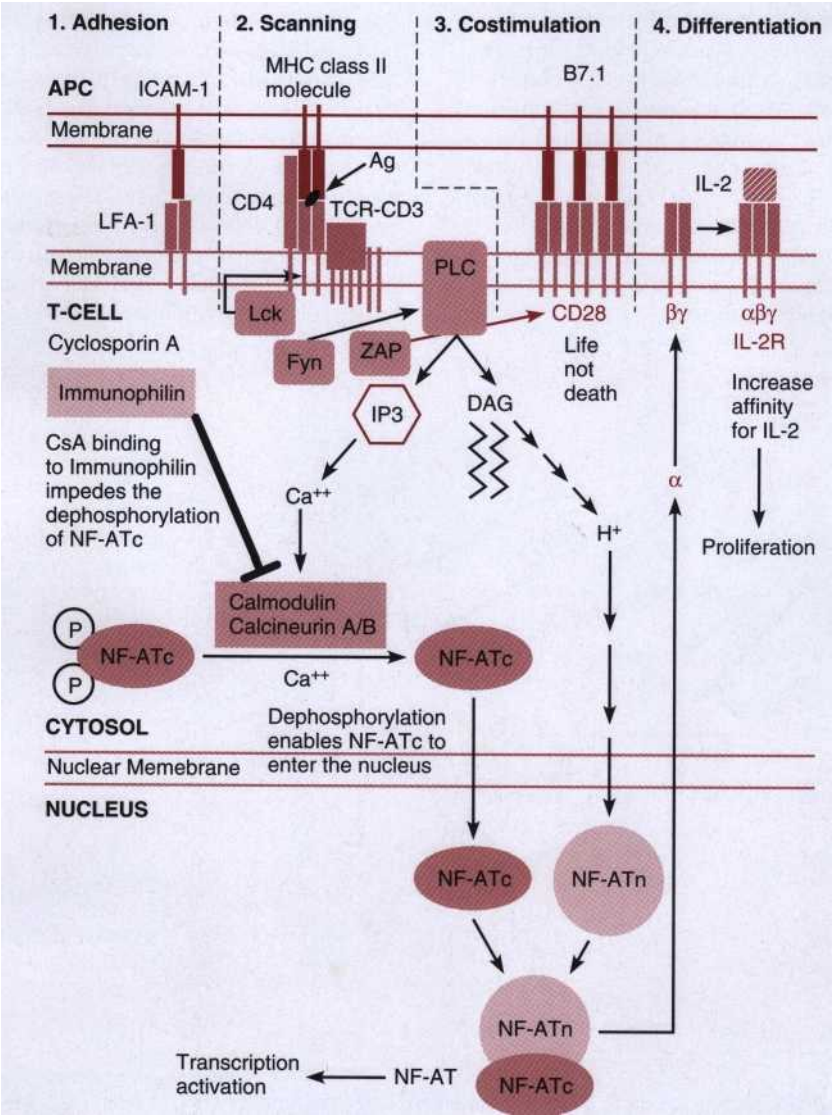

Fig. 7-9 Schematic illustration of receptor-mediated events leading to T-cell activation. 7, Adhesion between the T -cell and the antigen presenting cell (APC) i5 mediated by adhesins such as LFA-1 and ICAM-1. 2, Scanning of the APC by the T-cell coreceptors, CD4 or CD8, helps activate the TCR using the kinase Lck. Recognition of antigen by the TCR results in activation of phospholipase C (PLC) and CD28 by Fyn and ZAP, respectively. 3, Activated CD28 binds costimulatory factors such as B7-1. **The costimulatory factors are upregulated by environmental cues and reinforce the activation signal. 4, The scanning of antigen results in transcription of an important growth harmone receptor subunit, the IL-2 receptor a subunit. This increases the affinity of the IL-2 receptor. Later, the T-cell produces IL-2, which interacts with the IL-2 receptor to stimulate its own proliferation.**

with the IL-2R on the same cell to stimulate proliferative differentiation.

Clinically important immunosuppressants block the intracellular processes of T-cell activation. Immunophilins are regulatory factors that diminish the action of calcineurin. Immunosuppressants such as cyclosporin A and tacrolimus bind and activate immunophilins, resulting in their immunosuppressive effects.

CD4+ T-cells mature to form phenotypic subpopulations that are distinguishable on the basis of their cytokine productionz[5,z9] (Fig. 7-10). In addition to antigen and costimulation, professional APCs provide immature Th T-cells with the maturational signal interleukin la (IL-1/3), which induces T-cell maturation to a multifaceted Th0 T -cell phenotype. Th0 T-cells produce cytokines, which can stimulate both B-cells and CD8+ Tcells. Other cells in the area-especially macrophages, dendritic cells, other T-cells, and NK-cells-provide further differentiation signals. High or low concentrations of interleukin-12 (IL-12) or cytokines such as interferon-y (IFNy, IL-2, IL-4, IL-10, and TGF-(3) then can induce Tcells to mature to the Thl, Th2, or Th3 phenotypes. The Thl phenotype is important in controlling altered cells and intracellular molecules, the Th2 phenotype is important in proinflammatory responses against extracellular antigens, and the Th3 phenotype is important in antiinflammatory responses against extracellular antigens. These later T -cell maturational subpopulations are important in B-cell development.

B-CELL RESPONSES AND ANTIBODIES

B-cells produce immunoglobulin. An immunoglobulin that binds a known antigen is an antibody. Once antigen is bound, a number of consequences can occur, as dictated by the type (isotype) of immunoglobulin involved (Table 7-6). Immunoglobulin accounts for about 20% to 25% (15 mg/mL) of **the total serum** protein (60 to 70 mg/mL). Humans possess 9 genetically distinct isotypes of immunoglobulins: IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgAl, IgA2, and IgE. When B-cells exit the bone marrow, they possess receptors bearing only IgM and the cells are capable of producing soluble IgM. IgM functions in **the primitive agglutination reactions that facilitate antigen clearance.** Secondary imunoglobulin response classes permit a more discriminating response. To form secondary response isotypes, B-cells must enter a pathway of differentiation. In this memory pathway, B-cells undergo the process of isotype switching. One example of the significance of this process to periodontal diseases is that certain pathogens, such as *Actinobacillus actinomycetemcomitans,* can only be con-

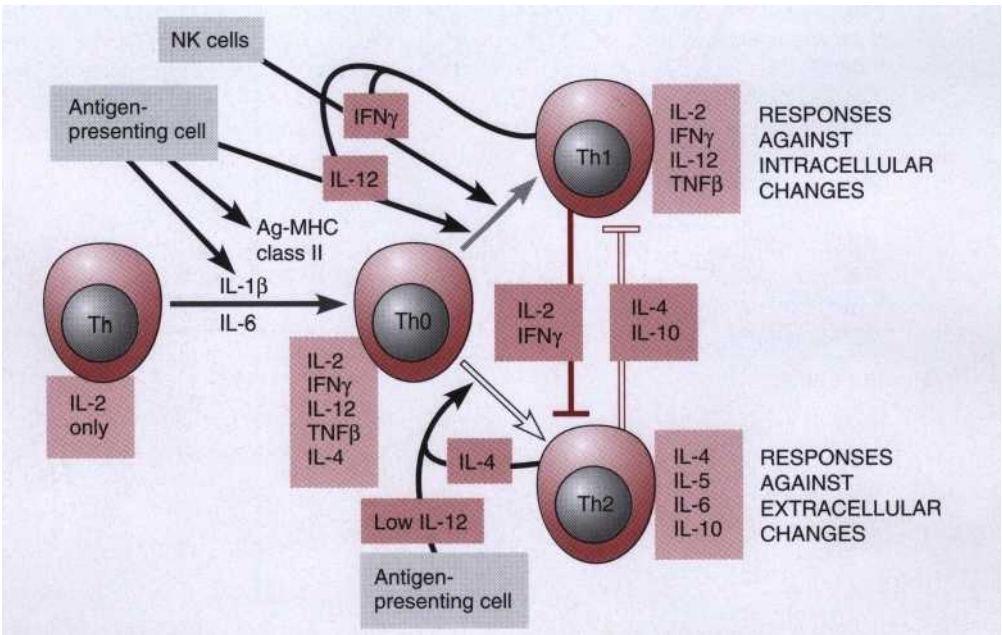

Fig. 7-10 Schematic illustration of T -cell differentiation. Early inflammatory signals from macrophages and peripheral dendritic cells such a5 IL-1(3 activate the CD4+ T-helper (Th) T-cell. The Th cell then produces many cytokines, including IL-2, INFy and IL-4, and is referred to as a *Th0 T-cell.* **The Th0 T-cell further differentiates to form Thl or Th2 T-cells, which regulate immune responses against intracellular and extracellular antigens, respectively. A key signal determining which pathway the T-cell follows i5 the level of IL-12 provided by the antigen presenting cell. High levels of IL-12 favor the Thl pathway, and low levels of IL-12 favor the Th2 pathway. Subsequently, the Thl phenotype is favored in the presence of Thl cytokines such as IFNy, which stimulates Thl differentiation and blocks Th2 differentiation. Similarly, the Th2 cytokines such as IL-4 block Thl differentiation while promoting Th2 differentiation. The Th3 T-cell, which produces IgA and functions in mucosal defense, is not illustrated here.**

trolled by neutrophils when opsonized by antibody of the IgG isotype. Complement, LPS-binding protein (LBP), and any other immunoglobulin isotypes are not effective.

The ability of B-cells to respond to antigen is dependent on the B-cell antigen receptor (BCR). The BCR is formed partly by immunoglobulin molecules on the B-cell surface, which serve as highly specific antigen receptors, and partly by transductory elements of the immunoglobulin superfamily. The BCR binds antigen with a high affinity and is designed for binding. This contrasts with the low-affinity binding of the TCR, which is ideal for scanning. B-cells are capable of responding to certain antigens in the absence of T -cells. This is referred to as *T-independent B-cell antibody response.* However, these B-cell responses do not mature (i.e., they do not enter the memory pathway). The cells maintain an IgM isotype, and their antibody products retain a relatively low affinity for antigen binding. B-cells must interact with T-cells to enter the memory pathway, thus the memory pathway is considered to be Tcell dependent.

B-cells bind soluble antigens using the BCR. If enough antigen is bound, they then are ingested and processed, and parts of the antigen are presented to specific CD4+ T-cells using MHC Class II molecules. After antigen presentation, the T-cells provide an activation signal to the B-cell. T-cell activators are transmembranous molecules, analogous to the costimulatory factors for T-cells discussed previously. Activators include T-cell-derived Gp39 and Gp34, which interact with the B-cell receptors, CD40 or OX40, respectively. Mutations in the gene for Gp39 lead to a condition called *X-linked hyperimmunoglubulinemia M syndrome,* characterized by a deficiency in most immunoglobulin isotypes and a compensatory increase in IgM.z T-cell Gp39 enables B-cell entry into the memory pathway, whereas the absence of Gp39 leads to terminal differentiation of the B-cells toward IgM, producing plasma cells.[3] B-cells upregulate B7-1 and B7-2 if activated by Gp39. These costimulatory factors enable the T-cells to differentiate, both with respect to proliferation and in the production of cytokines. Some T-cell cytokines are switch factors; these cytokines fall into three classes: TH1 (IL-2, IFNy), TH2 (IL-4, IL-10), or TH3 (TGFß). TH1 and TH2 switch signals generally promote switching to inflammatory immunoglobulins (IgG or IgE). The TH3 signal promotes a switch to an antiinflammatory isotype (IgA).[5] Unlike the activator, switch factors are usually soluble rather than membrane associated. Some effects of various combinations of activators and switch factors are shown in Fig. 7-11.

B-cells that differentiate to become plasma cells no longer express surface immunoglobulin and CD40; however, they do express secreted immunoglobulin. IgM is a primordial, all-purpose, primary response immunoglobulin. IgM is capable of complement activation but not direct opsonization (i.e., no Fc receptors exist for IgM). IgD is often coexpressed on B-cells with IgM, and it is believed to help increase B-cell responses to antigen. The memory B-cells give rise to the secondary response immunoglobulins. These B-cells produce immunoglobulin isotypes that can be divided into the IgE or IgG mediated inflammatory isotype responses, or the IgA mediated anti-inflammatory isotype responses. IgA is considered antiinflammatory because it does not stimulate complement activation, tends to antagonize IgE and IgG, and does not serve as a direct opsonin. Daily, humans produce about three times more IgA than all other immunoglobulin isotypes combined. IgA protects mucosal surfaces above and below the epithelium and is an important molecule in mucosal immunity.

TABLE 7-6

Selected Properties of Immunoglobulin Isotypes

Immunoglobulin Isotype	IgG1	IgG2	IgG3	IgG4	IgM	IgA1	IgA2	IgD	IgE
Concentration in serum (mg/ml)	9	3	1	0.5	1.5	3	0.5	0.03	0.00005
Molecular weight (kilodaltons)	146	146	170	146	970	160	160	184	188
Present on naïve B cells	–	–	–	–	+	–	–	+	–

Functions as opsonin without complement	+	–	+	+	–	–	–	–	–
With antigen stimulates mast cells	–	–	–	–	–	–	–	–	++++
With antigen stimulates eosinophils	–	–	–	–	–	–	–	–	++
Functions in mucosal immunity	–	–	–	–	–	+	+	–	–

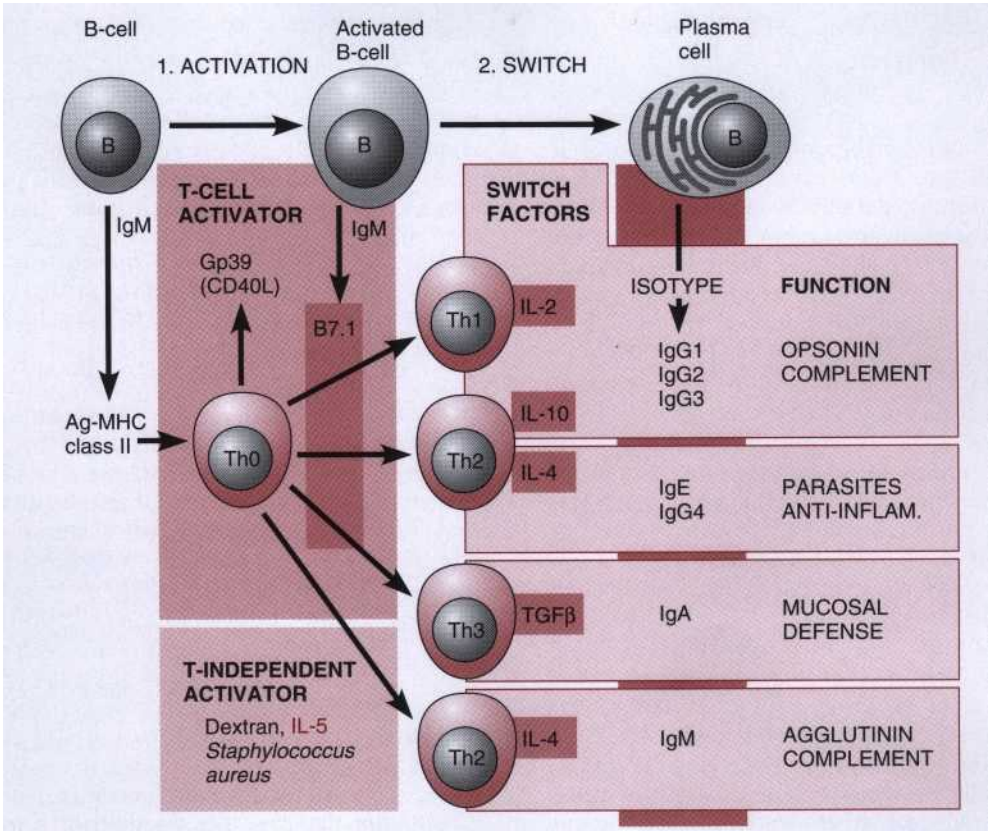

Fig. 7-11 Schematic illustration of B-cell differentiation. The essential signals in B-cell differentiation are activator and switch factors. 1, The activator signal often requires cell contact because T-cell activators (Gp37, Gp34) are transmembranous. T-cells express Gp39 after antigen has been scanned. In the absence of T -cell switch signals, T-independent activation can result in an IgM response. Once the B-cell is activated, it can provide costimulation to the T-cells, which allows them to respond to differentiation signals (see Fig. 7-10). 2, Switch signals also are derived from Tcells, and T-cells are required for isotype switching. Notice that IgGl-|gG3 can function in responses against both extracellular (Th2) and intracellular (Th2) pathogens. In contrast, Thl responses are not that important for generation of IgA and IgE, which function in mucosal defenses.

SUMMARY

This chapter focused on the role of the immune system in inflammation, which is the host response to injury or insult and a central feature of the majority of periodontal diseases. Innate immunity provides critical early phase defenses against invading microorganisms. Adaptive immunity, including the development of the specific immune response, provides mechanisms by which the host can become more efficient in protecting against specific pathogens. Chapter 8 will discuss the interaction of the immune system with microbial pathogens involved in periodontal diseases.

SUMMARY

ingivitis and periodontitis, as well as other less common periodontal diseases, are chronic infectious diseases. The interaction of the microorganism with the host determines the course and extent of the resulting disease. Microorganisms may exert pathogenic effects directly by causing tissue destruction itself or indirectly by stimulating and modulating the host response. The host response is mediated by the microbial interaction and inherent characteristics of the host, including genetic factors that vary among individuals. In general, the host response functions in a protective capacity, preventing the local infection from progressing to a systemic, life-threatening infection. However, local alteration and destruction of host tissues, which is evident as periodontal disease, may result. The varying balance between locally harmful and beneficial effects of the pathogenic microorganisms and the host accounts for the wide variety of patterns of tissue changes observed among patients.

MICROBIOLOGIC ASPECTS OF THE MICROBIAL-HOST INTERACTION

The specific microorganisms that have been found to be associated with differing states of health and disease are discussed in Chapter 6. In general, gram-negative facultative or anaerobic bacteria appear to represent the predominant microorganisms associated with disease. Predominant bacterial species that have been implicated in the disease processes include *Porphyromonas gingivalis, Actinobacillus actinomycetemcomitans, Treponema denticola, Bacteroides forsythus, Fusobacterium nucleatum, Prevotella intermedia, Campylobacter rectus, Peptostreptococcus micros,* and *Eikenella corrodens.* This chapter focuses on how the interaction of bacterial pathogens with host tissues results in disease. These issues relate to three of the criteria established by Socransky to identify periodontal pathogens (see Chapter 6). Studies of microbial interactions with the host involve analysis of the *host response* as well as the ability of a microorganism to cause disease

in an *animal model* system. The properties of a microorganism that enable it to cause disease are referred to as *virulence factors.*

Considerable research is currently focused on defining the virulence factors of periodontal pathogens. From a simplistic viewpoint, to function as a pathogen, a **bacterium must colonize the appropriate host tissue site and then cause destruction of the host tissues.** In periodontitis, the initial step in the disease process is the colonization of the periodontal tissues by pathogenic species. Entry of the bacterium itself (invasion) or of bacterial products into the periodontal tissues may be important in the disease process. Furthermore, inherent in successful colonization of host tissues is the ability of the bacterium to evade host defense mechanisms aimed at eliminating the bacterium from the periodontal environment. The process of tissue destruction results from the interaction of bacteria or bacterial substances with host cells, which directly or indirectly lead to degradation of the periodontal tissues. Thus virulence properties can be broadly categorized into two groups: factors that enable a bacterial species to colonize and invade host tissues, and factors that enable a bacterial species to directly or indirectly cause host tissue damage.

TABLE 8-1

Selected Bacterial Adhesins and Target Substrates

Probable Attachment Surface	Substrate	Bacterial Species	Bacterial Adhesin	Substrate Receptor
Tooth	Saliva-coated mineralized surfaces	A. viscosus	Fimbriae	Saliva-treated hydroxyapatite
		A. viscosus	Fimbriae	Praline-rich proteins
	Saliva-coated surfaces	*S. mitis*	70-, 90-kd protein	Sialic acid residues
		F. nucleaturn	300- to 330-kd outer membrane protein	Glactosyl residue
Tissue	Epithelial cells	*P. gingivalis*	Fimbriae	Galactosyl residues

Bacterial Colonization and Survival in the Periodontal Region

Bacterial Adherence in the Periodontal Environment. The gingival sulcus and periodontal pocket are bathed in gingival crevicular fluid, which flows outward from the base of the pocket. Bacterial species that colonize this region must attach to available surfaces to avoid displacement by the fluid flow. Therefore adherence represents a virulence factor for periodontal pathogens.

The surfaces available for attachment include the tooth or root, tissues, and preexisting plaque mass. Numerous interactions between periodontal bacteria and these surfaces have been characterized, and in some cases the molecules responsible for mediating these highly specific interactions have been determined (Table 8-1). Bacteria that initially colonize the periodontal environment most likely attach to the pellicle- or saliva-coated tooth surface. A relevant example is the adherence of *Actinomyces viscosus* through fimbriae on the bacterial surface to proline-rich proteins found on saliva-coated tooth surfaces.[114]

Bacterial attachment to preexisting plaque is studied by examining the adherence between different bacterial strains (coaggregation). One of the best-characterized interactions is the adherence of *A. viscosus* through surface fimbriae to a polysaccharide receptor on cells of *Streptococcus sanguis.*[112] These types of interactions are thought to be of primary importance in the colonization of the periodontal environment. In addition, the adherence of bacteria to host tissues is likely to play a role in colonization and may be a critical step in the process of bacterial invasion. Thus the ability of P. *gingivalis* to attach to other bacteria,[82-84] epithelial cells,[28] and the connective tissue components fibrinogen and fibronectin[93,94] are all likely to be important in the virulence of this microorganism.

Host Tissue Invasion. The presence of bacteria in host tissues in patients with necrotizing ulcerative gingivitis (NUG) has been recognized for years, based on histologic studies.[97] Investigations carried out largely in the 1980s demonstrated the presence of bacteria in periodontal tissues in gingivitis,[42] advanced chronic adult periodontitis,[45,143] and juvenile periodontitis.[19,22] Both gram-positive and gram-negative bacteria, including cocci, rods, filaments, and spirochetes, have been observed in gingival connective tissue and in proximity to alveolar bone. Bacteria may enter host tissues through ulcerations in the epithelium of the gingival sulcus or

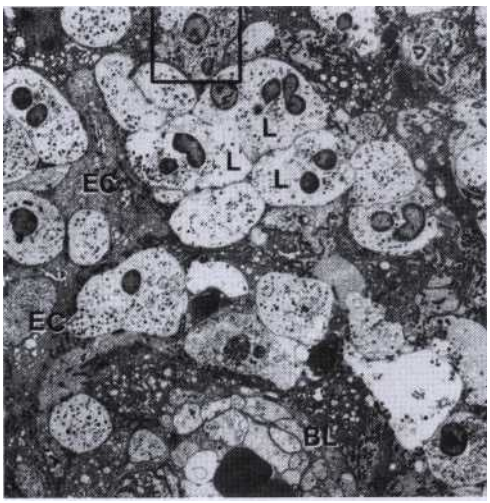

Fig. 8-2 Interface between pocket epithelium and connective tissue separated by the basement lamina (BL). Abundant bacteria can be seen in the intercellular spaces. Numerous infiltrating polymorphonuclear leukocytes (L) are seen between epithelial cells (EC). Some leukocytes show engulfed bacteria. (Magnification x3908.)

pocket and have been observed in intercellular spaces of the gingival tissues (Figs. 8-1 to 8-4). Another means of tissue invasion may involve the direct penetration of bacteria into host epithelial or connective tissue cells. Laboratory investigations have demonstrated the ability of *A. actinomycetemcomitans*,[156] *P gingivalis* (Fig. 8-5),[144] *P nucleatum*,[58] and *Treponema denticola*[173] to directly invade host tissue cells.

The clinical significance of bacterial invasion is not clear. Bacterial species that have been identified as capa-

ble of tissue invasion are strongly associated with disease, and the ability to invade has been proposed as a key factor distinguishing pathogenic from nonpathogenic gram-negative species or strains.102 Certainly, localization of bacteria to the tissues provides an ideal position from which the organism can effectively deliver toxic molecules and enzymes to the host tissue cells, and this may be the significance of invasion as a virulence factor. Indeed, some investigators have speculated that the "bursts of disease activity" observed in periodontitis may be related to phases of bacterial invasion of the tissues."' An additional possibility is that bacteria in the tissues may enable persistence of that species in the periodontal pocket by providing a reservoir for recolonization. Consistent with this hypothesis is the observation that mechanical debridement alone is insufficient, and that systemic antibiotics in combination with surgical therapy are required, to eliminate A. *actinomycetemcomitans* from lesions in patients with localized aggressive periodontitis (LJP).[21,86]

Bacterial Evasion of Host Defense Mechanisms. To survive in the periodontal environment, bacteria must neutralize or evade the host mechanisms involved in bacterial clearance and killing. Bacterial adherence and invasion are representative strategies by which microorganisms accomplish this task. The ability to adhere allows bacteria to avoid displacement by host secretions, and eukaryotic cell invasion disrupts the natural barriers formed by host tissue cells. Periodontal bacteria neutralize or evade host defenses via numerous other mechanisms; selected examples are presented in Table 8-2. For

TABLE 8-2

Selected Bacterial Properties Involved in Evasion of Host Defense Mechanisms

Host Defense Mechanism	Bacterial Species	Bacterial Property	Biologic Effect
Specific antibody	*P. gingivalis* *P intermedia* *P. melaninogenica* *Capnocytophaga sp.*	IgA and IgG degrading proteases	Degradation of specific antibody
Polymorphonuclear leukocytes	*A. actinomycetemcomitons*	Leukotoxin	Inhibition of PNM function
	F. nucleatum	Heat-sensitive surface protein	Apoptosis (programmed cell death) of PMN
	P. gingivalis	Capsule	Inhibition of phagocytosis
	P. gingivalis *T. denticola*	Inhibition of superoxide production	Decreased bacterial killing
Lymphocytes	*A. actinomycetemcomitans*	Leukotoxin	Killing of mature B and T cells; nonlethal suppression of activity
	A. actinomycetemcomitans	Cytolethal distending toxin	Impairment of function by arresting of lymphocyte cell cycle
	F. nucleatum	Heat-sensitive surface protein	Apoptosis of mononuclear cells
	e. *forsythus*	Cytotoxin	Apoptosis of lymphocytes
	P. intermedia *T. denticola* *A. actinomycetemcomitans*	Suppression	Decreased response to antigens and mitogens
Release o f IL-8	*P. gingivalis*	Inhibition of IL-8 production by epithelial cells	Impairment of PMN response to bacteria

example, immunoglobulins might function to facilitate phagocytosis of bacteria by opsonization or block adherence by binding to the bacterial cell surface and restricting access to bacterial adhesins. The production of immunoglobulin-degrading proteases by specific microorganisms may counteract these host defenses. Similarly, bacteria produce substances that suppress the activity of or kill polymorphonuclear leukocytes and lymphocytes normally involved in host defenses. An example of this is the production by A. *actinomycetemcomitans* of two toxins (a leukotoxin and cytolethal distending toxin) that may be important in the virulence of this microorganism in aggressive periodontitis and possibly in chronic periodontitis (see Chapter 9). Similarly, B. forsythus[2] and F. *nucleatum*[69] have been shown to induce apoptosis, a form of cellular "suicide," in lymphocytes. Many periodontal pathogens stimulate the production of interleukin-8 (IL-8), a proinflammatory chemokine that provides a signal for the recruitment of neutrophils (PMNs) to a local site (see discussion below). P. *gingivalis* is able to inhibit the production of IL-8 by epithelial cells, which may provide the microorganism with an advantage in evading PMN-mediated killing (see Chapter 9).

Microbial Mechanisms of Host Tissue Damage

Research on virulence factors has focused on the properties of bacteria related to the destruction of host tissues. These bacterial properties can be broadly categorized as those resulting directly in degradation of host tissues and those causing the release of biologic mediators from host tissue cells that lead to host tissue destruction.

Some bacterial products inhibit the growth or alter the metabolism of host tissue cells; these include a number of metabolic by-products such as ammonia; volatile sulfur compounds; and fatty acids, peptides, and indole.[149,170] An important class of molecules in tissue destruction is the variety of enzymes produced by periodontal microorganisms (Table 8-3). These enzymes appear to be capable of degrading essentially all host tissue and intercellular matrix molecules.[24,90] In particular, a wide range of proteolytic enzymes have been identified from P. *gingivalis* (see Chapter 9), including a trypsin-like enzyme and those that degrade collagen, fibronectin, and immunoglobulins. Bacterial enzymes may facilitate tissue destruction and invasion of bacteria into host tissues. However, the exact role of bacterially derived proteases in the disease process has not been determined because similar enzymes (e.g., collagenases) in the periodontal environment originate from host tissue cells. Indeed, one mechanism by which bacteria may indirectly cause tissue damage is by induction of host tissue proteinases such as elastase and matrix metalloproteinases (see discussion below).[29,30]

The host immune system involves a complex network of interactions among cells and regulatory molecules. Bacterial products may perturb the system, resulting in tissue destruction (Table 8-4). Well-characterized interactions involve the release of interleukin-1 (IL-1), tumor necrosis factor (TNF), and prostaglandins from monocytes, macrophages, and PMNs exposed to bacterial endotoxin (lipopolysaccharide).[137,180] These host-derived mediators have the potential to stimulate bone resorption and activate or inhibit other host immune cells. Many additional examples of this type of interaction exist, and the mechanisms underlying their manipulation of the host response is the focus of the next section.

IMMUNOLOGIC ASPECTS OF THE MICROBIAL INTERACTION WITH THE HOST

Periodontal disease is dependent on bacteria, as discussed previously, and bacteria may directly interact with the host tissues in mediating tissue destruction. In addition, many tissue changes associated with periodontal diseases appear to be well-orchestrated responses, suggesting the influence of host regulation. Among the orchestrated responses are the antimicrobial activities by acute inflammatory cells (neutrophils) and the adaptive activities brought about by monocytes/macrophages and lymphocytes. Adaptive responses include the epithelial alterations, angiogenesis, episodic remodeling of the underlying of hard and soft connective tissues, and antigen-specific immune responses. Remodeling of the connective tissues appears to be episodic and occurs in cycles of destruction and reconstruction. Excessive destruction or inadequate reconstruction can result in periodontal disease.

In this section, a paradigm for the role of the immune system in periodontal pathogenesis is presented. The paradigm is consistent with the specific plaque hypothesis, current concepts in immunology, and the classic clinical and histologic observations (see Chap-

TABLE 8-4

Examples of the Effects of Bacteria and their Products on Production of Biologically Active Molecules by Host Tissues

Effect on Cytokine Levels	Bacterial Species	Bacterial Component Involved	Target Host Tissue
Increased release of Interleukin-1	*A. actinomycetemcomitans*	Lipopolysaccharide (LPS)	PMNs
	F. nucleatum		
	A. actinomycetemcomitans	37 kDa protein	Macrophages
	P. gingivalis	LIPS	Monocytes
Increased release of Interleukin-6	*A. actinomycetemcomitans*	37 kDa protein	Macrophages
	A. actinomycetemcomitans	Whole cells	Gingival fibroblasts
	C. rectus		
	E. corrodens	Whole cells	Epithelial cells
Increased release of Interleukin-8	*A. actinomycetemcomitans*	Whole cells	Epithelial cells

Adapted from Socransky SS, Haffaiee AD: Microbial mechanisms in the pathogenesis of destructive periodontal diseases: A critical assessment. i Periodontal Res 1991; 26:195; and data compiled from referencesz6,31,47,58,65,66,137,161,180,181.

ters 15 and 21) regarding periodontal diseases. *The paradigm is that in response to bacterial infection, 1) innate factors such as complement, resident leukocytes, and especially mast cells play an important role in signaling endothelium, thus initiating inflammation; 2) acute inflammatory cells (i.e., neutrophils) protect local tissues by controlling the periodontal microbiota within the gingival crevice and junctional epithelium; and finally, 3) chronic inflammatory cells, macrophages, and lymphocytes protect the entire host from within the subjacent connective tissues and do all that is necessary to prevent a local infection from becoming systemic and life threatening, including the sacrifice o f local tissues.*

In this paradigm, periodontal disease represents a well-regulated response to protracted bacterial infection directed by the inflammatory cells of the host immune system (Fig. 8-6). Neutrophils function primarily as antimicrobial cells, and chronic inflammatory cells orchestrate adaptive responses. Neutrophils function to contain the microbial challenge through phagocytosis and killing and may contribute to local tissue changes by the release of tissue-degrading enzymes. The chronic inflammatory cells, the lymphocytes and monocytes, orchestrate connective tissue changes associated with both periodontal infection and periodontal repair and healing. They also function to assist the neutrophils in controlling bacterial infection by forming specific opsonic antibodies. The host response in the connective tissues may result in local destruction of the tissue, which is evident as periodontal disease. In recent years, the potential systemic impact of periodontal disease has been increasingly recognized (see Chapters 12 and 13). However, the end result of the periodontal host response is largely successful for the host in preventing progressive spread of the infection despite local tissue destruction.

Innate Factors and the Initiation of Inflammation

The onset of inflammation involves the development of edema and erythema, which are signs of vascular changes. Complement activation in response to bacterial infection results in generation of the complement-derived anaphylatoxins C3a and CSa. Anaphylatoxins are substances that stimulate vascular changes indirectly by causing degranulation of the resident leukocytes, the mast cells. Degranulated mast cells increase within the gingival connective tissue as gingival inflammation increases. Mast cells constitutively transcribe TNF-a, transforming growth factor ß (TGFß), interleukin 4 (IL-4), and interleukin 6 (IL-6); when stimulated, they induce transcription of proinflammatory cytokines such as IL-1, IL-6, IFNy, and others.115 The stimulation of endothelial cells by C5a, IL-1ß, TNF-a, and bacterial LPS results in the expression of selectins on the lumenal surface of the endothelial cells and release of

chemokines from the endothelial cells. These processes are central in transendothelial migration of leukocytes (see Fig. 7-4), which results in the movement of leukocytes into the local tissues.

In healthy individuals, complement levels in gingival crevicular fluid (GCF) are about 3% of that in serum. As periodontal inflammation increases, a concomitant increase in the levels of complement components occurs. The levels of C3 and C4, for example, can increase to 25% and 85% of that in serum.[111] The level of complement components in GCF are more than adequate to support the recruitment of acute and chronic inflammatory cells, opsonization and neutralization of pathogens or pathogenic substances, and local regulation of connective tissue changes.

Controlling the Bacterial Challenge: A Primary Role for Neutrophils

Neutrophils are believed to play an important role in controlling the periodontal microbiota. They are the first leukocytes to arrive at the site of inflammation and are always the dominant cell type within the junctional epithelium and the gingival crevice. (See Chapters 15 and 21.) For neutrophils to effectively control bacterial infections, their functions-including transendothelial migration, chemotaxis, transepithelial migration, opsonization, phagocytosis and intraphagolysosomal killing-must be intact. Disorders of neutrophils are associated with invasive periodontal infection and aggressive periodontitis (Table 8-5). For example, severe periodontal destruction involving both the primary dentition and

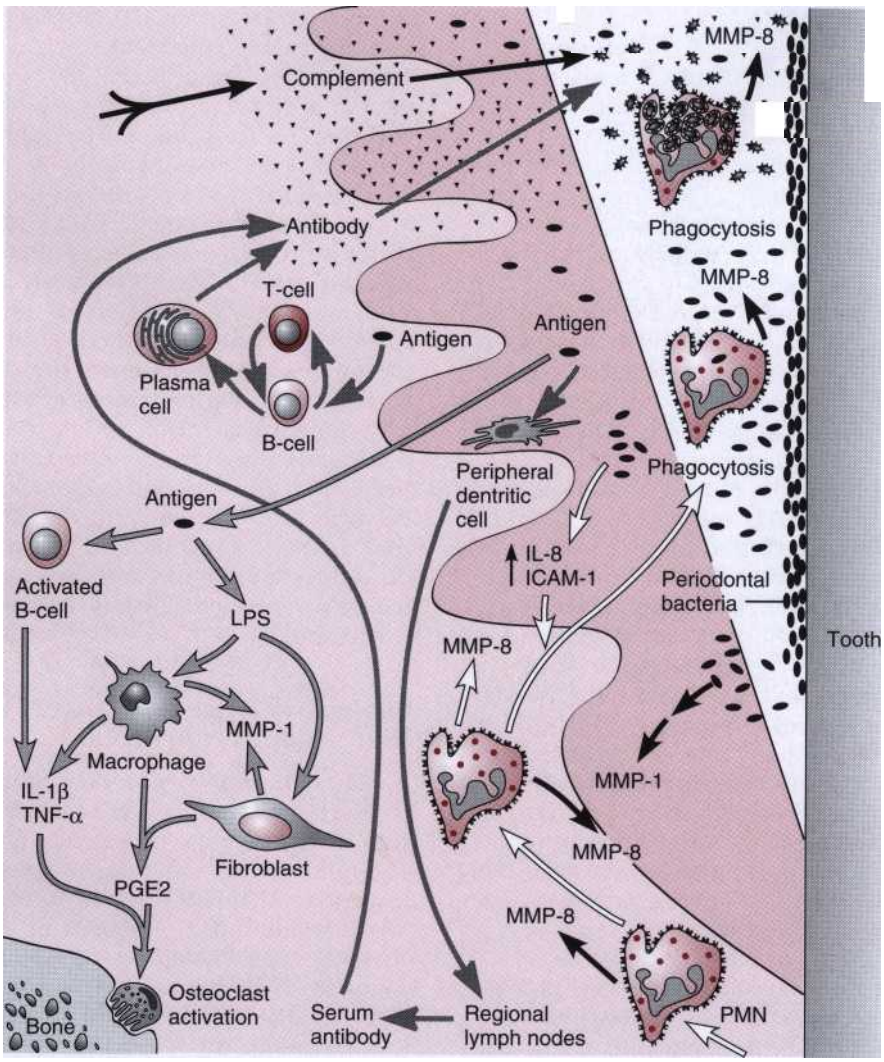

Fig. 8-6 **Schematic illustration of key processes of the host bacterial interaction in periodontal diseases. Interactions of the bacteria or bacterial antigen with host tissues leads to neutrophil recruitment** *(white arrows),* **antibody production (gray** *arrows),* **and bone resorption** *(black arrows).* **IL-8 and ICAM-1 production in the epithelial cells in response to periodontal bacteria provides a chemotactic signal for neutrophils (PMN). Neutrophils function to control the bacterial assault by phagocytosis but also secrete matrix metaIloproteinases (MMP-8), which may contribute to tissue destruction. The interaction of bacterial antigens with peripheral dendritic cells leads to the generation of systemic antibody, whereas interaction with local B-cells leads to production of local antibody. Antibody specific to many of the periodontal microorganisms is essential for phagocytosis. Complement components also may contribute to efficient bacterial phagocytosis. The production of IL-1ß, TNF-a, and PGe_2 in response to bacterial LPS leads to bone resorption through osteoclast activation, proliferation, and differentiation.**

permanent dentition is evident in individuals with disorders affecting neutrophil chemotaxis and phagocytosis (Color Fig. 8-1). Also, otherwise healthy individuals with severe periodontal problems may have subtle defects in neutrophil function (discussed further below).

About 1% to 2% of all neutrophils migrate across the junctional epithelium on a daily basis. This transepithelial migration requires a chemotaxn gradient (see Fig. 8-6). The junctional epithelium expresses the chemotactic cytokine (chemokine) IL-8 and intercellular cell adhesion molecule 1 (ICAM-1). A gradient of the membrane-bound ICAM-1 and the soluble IL-8 molecules is formed, with increased expression toward the outer surface of the tissue."' This distribution is ideal for the migration of neutrophils into the gingival sulcus. Neutrophils may use their adhesins LFA-1, Mac-1, or both to bind ICAM-1 on the epithelial cell in the process of epithelial transmigration.

In vitro studies have shown that P. gingivalis impedes transepithelial migration of neutrophils[107] and prevents epithelial cells from secreting IL-8 in response to bacterial challenge.[26,65] These properties may contribute to the virulence of P. gingivalis by interfering with the host immune response (see Chapter 9).

Opsonization refers to the coating of particles, such as bacteria, with host proteins that facilitate phagocytosis (see Fig. 8-6 and Fig. 8-7). For example, a bacterial cell may be coated with molecules derived from complement components (e.g., iC3b) for which the neutrophil has receptors (CR3). Similarly, bacterial cells may be coated with specific antibody that fixes complement and results in surface deposition of C3b that is recognized by the CR3 neutrophil receptor when converted to iC3b. Specific antibody of the IgG isotype also facilitates phagocytosis directly by binding with the neutrophil Fc receptor and appears to be essential for phagocytosis of certain periodontal pathogens (see below).

Patients with periodontitis often exhibit very high serum titers of IgG to specific periodontal pathogens. Although B-cells are directly responsible for antibody production, T-cells are required to regulate the isotype switch from IgM to IgG. Antigen-presenting cells (APCs) such as the peripheral dendritic cells (e.g., Langerhans cells, macrophages, and B-cells) are abundant within the gingival tissues[127] and can transport antigen to regional lymph nodes, thus promoting the production of serum IgG antibody. Local immunoglobulin production also has been documented within the gingiva, and the gingival tissues are impregnated with very high levels of immunoglobulins.

Scaling and root planing stimulates antibody production against microorganisms such as P. gingivalis and A. actinomycetemcomitans.[20,150] Variability in the levels, types, and strength of binding of the antibody is evident in different patients, and the significance of the antibody depends on its functional capabilities.[81] Antibody may function to facilitate host clearance of periodontal pathogens. For example, antibody appears to be essential for opsonization and phagocytosis of A. actinomycetemcomitans[10] and virulent strains of P. gingivalis.[25] Antibody also may function to neutralize bacterial components important in colonization or host cell interactions. A monoclonal antibody preparation specific for a hemagglutinin of P. gingivalis has been shown to prevent recolonization of deep periodontal pockets in vivo in periodontitis patients.[14,74] More information is needed to clarify the role of antibody to specific bacterial epitopes in disease progression and resolution. It is noteworthy that in LJP, the absence of a host antibody response has been postulated to contribute to disease progression (see discussion below).

Once the bacterial cell is bound to the neutrophil, ingestion (phagocytosis) results in entrapment of the bacterial cell into the membrane-delimited structure known as the phagosome. Bacteria within the phagosome and phagolysosome may be killed by oxidative or nonoxidative mechanisms. The gingival sulcus is characterized by a diminished level of oxygen, and the reduction-oxidation potential of the periodontal pocket is more reduced than the gingival sulcus. This is indicated by measurements of crevicular oxygen levels and reduction-oxidation potential[75] and reflected by the growth of strictly anaerobic bacteria such as P. gingivalis and the oral spirochetes. The oxidative killing mechanisms of crevicular neutrophils may be intact in a healthy sulcus but impaired in the periodontal pocket. A shutdown of oxidative killing may be an important factor in the progression to periodontitis. Nonoxidative mechanisms of killing involve phagosome-lysosome fusion, resulting in secretion of bactericidal substances such as lysozyme, cathepsin G, and a-defensins into the phagolysosome containing the ingested bacterium. Some periodontal pathogens evade phagocytic cells as a virulence mechanism. For example, the leukotoxin of A. actinomycetemcomitans kills phagocytes by binding to the LFA-1 adhesin and subsequently lysing the eukaryotic cell.[92] Recently it was demonstrated in vitro that specific antibodies to A. actinomycetemcomitans or antileukotoxin serum protects neutrophils from leukotoxin-mediated injury and enables phagocytosis to proceed.[70]

Connective Tissue Alterations: Tissue Destruction in Periodontitis

A central feature of periodontitis is the remodeling of connective tissues that leads to a net loss of local soft tissues, bone, and the periodontal attachment apparatus. The fundamental event in the transition from gingivitis to periodontitis is the loss of the soft tissue attachment to the tooth and the subsequent loss of alveolar bone. Bacterial components that contribute directly or indirectly to tissue destruction have been discussed previously. Mediators produced as a part of the host response that contribute to tissue destruction include proteinases, cytokines, and prostaglandins.

Proteinases. Matrix metalloproteinases (MMPs) are considered to be primary proteinases involved in periodontal tissue destruction by degradation of extracellular matrix molecules. MMPs are a family of proteolytic enzymes that degrade extracellular matrix molecules, such as collagen, gelatin, and elastin. MMP-8 and MMP-1 are both collagenases; MMP-8 is released by infiltrating neu-

TABLE 8-5

Systemic Neutrophil Abnormalities Associated with Aggressive Periodontitis

Condition	Neutrophil Abnormality	Periodontal Manifestations
Neutropenia, agranulocytosis	Decreased number of neutrophils	Severe aggressive periodontitis
Chediak-Higashi syndrome	Decreased neutrophil chemotaxis and secretion. Neutrophil granules fuse to form characteristic giant granules called *megabodies.*	Aggressive periodontitis and oral ulceration. The syndrome is caused by a mutation in the vesicle trafficking regulator gene, LYST.
Papillon-LeFevre syndrome	Multiple functional neutrophil defects,. including myeloperoxidase deficiency as well as defective chemotaxis and phagocytosis	Severe aggressive periodontal destruction at an early age, which may involve the primary and permanent dentition. Recently associated in affected individuals with a mutation in the cathepsin C gene (see Chapter 10).
Leukocyte adhesion deficiency Type I	Defects in leukocyte function due to lack of integrin ß2 subunit (CD18). Neutrophil defects include impaired migration and phagocytosis. Histologically, almost no extravascular neutrophils are evident in periodontal lesions.	Aggressive periodontitis, at an early age and affecting primary and permanent dentition, in individuals who are homozygous for the defective gene.
Leukocyte adhesion deficiency Type II	Neutrophils fail to express the ligand (CD15) for P- and E-selectins, resulting in impaired transendothelial migration in response to inflammation	Aggressive periodontitis at a young age

Data compiled from references' [1,27,49,59,60,120,135,148,171]

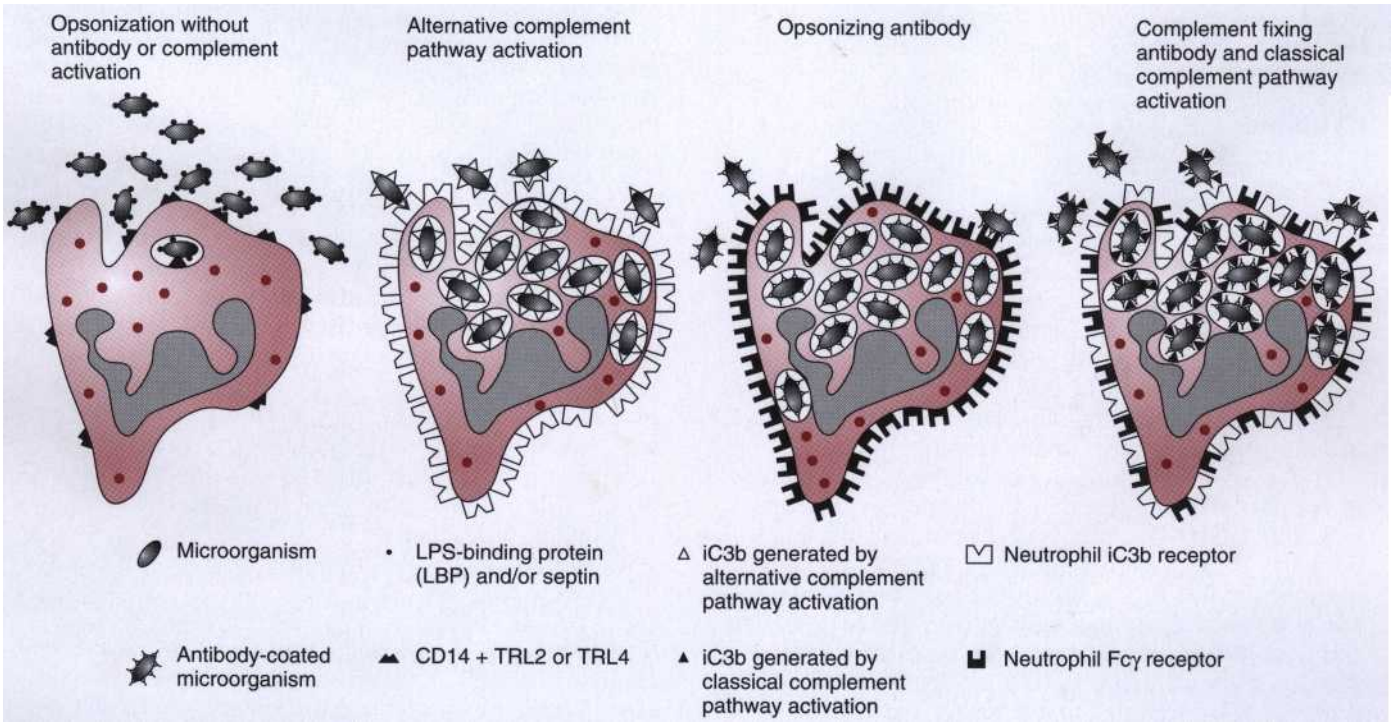

Fig. 8-7 Schematic illustration of some routes of opsonization and phagocytosis. Bacterial control in the periodontal environment is achieved largely by opsonization, phagocytosis, and killing of the bacteria by neutrophils. *Opsonization* refers to the coating of the bacterial cell with host-derived proteins such as LPS-binding protein (LBP), specific antibody, or the complement component iC3b. Opsonization with specific antibody of the IgG subclass is required for phagocytosis of certain bacteria, such as *Actinobacillus actinomycetemcomitans.* See text for further details.

trophils whereas MMP-1 is expressed by resident cells including fibroblasts, monocytes/macrophages, and epithelial cells (see Fig. 8-6). Collagenase is elevated in tissues and GCF associated with periodontitis, as compared with gingivitis or healthy controls.[68-138]

MMPs are secreted in an inactive (latent) form. Enzyme activity in the tissues is partly controlled by activation of the latent enzyme and the level of enzyme inhibitors present. One mechanism of MMP activation involves the proteolytic cleavage of a portion of the latent enzyme. Proteases capable of activation MMPs include bacterial enzymes such as the chymotrypsin-like protease produced by T. *denticola,* as well as host cell enzymes such as neutrophil cathepsin G. MMPs are inactivated by a-macroglobulins that are found in serum and gingival crevicular fluid, and tissue inhibitors of MMPs (TIMPs) that are produced by many cell types and are common in host tissues and fluids.[13]

Other proteinases associated with periodontitis include the neutrophil serine proteinases, elastase and cathepsin G. Elastase is capable of degrading a wide range of molecules including elastin, collagen, and fibronectin. Cathepsin G is a bactericidal proteinase that also may function in the activation of MMP-8. Endogenous inhibitors of elastase and cathepsin G (e.g., alproteinase inhibitor, al-antichymotrypsin, and a2 macroglobulin) are found in plasma and GCF.[67] The role of these enzymes in pathogenesis is likely to depend on the balance of enzyme and enzyme inhibitor in the local tissue. Cathepsin G is elevated in the gingival tissues and GCF in adult periodontitis.[163] Elevated levels of elastase in GCF are associated with active periodontal attachment loss,[3] and elastase may provide a convenient clinical marker of disease progression.

Cytokines. Two proinflammatory cytokines, IL-1 and tumor necrosis factor (TNF), appear to have a central role in periodontal tissue destruction (see Fig. 8-6).[53,132] IL-1 is found in two active forms, IL-la and IL-1ß encoded by separate genes. Both are potent proinflammatory molecules and are the main constituents of what was once called "osteoclast activating factor." The IL-1 family also includes the IL-1 receptor antagonist (IL-lra), which will bind the IL-1 receptor without stimulation of the host cell. TNF also is found in two forms, TNF-a and TNF-/3. TNF-a shares many of the same biologic activities as IL-1, including the stimulation of bone resorption.

IL-1 is produced primarily by activated macrophages or lymphocytes but also may be released by other cells, including mast cells, fibroblasts, keratinocytes, and endothelial cells. Bacterial LPS is a potent activator of macrophage IL-1 production, whereas TNF-a and IL-1 itself also can activate macrophage IL-1 production. The ability of IL-1 to upregulate its own production may provide a significant amplification mechanism. TNF-a also is produced by activated macrophages, particularly in response to bacterial LPS. TNF-ß is primarily produced by the Thl subset of CD4+ T-cells that have been activated by antigen or mitogen. The proinflammatory effects of IL-1 and TNF-a include stimulation of endothelial cells to express selectins that facilitate recruitment of leukocytes, activation of macrophage IL-1 production, and induction of prostaglandin E2 (PGE2) by macrophages and gingival fibroblasts.[132]

The properties of these cytokines that relate to tissue destruction involve stimulation of bone resorption and induction of tissue-degrading proteinases. IL-1 is a potent stimulant of osteoclast proliferation, differentiation, and activation. TNF-a has similar effects on osteoclasts but is far less potent than IL-1. Both IL-1 and TNF-a induce production of proteinases in mesenchymal cells, including MMPs, which may contribute to connective tissue destruction.[53,132]

Substantial data from *in vivo* studies support the concept that IL-1 and TNF-a are key molecules in the pathogenesis of periodontitis. IL-1 and TNF-a are found in significant concentrations in GCF from periodontally diseased sites, and reductions in IL-1 concentration are associated with successful treatment.[10,157] Increasing severity of periodontitis is associated with increased concentrations of IL-1 and decreasing concentrations of IL-1ra.[136] In a primate model of experimental periodontitis, application of antagonists to IL-1 and TNF resulted in an 80% reduction in recruitment of inflammatory cells in proximity to the alveolar bone and a 60% reduction in bone loss.[1]

Prostaglandins. Prostaglandins are arachidonic acid metabolites generated by cyclooxygenases (COX-1, COX-2). Arachidonic acid is a 20-carbon polyunsaturated fatty acid found in the plasma membrane of most cells. COX-2 is upregulated by IL-1/3, TNF-a, and bacterial LPS and appears to be responsible for generating the prostaglandin PGE2 that is associated with inflammation. The primary cells responsible for PGE2 production in the periodontium are macrophages and fibroblasts. PGE2 is increased in periodontal sites demonstrating inflammation and attachment loss.[88-129] Induction of MMPs and osteoclastic bone resorption is induced by PGE2 (see Fig. 8-6).

PGE2 appears to be partly responsible for the bone loss associated with periodontitis. Studies in vitro demonstrated that bone loss associated with several periodontal pathogens was inhibited in part by inhibitors of prostaglandin synthesis.[1] In addition, use of a nonsteroidal antiinflammatory agent as an inhibitor of prostaglandin synthesis in human subjects with advanced periodontitis resulted in significantly less bone loss as compared to placebo.[1] PGE2 release from monocytes from patients with severe or aggressive periodontitis is greater than that from patients with little to no periodontal destruction.[48,129] It has been postulated that high-risk periodontal patients have a "monocyte hypersecretory trait" that results in an exaggerated response both locally and systemically to bacterial LPS.[129]

Summary. The production of these proteinases and mediators as well as their inhibitors by host tissue cells are influenced by bacteria and regulatory molecules produced by host cells that are resident within, or recruited to, the periodontal tissues. In normal tissue turnover, a balance exists such that no net loss of tissue occurs. In disease, tissue loss occurs, suggesting that this balance is disrupted. In addition, although bacterial proteinases do not appear predominant in this environment, their ef-

fects locally within the periodontal econiche may be significant. Loss of bone in periodontal diseases appears to occur in part through the action of regulatory molecules, including IL-1, TNF-a, and PGE_2.

Connective Tissue Alterations: Healing Processes in Periodontitis

The chronic immune system plays an important role in healing processes, which consist of regeneration and repair. Regeneration involves the replacement of tissues with new, identical tissues that function like the original tissues. Periodontal tissues are limited in their regenerative capacity, and considerable research is being devoted to developing techniques and materials to augment host processes that facilitate regeneration (see Chapters 63 and 71).

Repair involves replacement of one tissue with another tissue, such as fibrous connective tissue, which may not function like the tissue replaced. After traumatic or surgical injury, healing is initiated as part of the immediate and acute inflammatory responses. A clot that usually provides hemostasis almost immediately after injury also forms a matrix rich in platelet-derived cytokines that stimulates and facilitates healing. In contrast, periodontal infections do not normally produce the massive, platelet-rich clot observed in traumatic injury. Thus the periodontal "healing" cycle during the pathogenesis of periodontal disease is primarily postinflammatory; and cellular elements other than platelets provide important signals in this process. Periodontal repair occurs in overlapping phases of inflammation shutdown, angiogenesis and fibrogenesis.

In the postinflammatory healing process, the shutdown of inflammatory processes and initiation of postinflammatory healing is orchestrated by leukocytes. Some of the important antiinflammatory signals generated by leukocytes include IL-1 receptor antagonist (IL-Ira) and transforming growth factor /3 (TGF-ß),[50] In inflamed periodontal tissues, macrophages are a source of IL-1ra,[71] whereas neutrophils, macrophages, and mast cells and lymphocytes produce TGF-ß.[158]

Angiogenesis and fibrogenesis, as well as cytokines such as IL-1ß and TNF-ß that help to induce these processes, participate in both inflammation and healing. IL-1ß and IL-la are indirectly involved in inducing fibroblast proliferation and collagen synthesis by stimulating the production of PGE_2 or the release of "secondary" cytokines such as platelet-derived growth factor (PDGF) and TGF-/3. PDGF is a protein complex formed by different combinations of a and ß chains, resulting in three isoforms, PDGF-AA, PDGF-AB and PDGF-BB. It is produced by numerous cells and tissues, including endothelium, vascular smooth muscle, and macrophages. PDGF activates fibroblasts and osteoblasts, resulting in the induction of protein synthesis." The PDGFs are related structurally and functionally to vascular endothelial growth factor (VEGF), an important factor in endothelial proliferation. VEGF is a glycoprotein produced by many cells, including monocytes/macrophages, and it is induced by antiinflammatory factors such as TGF-/3.

TGF-ß is a multifunctional peptide that stimulates osteoblasts and fibroblasts and inhibits osteoclasts, epithelial cells, and most immune cells. Receptors for TGF-ß are found in almost all cells. TGF-ß is produced as a propeptide, and activation requires acidic conditions. TGF-ß is known for its ability to promote the elaboration of fibroblast extracellular matrix adhesion.

Other fibrogenic cytokines that may play a role include basic fibroblast growth factor (bFGF), TGF-a, and TNF-a. TGF-a and TNF-a are produced mainly by cells of the monocyte lineage, and within the periodontium, bFGF is produced primarily by PDL cells and endothelium.[46]

In the healing of alveolar bone, regeneration of bone within a defect clearly can occur. The immune system can induce regenerative bone healing by preventing osteoclast formation and activation and by activating osteoblasts. By blocking osteoclast formation or increasing osteoclast death, it is possible to cause a marked decrease in osteoclastic activity. TGF-/3 is a potent inhibitor of osteoclast formation. Bone matrix itself contains TGF-/3, which is released by osteoclastic resorption,[119] and osteoclasts may provide the acidic conditions necessary for TGF-ß activation. Osteoclast differentiation and activation are inhibited by interferon-y (IFN-y), which is secreted by NK-cells, Thl T-cells, and macrophages. The main effect of IFN-y appears to be inhibition of IL-1 and TNF-a-induced osteoclast activation. IL-1ra also is effective in blocking IL-1 and TNF-a-induced osteoclast activation.

Much research in bone healing has focused on activation of osteoblasts and PDL cells as a means of promoting regenerative healing. Two substances, insulinlike growth factor I (IGF-I) and PDGF, have been shown to induce or augment regenerative repair.",[104,133] The insulinlike growth factors induce osteoblast growth, differentiation, and synthesis of collagen. Several studies in nonhuman primates indicate that the combination of IGF-1 and PDGF effectively and significantly enhances regeneration of periodontal structures, including new bone and cementum.[51,140]

MICROBIOLOGY AND IMMUNOLOGY IN GINGIVAL HEALTH

The gingival crevice harbors bacteria in both health and disease. In a clinically healthy periodontium, the microbial flora is largely composed of gram-positive facultative microorganisms, predominately species such as Actinomyces and Streptococcus spp. Gram-negative species and spirochetal forms also may be found, but they are considerably less prevalent and occur in much smaller numbers. Serum antibodies to microorganisms are usually in low titers, suggesting the minimal systemic antigenic stimulation by plaque during gingival health. The gingival tissues typically demonstrate some evidence of inflammation. Tissues are usually infiltrated with chronic inflammatory cells, generally lymphocytes. Neutrophils also are common within the junctional epithelium and in the gingival crevice. The infiltration of inflammatory cells is thought to be a response to bacterial plaque, and host defense mechanisms in a healthy individual are effective in managing the bacterial challenge. Physical

mechanisms of host defense include the integrity of the epithelial cell layer, as well as the shedding of epithelial cells and the flow of crevicular fluid that may function to clear bacteria and their products from the subgingival environment. It is likely that the complement, neutrophils, and antibody production contribute to controlling the sulcular microbiota.

MICROBIOLOGY AND IMMUNOLOGY IN PERIODONTAL DISEASES

Gingivitis

The most common form of gingivitis is plaque-induced gingivitis.[108] Common clinical findings in gingivitis include erythema, edema, tissue enlargement, and bleeding. Two forms of plaque-induced gingivitis have been investigated: a naturally occurring gingivitis and experimental gingivitis. Experimental gingivitis is a longitudinal clinical model that has been widely used in human and animal studies.[98] In humans, experimental gingivitis is induced through abstinence from oral hygiene measures; in animal studies a soft diet favoring plaque accumulation is instituted. The studies of experimental gingivitis have provided a clear demonstration that plaque accumulation invariably causes gingivitis and that gingivitis is reversible with removal of the plaque deposits.

Page and Schroeder reviewed the histopathology of human and animal experimental gingivitis in a classic article[130] that delineated three temporal stages of gingivitis, including the initial, early, and established lesions (see Chapter 15). Central to the histopathologic changes are the vascular inflammation and infiltration of neutrophils and then lymphocytes in the early stages. The early lymphocytic infiltrate is dominated by T-cells, but eventually B-cells become dominant. The established lesion is characterized by a predominance of B-cells that have transformed into plasma cells in the connective tissues. Neutrophils continue to dominate the junctional epithelium and gingival crevice with a marked increase in crevicular fluid flow. It is noteworthy that collagen loss in the involved tissues is evident in the earliest stages of gingivitis. Page and Schroeder report a predominance of plasma cells in the established lesion. Several studies of human experimental gingivitis have failed to demonstrate plasma cell dominance'[5,16,146]; however, increases in the proportions of plasma cells are evident with long-standing gingivitis.[15]

The development of experimental gingivitis occurs in parallel with a tremendous increase in the number of bacteria present in plaque. A distinct shift in the bacterial composition of the plaque also occurs, with increasing proportions of gram-negative anaerobes.[159] Studies on the microbiology of naturally occurring gingivitis indicate relatively equal proportions of gram-positive facultative and gram-negative anaerobic bacteria,'" with evidence of a greater shift as compared with experimental gingivitis. The host response to plaque bacteria is fundamentally an inflammatory response involving the processes described previously. Although gingivitis is not associated with loss of connective tissue attachment, it is evident histologically that some loss of collagen occurs within the connective tissues.

Specialized forms of gingivitis include those associated with hormonal changes, with medications, and with systemic disease.[108] In these instances, evidence exists of an altered host environment that appears to contribute to an increase in host susceptibility to gingivitis. For example, the inflammatory response to plaque during pregnancy appears to be exaggerated, with an increased prevalence and severity of gingivitis beyond that expected for the level of plaque accumulation.[107] Alterations in the subgingival microbiota and the host immune response to bacterial antigens during pregnancy have been reported.[85,103] For example, increases in hormone levels appear to correlate with increases in the subgingival proportions of P. *intermedia,* a microorganism that can substitute progesterone or estradiol for vitamin K as an essential bacterial growth factor.[85] These alterations, as well as the increased clinical susceptibilty to gingivitis, resolve postpartum.

Chronic Periodontitis

Gingivitis and periodontitis share the clinical feature of inflammation. In contrast, periodontitis involves clinically detectable levels of host tissue destruction that are not found in gingivitis. These include clinical attachment loss, periodontal pocketing, and alveolar bone loss. In the common form of periodontitis, chronic periodontitis, the amount of tissue destruction is consistent with the local etiologic factors of plaque and calculus[44] and associated with a variable microbial pattern. The clinical course of disease follows a slow to moderate rate of progression, but periods of rapid progression may occur.[12]

Bacterial Etiology in Chronic Periodontitis. Despite a remarkable diversity of bacteria found in the periodontal microbiota, only a few species have been associated with periodontitis (see Chapter 6). These include P. *gingivalis, B. forsythus, P. intermedia, C. rectus, E. corrodens, E. nucleatum, A. actinomycetemcomitans, P. micros,* and T. *denticola.*[89,91,100,106,117,151,153,154,162] Studies of the microbiologic responses to periodontal therapy support a role for these species in the disease process. Decreases in the prevalence and numbers of P. *gingivalis, B. forsythus,* and T. *denticola* are associated with successful clinical treatment of disease.[23,57,101] When diseased sites with recent attachment loss are compared with inactive sites, increases in the recovery of P. *gingivalis, F. nucleatum, P. intermedia, B. forsythus, E. corrodens, A. actinomycetemcomitans,* and C. *rectus is* evident in the active sites.[32,33,36] In addition, when treatment results are compared with microorganisms detected before treatment, poorly responding sites demonstrate higher levels of *E. nucleatum* and P. *micros.*[55]

Alterations in the host response associated with specific periodontal pathogens are clearly evident. Increases in serum and crevicular fluid antibody specific to putative pathogens,[35,36,81,125] including P. *gingivalis, A. actinomycetemcomitans, P. intermedia, E. corrodens, F. nucleatum,* and C. *rectus,* are evident in patients with periodontitis. Therapy itself is associated with initial increases in serum

antibody levels, which return to pretreatment levels by 8 to 12 months posttreatment.[9,34]

Studies in animal models have been used to demonstrate the pathologic potential of periodontal microorganisms in vivo. A commonly used animal model involves abscess formation in mice, and P. gingivalis, C. rectus, P. micros, P. intermedia, P. nigrescens, A. actinomycetemcomitans, *F.* nucleatum, and T. denticola are pathogenic in this system.",[77,78,121,167] Differences in the virulence of distinct strains of the same species also are evident in the abscess model .[121] Furthermore, P. gingivalis, C. rectus, and A. actinomycetemcomitans demonstrate increased virulence in mice that are depleted of neutrophils, indicating an important role for neutrophils in responding to the bacterial challenge.38

Synergistic interactions between microbial pathogens appear to be important in bacterial virulence. In the mouse model, simultaneous infection with P. gingivalis and *F.* nucleatum enhanced virulence as compared with infection with P. gingivalis alone.41 In a rabbit abscess model, B. forsythus in combination with either P. gingivalis or *F.* nucleatum produces abscesses, whereas none of the microorganisms alone causes abscess formation.[160] Evidence of synergy in virulence, exemplified by these data, is an important consideration in infections that are polymicrobial.

Another area that has been addressed using animal model systems is the generation of immunity to infection. Inoculation with a specific microorganism or specific bacterial component that results in protective immunity suggests that the microorganism or molecule may be important in the disease process. Studies in which P. gingivalis outer membrane or fimbriae were used as immunogens have demonstrated a protective effect in a rodent model.12,40 Using a nonhuman primate model of periodontal disease, immunization with whole cells of P. gingivalis or the cysteine protease of P. gingivalis has resulted in decreased periodontal destruction.[111,134] Although these investigations are useful in assessing microbial interactions in the disease process, much more investigation is needed for consideration of vaccine therapy in humans, particularly with regard to the polymicrobial nature of periodontitis.

Immunologic Considerations in Chronic Periodontitis. Considerable information is available regarding components of the host immune response that are not specific to a given microbial pathogen but occur in response to the infection and are likely to contribute to pathogenesis. Chronic periodontitis is characterized primarily as involving alternative pathway activation of complement, with C3 and B cleavage in gingival fluids observed. This suggests that even though pathogen-specific antibodies are formed in chronic periodontitis, activation of the classical complement pathway by processes involving antibody-antigen binding does not predominate. It also is possible that specific cleavage products in crevicular fluid result from the action of bacterial enzymes. P. gingivalis, for example, produces an enzyme that can cleave CS to its active metabolite, C5a.[178]

Collagenase activity is associated with active periodontal destruction.96 MMP-8 is elevated in chronic periodontitis, whereas the levels of TIMP (TIMP-1) are not." The ability of the chymotrypsin-like enzyme of T. denticola to activate MMPs may contribute to MMP-mediated tissue destruction at periodontitis sites with high levels of this microorganism.[155] In addition, studies of GCF in chronic periodontitis reveal that collagenase activity is as much as sixfold greater than that of gingivitis. Most of the collagenase activity associated with chronic periodontitis is due to the neutrophil collagenase MMP-8.138 Some microorganisms may modulate neutrophil secretion of collagenase. For example, the phagocytosis of *F.* nucleatum and T. denticola are associated with the release of high levels of elastase and MMP-8 from neutrophils.[29,30]

Clear evidence of variations exists among individuals in their susceptibility to periodontitis. Despite considerable accumulation of bacterial plaque including the presence of putative pathogens, some individuals appear to be resistant to the disease process whereas others develop disease. These differences relate primarily to variability in the host immunoinflammatory response to the infectious challenge, but the underlying basis for varying susceptibility may be genetic or environmental in nature.

Systemic factors that modify susceptibility to periodontitis include conditions such as diabetes or HIV infection and environmental influences such as smoking and stress." Epidemiologic studies indicate that the prevalence and severity of periodontitis are increased in diabetics, and poorly controlled diabetics appear to be particularly susceptible.'" Periodontitis has been recently recognized as one of six primary complications of diabetes.[99] HIV infection is associated with alterations in the CD4+ T -cells and monocytes/macrophages. HIV patients may exhibit acute necrotizing periodontal conditions, particularly when CD4+ T-cell levels are very low.[80,126] Smoking is strongly associated with periodontitis in epidemiologic studies. Smoking affects the vasculature, immune system, and inflammatory processes and is an important risk factor for development of periodontitis.[80] Stress is associated with necrotizing ulcerative gingivitis (NUG) and an increased prevalence of periodontitis. The effects of stress may be mediated by alterations in the immune response and inflammatory processes.$° Diminished wound healing is associated with stress, and thus diminished reparative processes may play a role in periodontal pathogenesis.[79,109] Although the specific mechanisms behind the association of these conditions with periodontitis are not clear (see discussions in Chapter 13), a central role of alterations in the host inflammatory processes appears to be a consistent theme.

A genetic basis for variations in periodontal disease susceptibility is indicated by recent studies demonstrating an association between a composite genotype involving the IL-1 genes and the occurrence of chronic periodontitis. The composite genotype consists of a variant of the IL-1ß gene with a single base pair alteration in the DNA sequence at the +3953 position, in combination with similar alterations at the -889 and the +4845 positions of the IL-Ia gene .[39,87] Studies indicate that individuals, primarily those of Caucasian European decent, carrying the composite genotype are at significantly increased odds (odds ratio of approximately 5 to 7) of having moderate to severe periodontitis.[81,111] The occur-

rence of these alleles in the IL-1 genes are considerably lower in individuals of Chinese and African-American heritage.',' [72] Thus these genetic polymorphisms may not contribute to variations in susceptibility and may be less useful as markers in these populations. The IL-1ß allele (+3953) of the composite genotype is known to be associated with a twofold to fourfold increase in IL-1ß production. Individuals negative for the composite genotype undergoing periodontal treatment demonstrate decreases in GCF levels of IL-1ß, whereas those with the composite genotype do not demonstrate this response to treatment .[39] These data provide some information as to the molecular basis for variations in host susceptibility, and it is likely that additional genetic loci will be identified that also influence these processes.

Refractory Periodontitis. The majority of patients with chronic periodontitis are successfully managed with conventional treatment regimes. However, a small proportion of patients do not respond to treatment and demonstrate continued clinical periodontal destruction. These individuals are referred to as refractory periodontitis patients. Prominent periodontal pathogens such as P. gingivalis, *B.* forsythus, *F.* nucleatum, P. micros, *E.* corrodens, and S. intermedius have been found to be elevated in patients who do not respond to treatment."',"' Often, patients identified as refractory to treatment have other factors, particularly smoking, that may contribute to the disease process.[12,13] The impact of smoking on the response to treatment may relate to alterations in neutrophil chemotaxis and phagocytosis, as well as altered levels of cytokines (e.g., IL-1, IL-6) at the local sites .[61,76,91,101]

Aggressive Periodontitis

A primary characteristic of aggressive periodontitis that differentiates it from chronic periodontitis is the rapid progression of attachment and bone loss evident.[166] Other consistent features of patients with aggressive periodontitis are that they are otherwise healthy and that the disease demonstrates a familial pattern of occurrence. A number of features are generally, but not universally, associated with aggressive periodontitis. These include inconsistencies between the amount of microbial deposits and the severity of periodontal destruction; the presence of elevated levels of A. actinomycetemcomitans; and evidence of phagocyte abnormalities and hyperresponsive monocytes/macrophages, leading to elevations in PGE_2 and IL-1ß. Furthermore, the disease process is self-limiting in some cases of aggressive periodontitis.

Aggressive periodontitis may be localized or generalized. The classic form of localized aggressive periodontitis was initially referred to as "periodontosis"'122 and then as localized juvenile periodontitis (LIP). Classic LJP was defined by several distinguishing characteristics: onset around the time of puberty, aggressive periodontal destruction localized almost exclusively to the incisors and first molars, and a familial pattern of occurrence. The incidence of LJP is low, ranging between 0.1% to 2.3% of juveniles and adolescents .[43] However, studies of this distinctive disease process have provided a window into the processes underlying periodontal pathogenesis. Localized aggressive periodontitis (LAP) is the new classification designated to replace LJP. Thus in the following discussions, LAP will be used synonymously with LJP. Generalized aggressive periodontitis is differentiated from the localized form by the extent of involvement of the permanent teeth, and it is considered to include some of the individuals previously categorized as having rapidly progressive periodontitis.[4]

Bacterial Etiology of Localized Aggressive Periodontitis. Early microbiologic studies of LAP provided clear evidence of a strong association between disease and a unique bacterial microbiota predominated by a microorganism later identified as A. actinomycetemcomitans.[112-124] Other microorganisms that have been associated with LAP include P. gingivalis, *E.* corrodens, C. rectus, *F.* nucleatum, *B.* capillus, and Capnocytophaga spp. and spirochetes.[86,116,122,123] However, subsequent research has continued to provide support for a primary etiologic role of A. actinomycetemcomitans in LAP. These findings are summarized as follows:

1. The prevalence of a humoral immune response to this organism is elevated in patients with LAP. A. actinomycetemcomitans has been isolated in up to 97% of LAP patients, compared with 21% of adult periodontitis patients and 17% of healthy subjects.[182] Not only is the prevalence of A. actinomycetemcomitans six times greater in LAP than in healthy patients, but its proportion of the cultivable subgingival flora also is elevated. Among the three serotypes, serotype B is the most common, followed by serotype A.
2. The incidence of A. actinomycetemcomitans is greater in younger LAP patients than in older LAP patients.' If age is considered relative to the duration of the disease, younger patients have more destructive disease developing within a shorter period. This suggests that the presence of this organism correlates with disease activity.
3. A large number of A. actinomycetemcomitans organisms occur in lesions in LAP patients, but such organisms are absent or occur in low numbers in healthy sites.43
4. A. actinomycetemcomitans can be identified by electron microscopy, immunofluorescence, and culture from LAP lesions within the gingival connective tissues.[183]
5. A. actinomycetemcomitans is quite virulent, producing a leukotoxin, collagenase, phosphatases, and bone-resorbing factors, as well as other factors important in invasion of host tissue cells, evasion of host defenses, immunosuppression, and destruction of periodontal tissues.[43,70]
6. A positive correlation exists between the elimination of this organism from the subgingival flora and successful clinical treatment of LAP.[21,152]

A primary focus of studies on the virulence properties of A. actinomycetemcomitans has been on the leukotoxin produced by this bacterium. The ability of this molecule to bind to and lyse phagocytes is considered to be an important mechanism of host defense .[70,92] Early studies revealed that the levels of leukotoxin produced by different strains varied considerably. More recent investiga-

tions have linked the strains producing high levels of leukotoxin with a deletion in the promoter region of the leukotoxin gene[17] and further linked the onset of LAP in a high-risk population with the presence of these high leukotoxin-producing strains.[18] The molecular basis of leukotoxin expression is discussed further in Chapter 9. Another potentially important virulence determinant is the production of an immunosuppressive factor[147] capable of inhibiting lymphocyte functions.

The familial occurrence of LAP raises the question as to whether transmission of specific strains of A. *actinomycetemcomitans* between family members could contribute to the disease process. Recognition of variations in virulence between different strains further suggests that this could be important. Genetic analyses of A. *actinomycetemcomitans* strains isolated from family members suggest that transmission of a strain between spouses or from parent to child occurred in approximately one third of the families investigated.'

Therapeutic approaches to infections involving A. *actinomycetemcomitans* must take into account the host parasite interaction. Mechanical methods alone do not predictably control this microorganism. The ability of A. *actinomycetemcomitans* to invade and reside within the gingival tissues appears to provide a reservoir by which the bacterium can rapidly repopulate the pocket, and sites that continue to deteriorate after treatment harbor substantial levels of the microorganism. Clinical studies suggest that surgery and antibiotic therapy may be required to control A. *actinomycetemcomitans.*[21,86,152]

Immunologic Considerations in Localized Aggressive Periodontitis. Numerous mechanisms of serum-mediated bacterial killing are available, including lysis by the membrane attack complex of complement and antimicrobial substances such as lysozyme. However, some bacteria, including all known strains of A. *actinomycetemcomitans* as well as some strains of most putative periodontal pathogens, are resistant to serum-mediated killing mechanisms.'° For serum-resistant bacteria, the neutrophil is the primary host response mechanism of bacterial control. Studies of LAP have revealed a number of aspects of neutrophil function that may result in a compromised bacterial killing and have been key in demonstrating the importance of neutrophil function in periodontal health and disease.

Approximately 75% of patients with LAP have dysfunctional neutrophils, involving a decreased expression of G-protein coupled receptors. The defect is evident as a decrease in the chemotactic response to several chemotactic agents, including the complement component C5a, N-formyl-methionyl leucyl phenylalanine (FMLP), and leukotriene B4.[128] The defect is associated with a 40% deficiency in a 110-kilodalton membrane glycoprotein, GP110, on the neutrophil surface.[169] The function of GP110 is unknown, but diminished GP110 expression is associated with diminished surface expression of all G-protein coupled receptors. For this reason, this neutrophil defect has been called a *global membrane receptor defect.* The precise dysfunction caused by the G-protein coupled receptor deficiency responsible for disease has not been identified. However, neutrophil transendothelial migration, transepithelial migration, chemotaxis, secretion, and priming can be effected. The molecular basis for the receptor defect is postulated to be inherited as an intrinsic cellular defect or a modulation of neutrophil receptor expression by elevated levels of proinflammatory cytokines including IL-1 and TNF-a.[1,168] LAP patients (25%) that do not have the G-protein coupled receptor deficiency present have the same clinical picture as those with this neutrophil defect. This suggests that the G-protein coupled receptor deficiency is sufficient but not essential for LAP, and other alterations of the host bacterial interaction may yield a similar clinical outcome.

In LAP the predominant collagenase found in tissues and crevicular fluid is MMP-1, and elevated levels of TIMP-1 are present.[68] This contrasts the situation found in chronic periodontitis, in which the collagenous activity is due to MMP-8 from neutrophils. The differences in MMPs may relate to altered neutrophil functions and further underscore the evidence that varying mechanisms of tissue destruction occur in these different forms of periodontal destruction.

Patients with LAP demonstrate elevated antibodies to A. *actinomycetemcomitans,"* and antibody as well as complement is essential for opsonization and efficient phagocytosis.[10] In LAP the dominant serum antibody isotype IgG2 is specific for surface antigens of A. *actinomycetemcomitans,* including LPS and at least one major outer membrane protein.[176,177] Some individuals possess a variant of the Fc receptor on neutrophils (R131 allele of FcyRII-a) that does not efficiently bind IgG2, and this is one possible basis for disease susceptibility.[175] It has been hypothesized that because this binding is less efficient, an antibody response more vigorous than normal is necessary to control the A. *actinomycetemcomitans* infection in LAP and that the progression in LAP is limited by the development of a strong antibody response. In comparison, individuals with generalized early onset periodontitis do not develop a strong antibody response,[54,164] which supports the hypothesis that antibodies function to limit the disease process.

Summary of Localized Aggressive Periodontitis. The evidence indicates that LAP is a form of periodontitis that is clearly distinct from chronic periodontitis. The pathogenesis of LAP is characterized by a highly specific infection involving predominantly A. *actinomycetemcomitans.* This bacterium is capable of tissue destruction and inhibition of host defenses through the production of a leukotoxin and an immunosuppressive factor. The host response is characterized by the high prevalence of neutrophil chemotaxis defects in affected individuals as well as a selective antibody response dominated by high titers of IgG2. This antibody response may necessitate particularly high levels of antibody for efficient opsonization and phagocytosis of A. *actinomycetemcomitans.*

Generalized Aggressive Periodontitis. The recent reclassifications limit the information available pertinent to this group of patients. Some but not all of the individuals previously classified as having rapidly progressive periodontitis (RPP) would likely be considered to

have generalized aggressive periodontitis. Studies of RPP indicate a diverse microbial pattern that includes microorganisms associated with chronic periodontitis and a host response often characterized by defects in either neutrophils or monocytes. [131]

Necrotizing Periodontal Diseases

Two forms of necrotizing ulcerative periodontal diseases are necrotizing ulcerative gingivitis (NUG) and necrotizing ulcerative periodontitis (NUP). These conditions represent acute forms of periodontal destruction typically associated with some form of host compromise.

The essential components of NUG are interdental gingival necrosis, pain, and bleeding; variable features include lymphadenopathy, fever, and malaise.[139] The tissue necrosis results in an appearance often described as "punched-out" papillae. Microbiologic studies indicate that predominant species associated with NUG include *P. intermedia, Fusobacterium spp.,* and spirochetal microorganisms. Electron microscopic studies of NUG reveal a zone of tissue infiltration of spirochetal microorganisms in advance of the region of tissue necrosis.[97] NUG is normally associated with predisposing host factors including stress, immunosuppression, and malnutrition. [139]

NUP is distinguished from NUG by the loss of clinical attachment and bone in affected sites, but the clinical presentation and etiologic factors are similar to that of NUG in the absence of systemic disease . [126] In the presence of systemic immunosuppression, exemplified by HIV infection, NUP may result in rapid and extensive necrosis to the tissues and underlying alveolar bone.' [71]

Periodontal Abscesses

Periodontal abscesses are purulent infections localized to the gingival, periodontal, or pericoronal regions. In the presence of periodontitis, a periodontal abscess represents an acute infectious process with active tissue and bone destruction. Microorganisms that are prevalent in periodontal abscesses are P. *intermedia, E nucleatum,* and *P. gingivalis;* but other periodontal pathogens also are found, including B. *forsythus, P. micros, Prevotella melaninogenica,* and C. *rectus.* [62,124] Histologic studies indicate the presence of neutrophils and macrophages surrounding an internal region of dead leukocytes and tissue debris. In the absence of periodontitis, abscesses are typically associated with impaction of foreign objects such as dental floss or a popcorn kernel. [63,113]

SUMMARY

The pathogenesis of periodontal destruction involves a complex interplay between bacterial pathogens and the host tissues. For some time it has been recognized that "not all dental plaque is equal" and that specific bacterial pathogens appear to be responsible for the changes resulting in disease. It also has been recognized for some time that in the process of effectively limiting the bacterial assault of the periodontal tissues, host defense mechanisms contribute to the destruction of tissues locally.

Recent investigations have revealed that not all strains of a specific microbial species are equal in their capacity to cause disease, and not all hosts are equal in their susceptibility to disease. The challenge for the future is to be able to better identify the more virulent bacterial strains and the more susceptible hosts. In this manner it may be possible to accurately predict the individuals at risk for future disease and to develop more effective strategies to prevent the onset and progression of periodontitis.

DESTRUCTION AT THE HOST TISSUE INTERFACE: THE PROTEASES OF *PORPHYROMONAS GINGIVALIS*
R gingivalis Proteolytic Activity
Molecular Characterization of the Gingipain Protease Genes
Functional Studies of the Gingipain Proteases
Inactivation of the Gingipain Genes
Summary
DISRUPTION OF HOST CELL COMMUNICATIONS: EPITHELIAL EXPRESSION OF INTERLEUKIN-8 (IL-8) AND INTERCELLULAR ADHESION MOLECULE-1 (ICAM-1)
Distribution of IL-8 and ICAM-1 in the Periodontal Tissues
Bacterial Modulation of IL-8 and ICAM-1 Protein Expression
Bacterial Modulation of IL-8 mRNA Levels
SUMMARY

It was only in the mid-1900s that deoxyribonucleic acid (DNA) was recognized as the molecule that carries genetic information. Subsequent work has clarified the fundamental processes of DNA replication as well as the transcription and translation processes leading to expression of gene products. The advent of recombinant DNA technology was possible only after the discovery and isolation of restriction endonucleases, enzymes produced by bacteria that cleave DNA at highly specific sites. The subsequent development of cloning technologies allowed the study of genes in the laboratory and furthered the development of genetic transfer of DNA into living organisms. These advances in molecular biology achieved in the latter half of the 20th century have revolutionized the study of biologic systems.

Utilization of molecular approaches in the study of periodontal diseases has followed on the heels of these developments. Periodontal diseases represent the outcome of a complex interaction between the host and the pathogenic microorganism in the unique environment of the tooth-to-tissue interface. Chapter 10 focuses on the association of human genetics with periodontal diseases. In this chapter, selected topics illustrate areas of progress in understanding the molecular basis of the host-parasite interaction in periodontal diseases. The work summarized in this chapter is at the very forefront of scientific investigation, and in some cases it challenges earlier paradigms of bacterial pathogenesis and host susceptibility.

NOT ALL *ACTINOBACILLUS ACTINOMYCETEMCOMITANS* ARE CREATED EQUAL: THE SPECIFIC PLAQUE HYPOTHESIS REVISITED

The gram-negative facultative anaerobe *Actinobacillus actinomycetemcomitans is* implicated as a pathogen in several forms of aggressive and chronic periodontitis, most

notably localized aggressive periodontitis. It is one of a few periodontal microorganisms that are strongly implicated in the etiology of periodontitis, providing support for the Specific Plaque Hypothesis (see Chapter 6). *A. actinomycetemcomitans* possesses the ability to kill human leukocytes through the production of a 116-kDa protein toxin termed a *leukotoxin.* Because leukocytes are critical to an effective host response against periodontal pathogens, the ability of this microorganism to kill leukocytes is an important mechanism in evading host defenses. Early studies indicated that not all strains of *A. actinomycetemcomitans* demonstrated the leukotoxic properties .z Recent investigations have revealed a molecular basis for this variability in leukotoxin expression and led to new insights on the role of specific strains of *A. actinomycetemcomitans* in periodontitis.

The Leukotoxin of A. *actinomycetemcomitans*

The *A. actinomycetemcomitans* leukotoxin (LtxA) is a member of a family of pore-forming toxins, characterized by a series of glycine-rich repeats in the C-terminal portion of the protein that are involved in cation binding and appear to be essential to toxin activity. This family of toxins has been designated as RTX (repeat in toxin) toxins, and they are produced by several pathogenic, gram-negative species. Other RTX toxins include the leukotoxin of *Pasturella haemolytica,* a respiratory pathogen of cattle, as well as hemolysins of pathogenic *Escherichia coli* and *Bordetella pertussis,* the causative agent of whooping cough. A high degree of specificity in the cells affected by the *A. actinomycetemcomitans* LtxA was evident in early studies. The affected target cells include human polymorphonuclear leukocytes (neutrophils or PMNs), monocytes and lymphocytes. Human platelets, fibroblasts, and endothelial and epithelial cells are resistant to the effects of the LtxA. [71,78] The target cell susceptibility is a result of cell surface expression of the ß2-integrin molecule, lymphocyte function-associated antigen 1 (LFA-1). [44,79] The identification of LFA-1 as the receptor for LtxA suggests that killing is a receptor-mediated process.

Mechanism of Leukotoxin Action

Evidence exists for two LtxA-mediated mechanisms of cell death: necrosis and apoptosis. Exposure of neutrophils and monocytes/macrophages to strains that produce large amount of LtxA results in killing within a relatively short period of time (Fig. 9-1, panels A-C) .2 This cell death is thought to result from the ability of LtxA to form pores in the membrane of target cells, leading to osmotic lysis caused by water influx into the cell .45 In contrast, prolonged exposure of lymphocytes and NK cells to LtxA results in the induction of apoptosis, a programmed sequence of cellular alteration progressing to cell death .[40,49,66] There is evidence that lower concentrations of LtxA result in apoptosis whereas higher concentrations result in necrosis .39 It has been hypothesized that the LtxA molecules in high concentration fuse to form large pores in the target cell membrane, resulting in more rapid necrotic destruction.

Molecular Characterization of the Leukotoxin Genes

The gene encoding the *A. actinomycetmecomitans* leukotoxin, ltxA, is part of an operon of four genes in the sequence *ItxC,* ltxA, ltxB, and ltxD (Fig. 9-2). This operon structure of C, A, B, and D genes in sequence is characteristic of the RTX family of toxins. Considerable sequence homology exists between the individual genes from these different organisms, suggesting a common evolutionary origin and function.[41,43] As is characteristic of genes clustered in an operon, these genes are all related to leukotoxin function. The A gene encodes the leukotoxin itself and is produced in an inactive "protoxin" state. The C gene product, ItxC, is required to activate the pro-toxin. In the case of the E. coli hemolysin, this process involves a chemical modification in which fatty acids are linked to two sites on the leukotoxin protein." Based on the similarity between the C genes and gene products, the ltxC gene product of *A. actinomycetemcomitans* also is thought to function in leukotoxin activation. The B and D genes are typically involved in secretion of the leukotoxin from the bacterial cell, and studies of the ltxB and ItxD genes of *A. actinomycetemcomitans* suggest similar functions .[22,43] For many years, it was thought that the leukotoxin of *A. actinomycetemcomitans* remained associated with the bacterial cell and was not secreted into the external environment. Recent studies have revealed that certain strains in their early growth phases secrete an abundant amount of leukotoxin into the environment. [13] Further studies of the factors governing the cellular retention or release of the leukotoxin may shed more light on the role of these properties in pathogenesis.

Molecular Basis of Variability in Leukotoxin Production

It has been long recognized that some strains of *A. actinomycetemcomitans* are highly toxic and produce high levels of leukotoxin, whereas other strains are weak or minimally toxic and produce low levels of leukotoxin. A key discovery in the study of the leukotoxin production in *A. actinomycetemcomitans* was the variation in the DNA sequence of the leukotoxin promoter region .[9,25] Bacterial promoters consist of specific segments of DNA that provide a recognition and binding site for the enzyme RNA polymerase, which is responsible for RNA (ribonucleic acid) synthesis. Different promoters vary in their level of transcription, leading to differences in the level of mRNA and thus differences in the amount of protein product generated. The regulation of gene expression based on the amount of mRNA produced is referred to as *transcriptional control.* Investigation of the DNA sequence upstream of the ltxC gene revealed that the highly toxic strains have a deletion of 530 base pairs (bp) of DNA as compared with the minimally toxic strains (see Fig. 9-2). Analysis of mRNA revealed the presence of two promoters functioning in the highly toxic strains (see Fig. 9-2, *A,* P1 and P2), but in the minimally toxic strains a single promoter is responsible for initiating transcription (Fig. 9-2, *B,* P3). This latter promoter (P3) resides within the 530 base pair region that is missing in the highly toxic

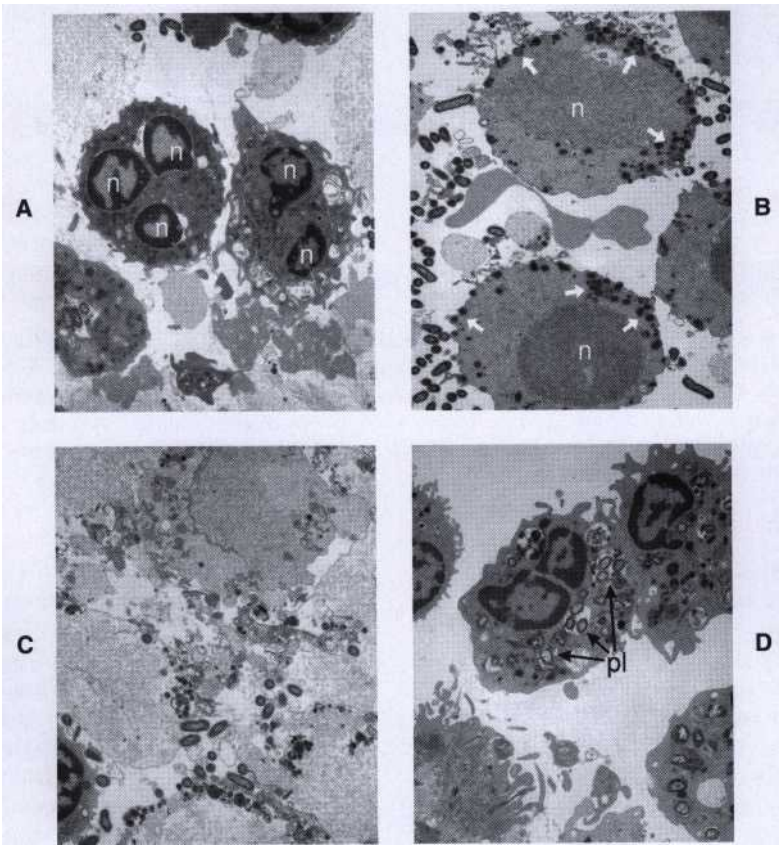

Fig. 9-1 Highly leukotoxic *A. actinomycetemcomitans* evasion of neutrophil phagocytosis. Electron micrographs of neutrophils challenged with the highly leukotoxic strain *A. actinomycetemcomitans* HK1519 for (A) 0 minute, (B) 7 minutes, and (C) 45 minutes. Cell morphology of the neutrophils initially appears normal, including the nuclei (n). By 7 minutes' incubation, nuclear degeneration and peripheralization of the neutrophil granules *(white arrows)* are evident. Further incubation reveals complete lysis of the neutrophils. In contrast, challenge with the minimally leukotoxic strain NCTC 9710 for 60 minutes (D) does not result in cytopathic alterations of the neutrophils. Rather, uptake of bacterial cells into phagolysosomes (pl) is evident. (From Johansson A, et al: Anaerobic neutrophil-dependent killing of *Actinobacillus actinomycetemcomitons* in relation to the bacterial leukotoxicity. Eur J Oral Sci 2000; 108:136. Figure courtesy of A. Johansson.)

strains. Studies of the regulation of transcription further differentiate the different promoters. The P3 promoter is regulated by the level of oxygen present during bacterial growth, with increased mRNA, increased leukotoxin expression, and a 3- to 4-fold increase in toxicity when the bacterium is grown under anaerobic conditions. In contrast, oxygen concentrations have no effect on the P1 or P2 promoters. The amount of mRNA and leukotoxin produced and the resulting toxicity are substantially greater in the highly toxic strains using the P1 and P2 promoters, regardless of the environmental conditions, as compared with the minimally toxic strains using the P3 promoter. It is hypothesized that the highly toxic strains may have evolved from a minimally toxic strain by the deletion of this DNA in the promoter region.

The leukotoxin is considered an important virulence determinant of A. *actinomycetemcomitans* because it allows the microorganism to neutralize host defense mechanisms. The interaction of highly versus minimally toxic strains with neutrophils is demonstrated in Fig. 9-1. The highly toxic strain rapidly induces degenerative changes and then lysis of the neutrophils (see Fig. 9-1, panels A-C). In contrast, the minimally toxic strain does not induce lysis of **the neutrophil, but rather the bacterial cells are phagocytosed and phagolysosomes containing the bacterial cells are evident microscopically (see** Fig. 9-1, panel D). The presence of the 530-bp deletion in the DNA sequence has provided a marker for distinguishing the highly versus minimally leukotoxic strains, which can be easily detected using PCR techniques. The occurance of the highly leukotoxic strain varies widely in different geographic regions as well as in different racial groups.23 In addition, in a population of children at risk for the development of localized aggressive periodontitis, those who harbored the highly leukotoxic strain were found to be more likely to develop disease.10

Summary

The significance of the findings related to leukotoxin expression ranges from theoretic to practical.64 The theoretic implications relate to the clear demonstration that not all A. *actinomycetemcomitans* are created equal, but rather that some strains are more virulent than others.

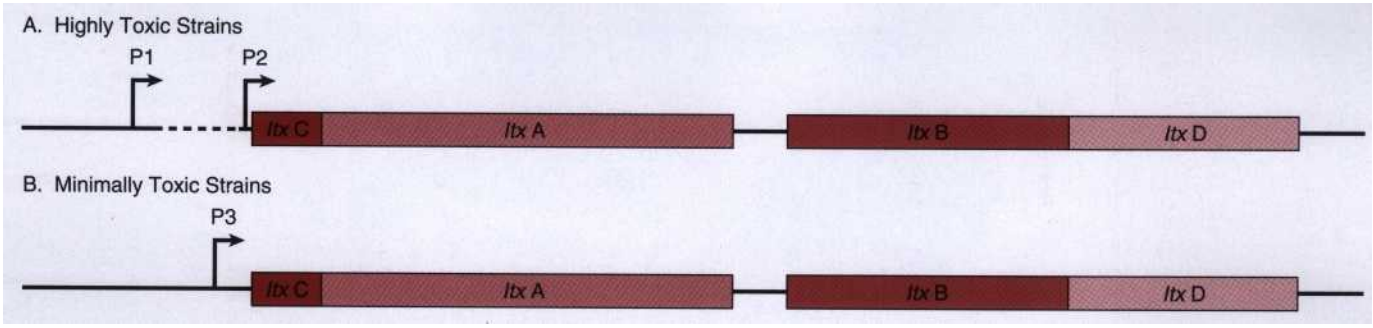

Fig. 9-2 Schematic illustration of the leukotoxin operon in highly and minimally toxic strains of *A. actinomycetemcomitans.* **The leukotoxin operon consists of the four genes** *ltxC,* **ltxA, ItxB, and** *ltxD,* **arranged in tandem. The leukotoxin itself is encoded by the ItxA gene. See the text for descriptions of the functions of the remaining gene products. The position of the 530 by** *DNA* **deletion in the highly toxic strains is indicated by the dotted line. The positions of the promoters (PI, P2, and P3) functioning in the highly versus minimally toxic strains are indicated.**

The specific plaque hypothesis (see Chapter *6)* states that disease is associated with specific bacterial species. The findings described here suggest that the specific plaque hypothesis should be revised to state that disease is associated with specific strains of a given species. It is likely that most, if not all, recognized periodontal pathogens demonstrate differences in phenotypic properties related to their ability to cause disease. Further investigation at a molecular level will undoubtedly continue to reveal the genetic basis for variability in virulence properties among pathogenic strains. Practical implications relate to microbial monitoring of periodontitis patients as well as assessments of risk in susceptible individuals. Current practices of microbial testing do not differentiate the highly toxic versus minimally toxic A. *actinomycetemcomitans* strains. This can lead to a situation where an individual with a minimally toxic strain might be inappropriately considered at high risk for disease development or progression. Furthermore, in clinical trials in which the presence of A. *actinomycetemcomitans is* evaluated as a risk factor for development or progression of disease, the inclusion of minimally toxic strains may dilute and essentially mask a stronger association of the highly leukotoxic strain with disease. Clarification of specific bacterial virulence factors that contribute to pathogenesis and development of the tools or probes needed to identify strains possessing virulence factors will enhance our ability to both prevent and manage periodontal diseases.

DESTRUCTION AT THE HOST TISSUE INTERFACE: THE PROTEASES OF *PORPHYROMONAS GINGIVALIS*

P. gingivalis is a periodontal microorganism that is strongly associated with chronic and aggressive forms of periodontal disease in humans (see Chapter 6). In addition, this gram-negative anaerobe has been shown to be pathogenic in nonhuman primate and rodent models of periodontitis.[19,24] Investigations in the laboratory have identified numerous properties of *P. gingivalis* that may account for its ability to cause disease, and preeminent among these is the ability of *P. gingivalis* to elaborate a variety of proteolytic enzymes. Investigations during the last 2 decades demonstrated that a wide variety of protein substrates are degraded by *P. gingivalis* proteases. This led to a period of considerable confusion regarding the number and activity of different proteases. Molecular analyses have now confirmed the presence of a relatively limited number of protease genes (Table 9-1) and clarified the relationships among genes characterized from different strains.[12]

It is noteworthy that *P. gingivalis* proteases are not inactivated by host proteinase inhibitors. Rather, evidence exists that the *P. gingivalis* proteases inactivate or degrade the host proteinase inhibitors.[57] This may lead to an imbalance in the normal host mechanisms of tissue turnover, contributing further to host tissue destruction. The proteases of *P. gingivalis* are important in the metabolism and ecology of the bacterium itself, but they additionally act at the host-parasite interface to contribute to pathogenesis through host tissue degradation and modulation of host defense mechanisms. Molecular analyses have been used to define the genetic basis of protease production and delineate the mechanisms by which the proteases may contribute to host tissue destruction. In addition, genetic approaches to specifically inactivate protease genes have been used to demonstrate that proteases play an important role in the virulence of *P. gingivalis.*

P. gingivalis Proteolytic Activity

P. gingivalis is unable to break down or degrade sugar substrates as a source of energy or to take up and use free amino acids as metabolic building blocks." Rather, *P. gingivalis* relies on its ability to degrade proteins into short peptides that are taken in and used metabolically in the generation of energy and as sources of carbon and nitrogen. In the periodontal environment, the host tissues provide an abundant source of proteins. For example, a major protein constituent of the periodontal tissues is collagen, and *P. gingivalis* possesses the proteolytic activity to degrade collagen into peptide components that it can use. The bacterial collagenase produced by *P. gingivalis* (PrtC), host cell collagenases, or probably both contribute to collagen degradation. Several peptidases found on the cell surface of *P. gingivalis* are suffi-

TABLE 9-1

Selected Proteases Produced by P. gingivalis

Enzyme	Gene	Molecular Weight of Protein Product	Enzyme Class	Cleavage Specificity	Comments on Function	References
Arg-gingipain (RgpA)	rgpA	50 to 110 kDa	Cysteine	Cleaves peptide bonds following an arginine residue	Gene also encodes an adhesin domain that appears to improve proteolytic efficiency	1, 18, 37, 58, 62
Arg-gingipain (RgpB)	rgpB	48 to 90 kDa	Cysteine	Cleaves peptide bonds following an arginine residue	Gene is homologous to rgpA but lacks the adhesin domain	53, 55, 68
Lys-gingipain (Kgp)	kgp	60 to 180 kDa	Cysteine	Cleaves peptide bonds following a lysine residue	Gene also encodes an adhesin domain	7,62
Periodontain	N/A	75 kDa heterodimer	Cysteine	Only cleaves denatured proteins; 55 kDa fragment possesses catalytic domain	Rapidly inactivates host plasma proteinase inhibitors, such as a-l-protease inhibitor, the primary inhibitor of human neutrophil elastase	57
Prolyl tripeptidase PtpA	ptpA	82 kDa	Serine	Cleaves tripeptides from the amino-terminal end, where proline is the third residue from the amino-terminal end	Enzyme is cell associated and may be important in generating tri-peptides used in bacterial nutrition	5
Prolyl dipeptidyl peptidase IV	dpp	78 kDa	Serine	Cleaves dipeptdy from the amino-terminal end, where proline is the second residue from the amino-terminal end	Enzyme is cell associated and may be important in generating di-peptides used in bacterial nutrition as well as host molecules	3, 38,42
Collagenase	prtC	38 kDa	Metallo-protease	Degrades type I collagen but cleavage specificity not determined	Differs from other bacterial collagenases in that it does not degrade gelatin	36

N/A, Not applicable.

cient to completely degrade the collagen fragments. These include dipeptidyl peptidase IV (DPPIV) and prolyl tripeptidyl peptidases (PtpA), proteases that generate di- and tri-peptide fragments, which may be transported into the bacterial cell. Another group of P. *gingivalis* proteases, the gingipains (discussed below), also are capable of degrading collagen fragments. The degradation of collagen and other host tissue molecules supports P. *gingivalis* metabolically but also contributes to pathogenesis because of the resulting host tissue damage.

Molecular Characterization of the Gingipain Protease Genes

The most intensely studied enzymes of P. *gingivalis* are a group of related proteases known as *gingipains. These* proteases occur in multiple forms that are found extracellularly or on the bacterial cell surface and in some cases are associated with protein regions or "domains" involved in adherence properties (Fig. 9-3). The gingipains specifically cleave proteins at the peptide bond following arginine residues (Arg-gingipains or Rgps) or lysine residues (Lys-gingipain or Kgp). Molecular studies revealed that the Arg-gingipains are encoded by two genes, rgpA and rgpB, whereas the Lys-gingipain is encoded by a single gene, kgpA. Analysis of the rgpA DNA sequence indicates that the protein product initially consists of three distinct domains: a propeptide domain at the amino-terminal end of the protein that is cleaved off when the protease is activated, a protease domain, and a carboxy-terminal adhesin domain (see Fig. 9-3). The propeptide and protease domains are very closely related to those of the second Arg-gingipain gene, rgpB. In contrast, rgpB lacks the adhesin domain. The Lys-gingipain gene kgp is similar in organization to rgpA, with propeptide, protease, and adhesin domains. The amino acid sequence of the Kgp protease domain demonstrates only 22% identity to that of RgpA, with key catalytic regions that are identical and substantial regions of unrelated sequence that may account for the differences in substrate specificity between

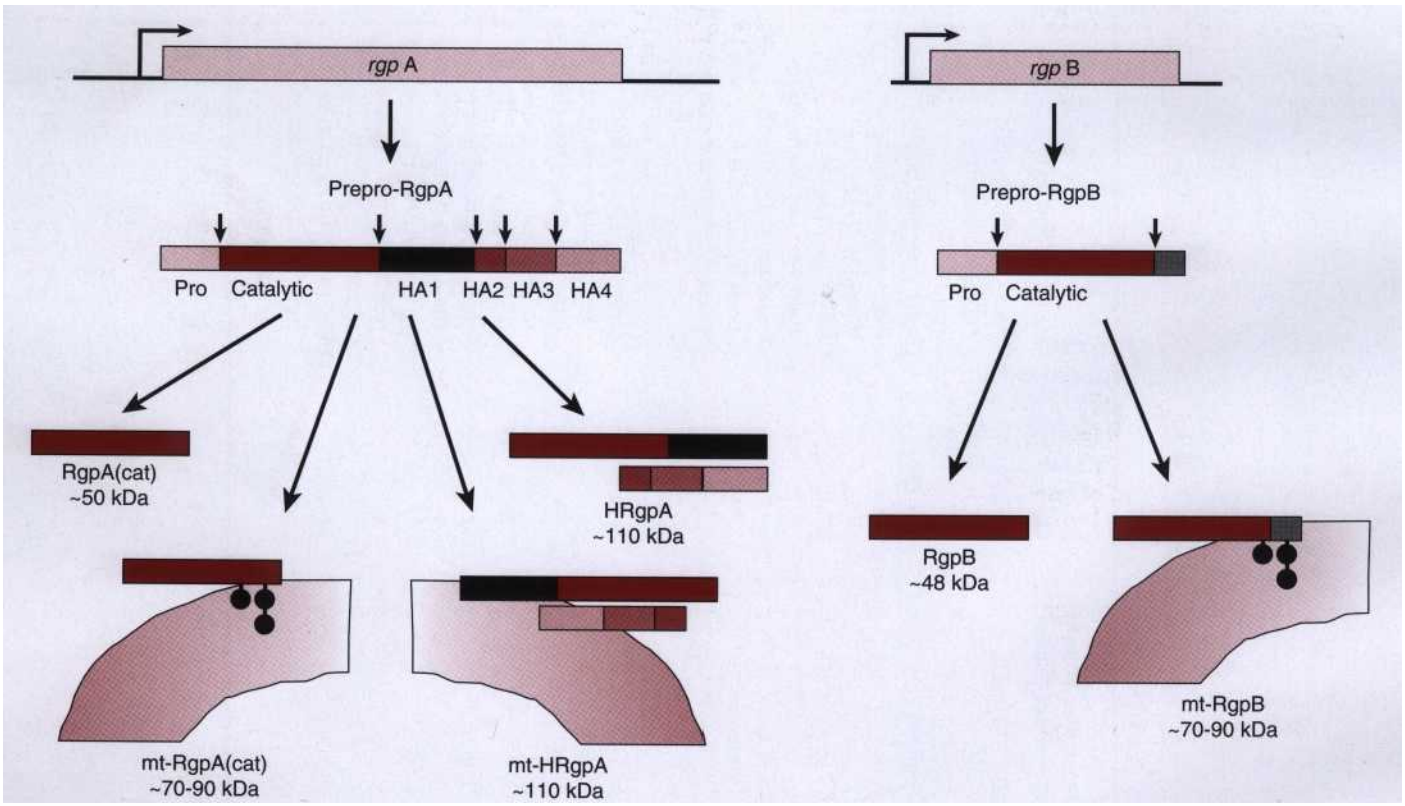

Fig. 9-3 Schematic illustration of the posttranslational processing of the initial translational products of the rgpA and rgpB genes. The initial translational products (prepro-RgpA and prepro-RgpB) of the genes include propeptide domains (pro) and catalytic domains. RgpA possesses an adhesin domain consisting of a number of defined regions related to hemagglutination genes (HAI, HA2, etc.). These initial protein products undergo posttranslational processing that involves cleavage of the protein (small arrows) and addition of carbohydrate groups (black circles) to generate multiple isoforms. The propeptide is cleaved off and is not present in the final protein products. A high molecular weight form of RgpA consists of the catalytic and adhesin domains and is designated HrgpA. Note that either the catalytic domain (RgpA[cat]) alone or the HrgpA may be associated with the bacterial cell membrane. The membrane-associated forms are designated as "mt-" forms; for example, mt-RgpA(cat). The posttranslational processing of prepro-RgpB is less complex in that the RgpB gene lacks the adhesin domain. (Adapted from Travis J, Potempa J: Bacterial proteinases as targets for the development of second-generation antibiotics. Biochimica et Biophysica Acta 2000; 1477:35.)

the two enzymes [61] The translational protein products of the rgp genes undergo posttranslational modifications, including cleavage and addition of carbohydrate groups, to yield multiple forms (termed iso forms) of the protease (see Fig. 9-3). Interestingly, the adhesin domains found in RgpA and Kgp share stretches of sequence that are closely related to adhesin domain sequences found in a hemagglutinin (HagA) and an outer membrane receptor protein (Tla) of P. gingivalis. It has been demonstrated that the adhesin domain mediates adherence of the protease-adhesin complex to connective tissue molecules, including fibrinogen, fibronectin, and laminin. [63] Furthermore, the adhesin-protease complex is about twice as effective in degrading fibrinogen and fibrin as compared with the protease lacking the adhesin.31 Adherence is an important component of pathogenesis, and the combination of adherence and protease activity is likely to facilitate the process of tissue degradation.

Functional Studies of the Gingipain Proteases

The gingipains of P. gingivalis are capable of disrupting normal host systems in a way that contributes to the growth and virulence of the bacterium and destruction of the host tissues (Table 9-2). The ability of gingipains to stimulate the release of bradykinin, resulting in increased vascular permeability, provides a mechanism to explain the increased crevicular fluid flow evident at sites of inflammation, a condition that improves the nutrient supply for resident microorganisms. The host immune response may be neutralized by the gingipains because they degrade the host cell receptor for LPS (CD14), the proinflammatory cytokines such as IL-1/3, IL-6, and the chemokine IL-8. In addition, the effects on neutrophil function and degradation of host inflammatory mediators alter the normal host inflammatory responses to the bacterial assault. The gingipains appear to both stimulate and inhibit the host immune response with re-

TABLE 9-2

Effects of P. gingivalis Gingipains on Host Biologic Systems: Selected Examples

Host Biologic System	P. gingivolis Protease	Mechanism of Action	Effect	References
PMN phagocytosis of bacteria	Rgps	Cleavage of complement component C5 to form C5a	Increased PMN recruitment to site of infection	16,80
	Rgps, Kgp	Specific cleavage of the cytokine IL-8, making it more active in PMN recruitment	Increased PMN recruitment to site of infection	52
	Membrane-associated Rgps	Degradation of IL-8	Decreased PMN recruitment to the site of infection	52
	Kgp (also membrane-associated serine proteases)	Cleavage of PMN cell surface receptor for C5a (C5aR)	Decreased phagocytosis	32
	Rgps	Degradation of the complement factor C3 and immunoglobulin IgG	Decreased opsonization and phagocytosis	64,80
Innate immune response	Rgps, Kgp	Degradation of monocyte CD 14, the receptor for LPS and activation of toll-like receptors	Inability of host cells to recognize and respond to bacteria	70
Host cytokine network	Rgps, Kgp	Degradation of II-1ß, IL-6, IL-8, and TNF-a	Disrupted host inflammatory response to infection	4, 11, 20
Kallikrein/kinin system	Rgps, Kgp	Activation with release of bradykinin, a potent inducer of vascular permeability	Increased vascular permeability, resulting in increased crevicular fluid flow, tissue edema, and increased supply of nutrients for bacterial growth and virulence	29, 76
Coagulation/ fibrinosysis systems	Rgps, Kgp	Paradoxical effects involved in activation of clot formation and clot (fibrinogen) degradation	Local dysregulation may relate to increased bleeding on probing at sites of periodontal disease	6, 30

gard to neutrophil function. For example, the soluble Rgps and Kgp cleave IL-8 in a manner that makes this proinflammatory cytokine more active in the recruitment of neutrophils. However, the membrane-associated Rgps are able to abolish IL-8 activity by completely degrading the molecule. This has led to the hypothesis that P. gingivalis has proinflammatory effects at long distances mediated by soluble proteases but antiinflammatory effects at close range mediated by membrane-associated proteases (Fig. 9-4).[52] Inherent in this hypothesis is the premise that P. gingivalis benefits from the presence of neutrophils in the area because the neutrophils release a wealth of proteolytic enzymes that undoubtedly contribute to tissue protein degradation and thus assist in the acquisition of nutrients for the bacterium. However, neutrophil function is thought to be inhibited in close proximity to P. gingivalis cells, by virtue of the membrane-associated proteases on the bacterial cells or vesicles released into the bacterial cell's immediate surroundings, to protect the bacterium from phagocytosis. Mechanisms for the inhibition of neutrophil function include the degradation of IL-8 by membrane-associated Rgps as well as molecules (e.g., complement component C3) and receptors (neutrophil C5a receptors) involved in opsonization and phagocytosis.

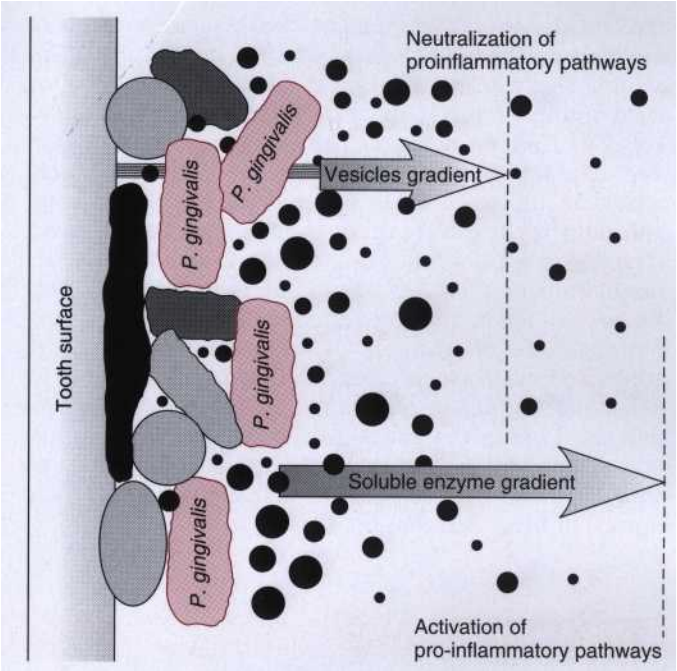

Fig. 9-4 Schematic illustration of the putative compartmentalization of pro- and anti-inflammatory effects of P gingivalis gingipains. The proinflammatory pathways are hypothesized to be mediated by soluble gingipains whose effects include activation of IL-8, which is involved in recruitment of neutrophils. The antiinflammatory effects are hypothesized to be mediated by membrane-associated gingipains such as vesicles (small *filled circles)* released by the bacterium. The antiinflammatory effects focus on an inhibition of neutrophil function as a means of bacterial evasion of host defenses. (Reprinted by permission of the Federation of the European Biochemical Societies. From Mikolaiczyk-Pawl inska J, Travis J, Potempa J, et al: Modulation of interleukin-8 activity by gingipains from Porphyromonas gingivalis: implications for pathogenicity of periodontal disease. FEBS Lett 1998; 440:282.)

Inactivation of the Gingipain Genes

Molecular studies often focus initially on isolating a particular gene of interest by cloning and expressing that gene in a foreign bacterial host system such as E. coli. This approach has been invaluable in isolating and characterizing genes and their products. Another powerful tool in molecular studies is to inactivate, or "knock out," specific target genes at the molecular level. This is typically achieved by inserting an unrelated "marker" gene, such as an antibiotic resistance gene, into the coding sequence of the target gene on the chromosome of the native microorganism. Transcription of the target gene is disrupted, and the presence of the "marker" antibiotic resistance gene is easily assessed by growth of the bacterium on media containing the relevant antibiotic. The resulting bacterial strain is termed an isogenic mutant. These mutants differ from the parental strain by the disruption of one, or in some cases several, defined gene(s) and provide an important technique for assessing the role of the gene product in the native host cell. P. gingivalis mutants in the rgpA and rgpB genes confirmed that both genes encode Arg-gingipains (Table 9-3). A mutant strain in which both the genes have been inactivated indicates that these two genes account for all of the Arg-gingipain activity found in P. gingivalis.[53] Similarly, the properties of an isogenic mutant in *kgp* indicates that this gene accounts for the Lys-gingipain activity.[59] The loss of hemagglutination in mutants with the rgpA or *kgp* genes inactivated supports a role for the protease-associated adhesin domains in hemagglutination.[53]

Analysis of the gingipain isogenic mutants further confirms studies on the role of these proteases in bacterial nutrition, tissue destruction, and modulation of the host immune response. The mutant with all three gingipain genes (rgpA, rgpB, and *kgp)* inactivated demonstrated a complete loss of extracellular proteolytic activity and diminished growth on complex media, presumably because of an inability to degrade proteins for use in bacterial metabolism.[67] Inactivation of the rgpA gene specifically resulted in loss of the ability of the bacterium to degrade type I collagen, a major component of the periodontal tissues.[73] Mutations in both rgpA and rgpB were associated with alterations in the bacterial-neutrophil interaction. The supernatants taken from cultures of P. gingivalis normally inhibit neutrophil function. Strains with either rgpA or rgpB inactivated partially lose the ability to inhibit neutrophil function, whereas inactivation of both rgpA and rgpB results in almost complete loss of the ability to inhibit neutrophil function. In addition, the rgpA mutant is less resistant to neutrophil phagocytosis.[65] This mutant demonstrated a loss in the ability to degrade the complement factor C3 and an increase in the accumulation of iC3b on the bacterial cell surface. Thus the loss of Arg-gingipain activity is associated with a loss in the ability of the bacterium to disrupt the processes of opsonization and phagocytosis.

Several unexpected findings also have emerged from the studies of the gingipain isogenic mutant strains (see Table 9-3). Inactivation of the rgp genes is associated

with altered expression or loss of the bacterial fimbriae normally found on the P. gingivalis cell surface. The fimbriae are important in adherence of the bacterial cells, as reflected in the alterations in adherence properties observed in the rgp mutant strains. Subsequent investigation revealed that Arg-gingipain plays an important role in the processing of prefimbrilin to form fimbrilin, a major component of the bacterial fimbriae.[34] Fimbrial expression is important in the virulence of P. gingivalis,[48] underscoring again the role of Arg-gingipain activity in pathogenesis. A second unexpected finding was that inactivation of kgp results in a loss of the black pigmentation of the P. gingivalis colonies as well as altered adsorption of hemoglobin and heme accumulation. P. gingivalis colonies normally turn black when grown on blood agar as the cells accumulate an oxidized form of heme, hemin. The hemin appears to be derived from hemoglobin and provides an important nutritional source of iron for the bacterium.[$] Subsequent studies revealed that Lys-gingipain is able to cleave human hemoglobin and thus appears to function as a hemoglobinase in the acquisition of heme and iron.[46] Interestingly, the hemoglobin receptor protein of P. gingivalis is encoded as part of the adhesin domain associated with the kgp, rgpA, and hagA genes.[54] The physical proximity of the hemoglobin receptor and the hemoglobinase in the protein product presumably facilitates this aspect of nutrient aquisition. Hemin levels are known to be important in the virulence properties of P. gingivalis.[51] The unexpected findings described here illustrate the importance of investigating gene function, not just in a foreign host system such as E. coli but in the native host cell (in this case, P. gingivalis), to fully understand the role of any particular gene or gene product in pathogenesis.

Phenotypic Alterations Resulting from Inactivation of Gingipain Genes in P. gingivalis

Protease Inactivated	Protease Gene Inactivated	Phenotypic Properties of Mutant Strain in Comparison with Parental Strain	References
Arg-gingipain (RgpA)	rgpA	Partial loss of Arg-gingipain activity • Loss of resistance to PMN phagocytosis Partial loss of ability to inhibit PMN function' Partial loss of adherence properties • Decrease in hemagglutination • Loss or altered expression of bacterial fimbriae • Deficient in adherence to other bacteria and type I collagen Loss of ability to degrade type I collagen Partial loss of virulence in mouse model of bacterial invasiveness	19, 53, 64, 73
Arg-gingipain (RgpB)	rgpB	Partial loss of Arg-gingipain activity Partial loss of ability to inhibit PMN function' Partial loss of adherence properties • Altered expression of bacterial fimbriae • Decreased adherence to other bacteria, as well as host epithelial cells, connective tissue matrix proteins, and type I collagen	56, 72
Arg-gingipain (RgpA and RgpB)	rgpA, rgpB	Complete loss of Arg-gingipain activity Loss of ability to inhibit PMN function' Loss of bacterial fimbriae Defective maturation of bacterial cell surface components	53, 56, 67
Lys-gingipain (Kgp)	*kgp*	Complete loss of Lys-gingipain activity Decreased hemagglutination • Loss of colony pigmentation • Decreased adsorption of hemoglobin and accumulation of heme Decreased fibrinogen degradation No loss of ability to inhibit PMN function' Partial loss of virulence in mouse model of bacterial invasiveness	46, 47, 59
Arg-gingipain and Lys-gingipain	rgpA, rgpB, *kgp*	Complete loss of Arg-gingipain and Lys-gingipain activity Complete loss of extracellular protease activity • Growth limitations on complex media Loss of hemagglutination • Loss of hemoglobin binding • Loss of colony pigmentation	67

Summary

Molecular studies have been instrumental in delineating the different proteolytic activities of P. *gingivalis* and their respective contributions to bacterial virulence. These findings are important to our understanding of the mechanisms of periodontal pathogenesis but also may provide a useful therapeutic approach to controlling periodontal diseases. Although the bacterial proteases are related to host-encoded enzymes, they are sufficiently different such that the development of inhibitors specifically targeting bacterial proteases has been proposed as a strategy for the development of a new generation of antibiotics." An example of this approach is the very successful use of inhibitors targeting proteases of the HIV virus in the treatment of AIDS patients.[21,77] The increasing resistance of microorganisms to conventional antibiotics has fostered considerable interest in new microbial targets.

DISRUPTION OF HOST CELL COMMUNICATIONS: EPITHELIAL EXPRESSION OF INTERLEUKIN-8 (IL-8) AND INTERCELLULAR ADHESION MOLECULE-1 ICAM-1

Epithelium has traditionally been considered a mechanical barrier, providing protection to the underlying connective tissues. However, in recent years, mucosal epithelium has been increasingly recognized as a dynamic component in the communication network involved in recognizing and responding to microbial pathogens in the host environment.[35] In essence, the mucosal epithelium functions as a sensor of the adjacent bacterial population and sends signals to the underlying tissues to activate inflammatory and immune responses. This signaling process thus activates host systems that are central to host defenses.

The periodontal region is a unique mucosal interface. Bacterial populations accumulate on the nonshedding surface of the tooth adjacent to the sulcular and junctional epithelium that cover the underlying connective tissues. The responsiveness of periodontal tissues to the adjacent bacterial load is clearly evident in the inflammation of gingivitis and periodontitis. The first leukocyte to arrive at the site of infection is the neutrophil, which is the host immune cell that consistently predominates in the junctional epithelium and periodontal pocket in close proximity to the periodontal bacteria. The critical role of the neutrophil also is evident in that individuals with defects in neutrophil function suffer severe forms of periodontal disease (see Chapter 8). The processes leading to recruitment of neutrophils to the site of infection involve a series of events (see Chapter 7), many of which involve molecules generated by host cells in response to their recognition of bacteria. Two key molecules in the recruitment and localization of neutrophils are the chemokine interleukin-8 (IL-8) and the cell adhesion molecule known as *intercellular adhesion molecule-1 (ICAM-1).* Over the last decade, molecular analyses have enabled a better understanding of the mechanisms by which these molecules control neutrophil distribution and function, as well as the role of periodontal bacteria in regulating these processes.

Distribution of IL-8 and ICAM-1 in the Periodontal Tissues

IL-8 is a proinflammatory chemokine, a potent chemoattractant and activator of neutrophils. IL-8 induces the neutrophil to express the integrin molecules, LFA-1 or Mac-1, on its cell surface and upregulates neutrophil binding activity. These integrin molecules, LFA-1 and Mac-1, bind to ICAM-1, an immunoglobulin-related glycoprotein found on host tissue cells.[15,50] The ability of neutrophils to migrate across epithelium is dependent on LFA-1 and Mac-1.[60] Thus IL-8 and ICAM-1 appear to be key molecules in the recruitment, localization, and activation of neutrophils.

IL-8 and ICAM-1 are produced in the epithelium of the lung, intestine, urinary tract, and gingival tissues in response to bacterial exposure. Histologic studies indicate that IL-8 and ICAM-1 are present in gingival tissues in both health and disease. IL-8 is localized to the epithelium, including the sulcular and junctional epithelium (Fig. 9-5).[17,27,74,75] ICAM-1 is strongly expressed in the junctional epithelium (Fig. 9-6), but minimal evidence of ICAM-1 has been found elsewhere in the gingival tissues.[27] The pattern of ICAM-1 distribution in particular indicates an increase in concentration toward the sulcular surface of the junctional epithelium. This pattern of distribution is closely matched by the tissue localization of neutrophils.[74,75] Thus studies of tissue localization are consistent with the role of IL-8 and ICAM-1 in recruiting neutrophils and facilitating their migration across the junctional epithelium.

Bacterial Modulation of IL-8 and ICAM-1 Protein Expression

A common approach to evaluating the effects of bacteria on epithelial cells is to incubate the bacteria with the host cells for an initial time period and then wash the cells and evaluate parameters of interest over time. Under these conditions, A. *actinomycetemcomitans* and *F. nucleatum,* as well as most other oral bacteria that have been examined, induce pronounced increases in oral epithelial cell secretion of IL-8 and expression of ICAM-1.[13,26,28] For example, when oral epithelial cells are challenged with *F. nucleatum,* increased secretion of IL-8 is evident at 2 hours after infection with a rapid accumulation of IL-8 in culture fluids (Fig. 9-7, A). In contrast to other bacteria, *P. gingivalis* induces a decrease of both IL-8 secretion and ICAM-1 expression in oral epithelial cells.[11,28] The decrease, or attenuation, in IL-8 in the extracellular fluids is observed by 2 hours after the initial epithelial challenge with the bacterial cells (Fig. 9-7, B). This distinctive effect of P. *gingivalis* has been of particular interest because of its potential role in bacterial evasion of the normal host response.

The attenuation of IL-8 levels by P. *gingivalis* may be accounted for in part by degradation of the IL-8 protein by the bacterial gingipains. However, P. *gingivalis* strains in which the gingipain genes rgpA, rgpB, or kgp are inactivated

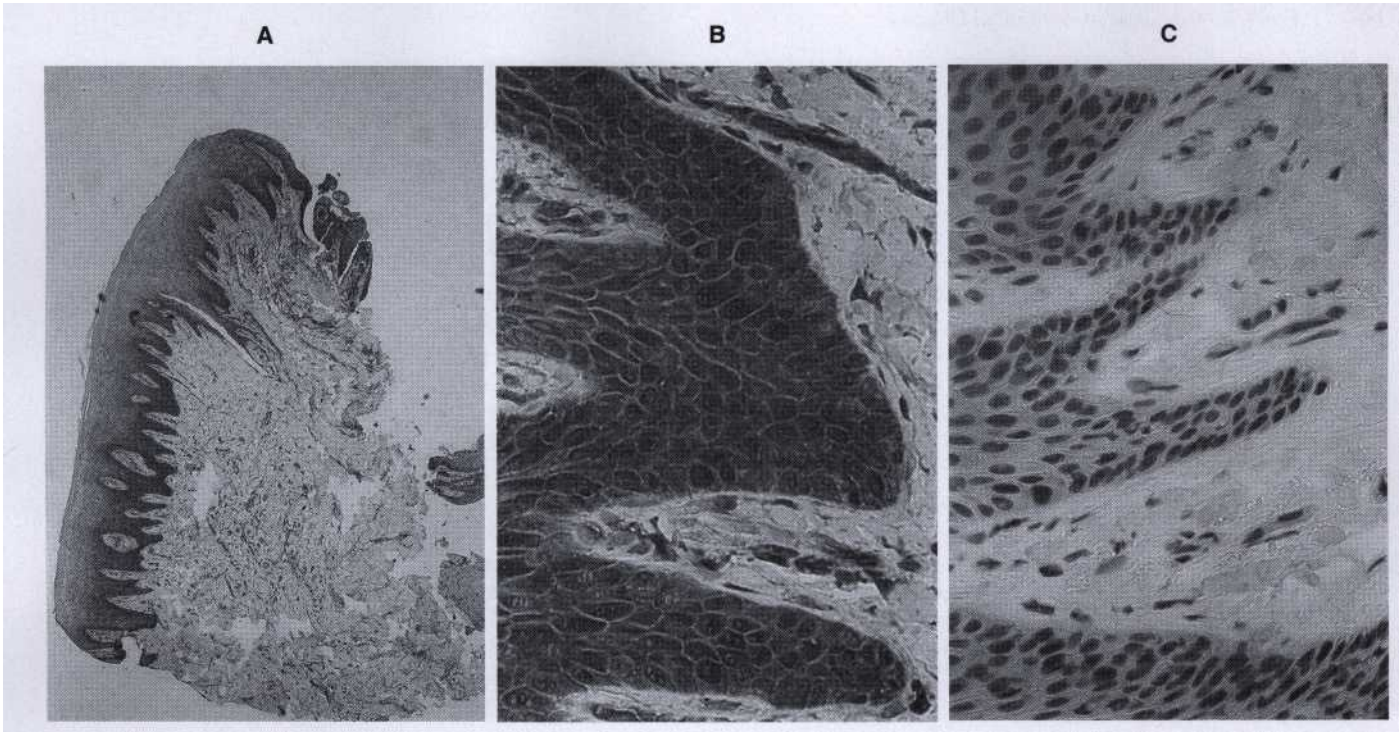

Fig. 9-5 IL-8 Immunohistochemical analysis of a diseased human gingival sample. The tissue samples were stained with antibody specific for human IL-8, or as a negative control nonimmune antibody. (From Huang GT, Zhang X: Immunohistochemical analysis of interleukin-8 and intercellular adhesion molecule-1 in human gingival epithelium. Internat J Oral Biol 1999; 24:7.)

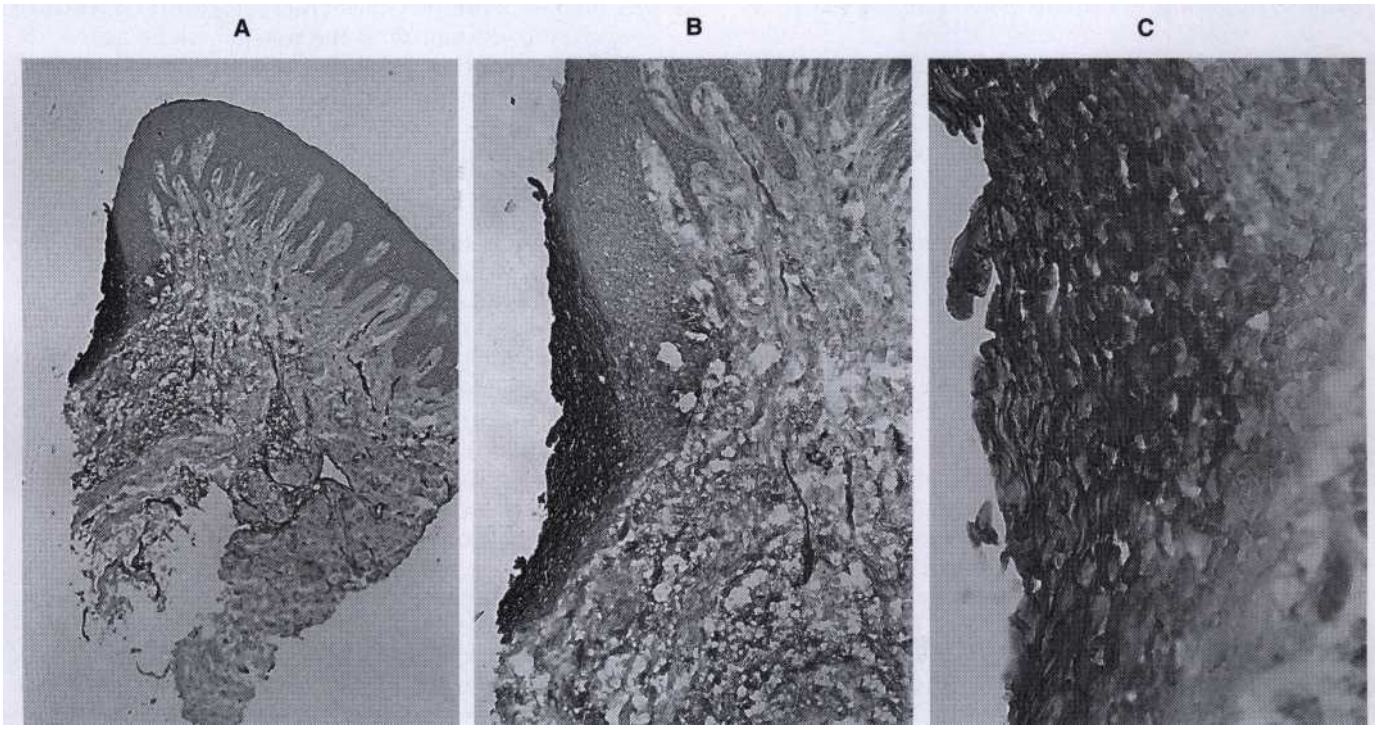

Fig. 9-6 ICAM-1 immunohistochemical analysis of a human gingival sample. The tissue samples were stained with a monoclonal antibody specific for human ICAM-1, or as a negative control nonimmune antibody. A, The tissues demonstrate no ICAM-1 in external gingival epithelium, but strong ICAM-1 staining is evident in the junctional epithelium. Magnification x40. B and C, Higher-power views of the sulcular and junctional epithelium indicate increased ICAM-1 staining in the cells towards the sulcus or tooth surface. Magnification X100 (B) and x400 (C). (From Huang GT, Zhang X: Immunohistochemical analysis of interleukin-8 and intercellular adhesion molecule-1 in human gingival epithelium. Internat J Oral Biol 1999; 24:7.)

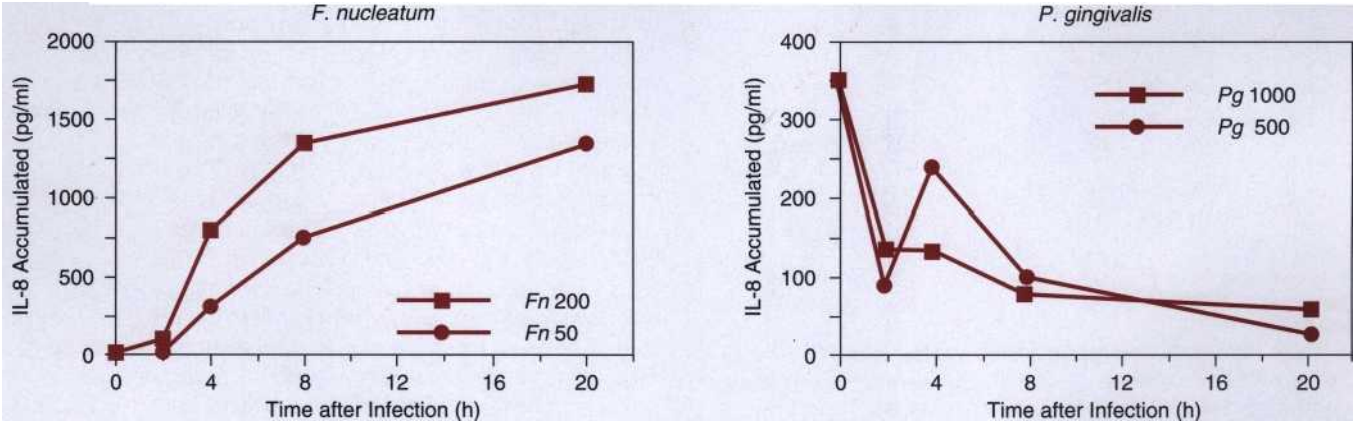

Fig. 9-7 Release of IL-8 by gingival epithelial cells following bacterial challenge. Epithelial cells were challenged by incubation with suspensions of either *F. nucleatum* or *P. gingivalis* for 2 hours. The cells then were washed and incubated with media containing antibiotics to kill any attached bacteria. At various time points, supernatant fluids were collected for measurement of IL-8 by enzyme-linked immunosorbant assay (ELISA). The ratio of bacterial cells per epithelial cell is indicated in the graph. For example, Fn 200 indicates that the results are from an assay using approximately 200 *F. nucleatum* cells per epithelial cell. *F. nucleatum* induced an increase in the secretion of IL-8 from the epithelial cells, whereas *P. gingivalis* causes an attenuation, or loss, of IL-8 from the supernatant. (From Huang GT, Kim D, Lee JK, et al: Interleukin-8 and intercellular adhesion molecule 1 regulation in oral epithelial cells by selected periodontal bacteria: Multiple effects of *Porphyromonas gingivalis* via antagonistic mechanisms. Infect Immun 2001; 69:1364.)

also produce the same IL-8 attenuation as the parental strains.[26] These findings suggest that proteases alone may not account for the alterations evident in IL-8 levels.

Bacterial Modulation of IL-8 mRNA Levels

Control of the level of protein expression can be regulated by degradation of the protein product, in this case IL-8. However, regulation also may occur via processes that govern the level of transcription and translation leading to the final protein product, and the level of specific mRNA in the cells is of interest in this regard. A Northern blot analysis used to evaluate IL-8 and ICAM-1 mRNA levels is presented in Fig. 9-8. The analysis involved probing mRNA samples isolated from the epithelial cells with radiolabeled IL-8- and ICAM-1-specific DNA. The DNA probe binds to complementary sequences in the mRNA sample, and the density of the labeled band reflects the concentration of the specific mRNA present. When oral epithelial cells are treated initially with either F. nucleatum or P. gingivalis, an increase occurs in IL-8 mRNA levels, peaking 2 to 4 hours after bacterial exposure, and then a decrease occurs in background levels. The levels of epithelial IL-8 mRNA from cells challenged with *E. nucleatum* (Fig. 9-8, panel B) is elevated over a 4-hour time period, regardless of whether the cells are challenged continuously (C) or only initially and then washed (W), as compared with untreated cells (mock). It can be seen that ICAM-1 mRNA levels also increase after *E. nucleatum* challenge. The human glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA levels are stable in the epithelial cells, so this probe provides a control to verify that equal amounts of total mRNA have been analyzed.

Northern analyses of mRNA samples from epithelial cells treated with P. gingivalis (Fig. 9-8, panel A) indicate that ICAM-1 mRNA levels are increased with either continuous (C) or initial (W) bacterial challenge. IL-8 mRNA levels also are elevated when epithelial cells are treated initially with the P. gingivalis cells (W). However, continuous incubation (C) of P. gingivalis with the epithelial cells results in a pronounced decrease of IL-8 mRNA levels (Fig. 9-8, panel A). Thus the P. gingivalis interaction with epithelial cells results in an initial increase or upregulation of IL-8 mRNA, followed by a decrease or downregulation of IL-8 mRNA. The mechanism of initial IL-8 mRNA upregulation may be similar to that used by other bacteria. The downregulation of IL-8 mRNA could result from either decreased transcription or an increased rate of IL-8 mRNA breakdown. The downregulation of IL-8 mRNA may be an important factor in the ability of P. gingivalis to attenuate IL-8 levels.

Summary

IL-8 and ICAM-1 are important molecules produced by epithelial cells in response to bacterial challenge. Most oral bacteria induce expression of these molecules, which function in the recruitment, localization, and activation of neutrophils. P. gingivalis possesses the novel ability to downregulate the expression of IL-8 and ICAM-1. The attenuation of IL-8 expression appears to result from a downregulation of IL-8 mRNA, probably in combination with degradation of the IL-8 protein. The regulation of IL-8 at the mRNA levels suggests that P. gingivalis is able to modulate the intercellular signaling pathways of the host epithelial cells, which govern gene

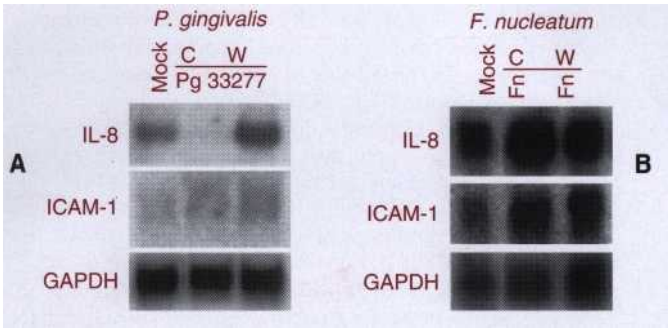

Fig. 9-8 Regulation of mRNA levels by gingival epithelial cells following bacterial challenge. Epithelial cells were challenged with *P. gingivalis* (panel A) or *F. nucleatum* (panel B), either continuously (C) for 4 hours or initially for 2 hours followed by washing and 2 hours of incubation with media without added bacterial cells (W). Control samples were incubated with media only for 4 hours (mock). RNA was isolated from the epithelial cells at 4 hours, and samples were probed with radiolabeled DNA probes specific for IL-8, ICAM-1, or human glyceraldehyde-3-phosphate dehydrogenase (GAPDH; a control for the amount of mRNA per sample). Initial and continuous incubation of *F. nucleatum* with the epithelial cells resulted in increases in the IL-8 and ICAM-1 mRNA, as reflected by the increased density of the reactive bands (panel B). Initial and continuous incubation of P. *gingivalis* with the epithelial cells resulted in increases in the ICAM-1 mRNA. In contrast, the level of IL-8 mRNA was increased with initial incubation, but greatly decreased with continuous incubation with P. *gingivalis.* (From Huang GT, Kim D, Lee JK, et al: Interleukin-8 and intercellular adhesion molecule 1 regulation in oral epithelial cells by selected periodontal bacteria: Multiple effects of *Porphyromonas gingivalis* via antagonistic mechanisms. Infect Immun 2001; 69:1364.)

regulation at either the transcriptional or posttranscriptional levels.

Understanding the molecular mechanisms involved in regulation provides insight into ability of bacteria to manipulate the host response. However, the goal is to understand the effects in the context of the host environment. In healthy individuals, large numbers of neutrophils are present at the site of periodontal lesions, and it is unlikely that *P. gingivalis* could block entirely neutrophil recruitment to the site. The ability of *P. gingivalis* to downregulate IL-8 may slow the recruitment of neutrophils sufficiently to provide an advantage for the bacterium in terms of host tissue degradation. In addition, the local levels of IL-8 may be diminished sufficiently to lessen neutrophil activation, thus lessening neutrophil-mediated phagocytosis of the local bacteria. The phenomena of P. *gingivalis* attenuation IL-8 expression has been referred to as *chemokine paralysis,* [13] and it provides a powerful approach by which the bacterium may be able to subvert host defenses. Further clarification of the mechanisms underlying these effects may lead to new strategies to counteract the effects of *P. gingivalis* on the periodontal tissues.

SUMMARY

As we enter the 21st century, a notable achievement in molecular biology has been the completion of genomic sequencing projects involving the human and bacterial genomes. Information on the genomes of human and periodontal microorganisms will open new avenues to investigate the molecular basis of the host-parasite interaction. It is important to recognize, however, that knowledge of DNA sequence is only one step in identifying and understanding genes that may be relevant to a disease such as periodontitis. A fundamental understanding of how a specific gene and its gene product participate in pathogenesis, and how that information can be used in assessment of risk and development of therapeutics, requires considerably more investigation. The examples discussed in this chapter represent some types of molecular approaches to the study of periodontal pathogenesis as well as potential prognostic and therapeutic implications that may result. Progress in delineating the molecular basis of periodontal pathogenesis in coming years will be greatly increased due to the tremendous advances in DNA sequence information and techniques for its use in molecular analyses.

CLINICAL IMPLICATIONS OF GENETIC STUDIES

FUTURE OF GENETIC STUDIES IN PERIODONTOLOGY

Additionally, periodontitis was thought to be strictly environmental in origin. Despite this belief, it was recognized that only a portion of the variability of disease in the population could be explained by environmental factors alone. In a classic longitudinal study of the natural history of periodontitis, Loe et al[51] found that among individuals with poor oral hygiene and no access to dental care, some developed disease at a rapid rate whereas others experienced little or no disease. This variation must have been attributable to either unrecognized components of the environment or differences among individuals in their susceptibilities to disease. Because host susceptibility may be defined in terms of genetic variation, a relatively recent focus in periodontology has been to quantify genetic risk and identify specific gene variants that determine disease susceptibility. At present, the specific role that genes play in defining susceptibility remains largely unknown. The purpose of this chapter is to provide the reader with a brief overview of some approaches used to ascertain genetic risk and to discuss genetic risk factors for the various forms of periodontal disease.

The American Academy of Periodontology recently established a new diagnostic scheme for the periodontal diseases (see Chapter 4). Diagnoses are now based primarily on the rate of disease progression. The terms *localized juvenile periodontitis* and *generalized juvenile periodontitis* have been replaced with *localized aggressive periodontitis* and *generalized aggressive periodontitis,* respectively. Although aggressive periodontitis, by definition, can occur at any age, it usually has a circumpubertal onset. Previously, juvenile periodontitis was defined within a relatively narrow age range-from puberty to the early 20s. The term *chronic periodontitis is* now used to describe any slow or moderately progressing disease. Previously, *adult periodontitis* referred to chronic disease in patients 35 years of age or older. Because the studies described in this chapter were based on the previous diagnostic classifications, which included these important age restrictions, the former terminology is used when referring to diseases.

Portions of this chapter were adapted from: Pihlstrom BL, Michalowicz BS: Genetic risk for periodontal diseases: A clinical perspective. Journal de Paradontologie D'Implantologie Orale, 1998; 17:123.

OVERVIEW OF GENETIC STUDY DESIGNS

A person's unique genetic code is contained in the sequences of nucleotide bases (adenine, thymine, cytosine, and guanine), which make up deoxyribonucleic acid (DNA). The human genome consists of more than 3 billion pairs of bases contained in 22 pairs of chromosomes, termed *autosomes,* and two sex chromosomes (Fig. 10-1). Genes are sequences of nucleotide bases contained in noncontiguous segments called *exons.* The exons provide the DNA template for the subsequent synthesis of polypeptides that regulate all developmental, physiologic, and immunologic processes in the body. Recent estimates indicate that the human genome contains about 25,000 to 35,000 genes.95

The genetic composition of an organism is termed the *genotype,* and the collection of traits or characteristics is termed the *phenotype.* The phenotype is determined by the interaction of genes and the environment." Traits and diseases might be caused by a single gene (monogenic), several genes (oligogenic), or many genes (polygenic). Diseases whose etiologies include both genetic and environmental factors are referred to as *multi factorial.* Most common diseases are multifactorial.

Specific locations on chromosomes are referred to as loci, and variations in the nucleotide sequence at a locus are termed alleles. At a given locus, an individual is considered homozygous if the alleles are identical on homologous chromosomes or heterozygous if the alleles are different. Some alleles are associated with profound changes in the phenotype, whereas others have no measurable effects. Phenotypic differences in the population may be caused by the effects of alleles in the coding region of a gene or in flanking noncoding regions that control gene transcription or expression.

The term genetic marker refers to any gene or nucleotide sequence that can be mapped to a specific location or region on a chromosome. From a genetic epidemiologic viewpoint, any marker that is sufficiently polymorphic, or variable, in the population can be used to map or locate disease alleles. Finally, there is an important distinction between the role of genes in monogenic disorders such as Huntington's disease and their role in complex multifactorial diseases such as periodontitis. In monogenic disorders, genes are referred to as *causative* because nearly everyone with the mutation develops the condition. Environmental factors generally play a minor role in determining the phenotype. In contrast, genes involved in complex multifactorial diseases are often referred to as *susceptibility genes* (or more correctly, *susceptibility alleles).* For these diseases, individuals who inherit susceptibility alleles will not develop disease unless they are exposed to deleterious environments. For the periodontal diseases, important environmental risk factors include gram-negative anaerobic microorganisms, cigarette smoking, and poor oral hygiene.

The theory that genes influence susceptibility to common diseases such as periodontitis is not new or revolutionary. Given its complex etiology and pathogenesis, variations in any number or combination of genes that control the development of the periodontal tissues or the competency of the cellular and humoral immune systems could affect an individual's risk for disease. In

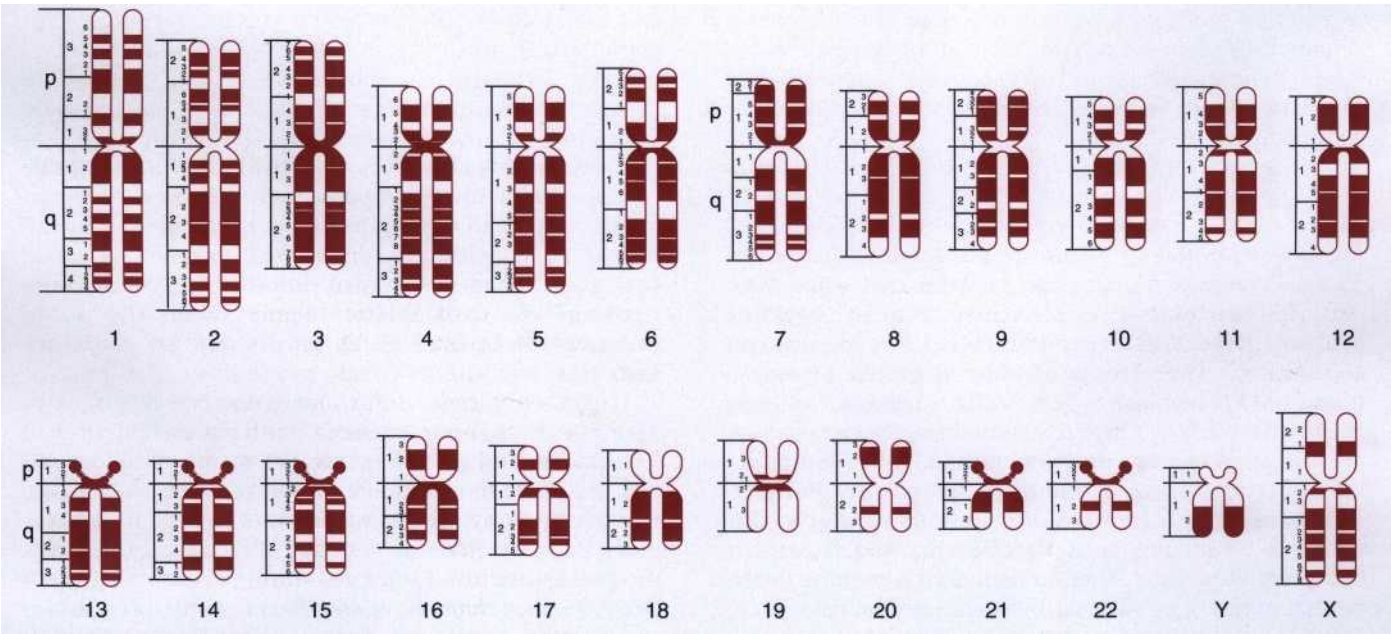

Fig. 10-1 The nomenclature used to locate positions along chromosomes is based on the physical appearance and staining patterns of chromosomes viewed during prophase or early metaphase. Each chromosome contains a short arm (p, or petite) and long arm (q). In this schematic, termed an *ideogram,* the chromosomes are depicted as they appear following Giemsa staining (hence the term G *banding patterns).* Genes are located based on their positions within these bands. For example, 11 q23 denotes a position in the third band of the second region on the long arm of chromosome 11. Sub-bands are designated by decimal points (e.g., 11 823.2). (From Jorde LB, Carey JC, White RL [eds]: Medical Genetics. St Louis, Mosby, 1995.)

fact, critics might argue that every trait and disease likely has some genetic variation and that merely confirming this fact has little or no practical value. Once the genetic basis for a disease has been established, it is equally important to determine which alleles have a measurable effect on the phenotype and whether the prevention, diagnosis, or treatment of the disease can be improved once disease alleles are identified. The former issue can be addressed in a systematic but nontrivial manner. The latter issue is more complex and involves debate on scientific, ethical, and public health grounds.

Segregation Analyses

Inherited diseases "run" in families. The pattern in which the disease is transmitted across generations depends on whether the disease alleles lie on autosomes or sex chromosomes, whether they are dominant or recessive, and whether they are fully or partially penetrant. Generally, a dominant allele determines the phenotype in a heterozygote with another recessive allele. A recessive allele determines the phenotype only when present at both loci on homologous chromosomes. Penetrance refers to the probability that a particular phenotype will result from a genotype. Partially penetrant means that only a fraction of individuals who inherit the disease alleles will be affected.

In segregation analyses, the observed pattern of disease in families is compared with patterns expected under various models of inheritance. The statistical power of this design depends on the number and composition of the families and the heterogeneity of the disease. Heterogeneity means that there are different causes of disease among families. Generally, segregation analyses have low power to resolve heterogeneity. Segregation analyses also cannot distinguish between genetic effects and unmeasured environmental causes of disease, such as the transmission of pathogenic organisms within families.21

Twin Studies

The relative influence of genetic and environmental factors on complex diseases can be estimated using twin data. In the classic twin study, reared-together monozygotic and dizygotic twins are compared to estimate the effects of shared genes. Monozygotic (MZ) twins are genetically identical, whereas dizygotic (DZ) or fraternal twins share on average 50% of their genes by descent. For binary traits (present or absent) a genetic effect is inferred if the positive concordance rate, or percentage of twin pairs in which both twins are affected, is greater for MZ than DZ twins. For continuous measures, such as periodontal probing depth or attachment loss, intraclass correlations are calculated. These correlations reflect the variation between twin pairs relative to the variation within pairs. Typically, twin data are used to estimate heritability, which is the proportion of phenotypic variation attributed to genetic variation. A heritability estimate of 50% means that one half of the variance in the population is attributed to genetic variance. It does not mean that there is a 50% chance that offspring of affected parents will be affected. Very large samples of reared-together twins are needed to estimate heritability with precision.

Heritability also can be estimated from MZ twins who are separated at birth and raised apart. Because they do not share a common environment, similarities between such twins may be attributed to the effects of shared genes. (Raised-apart twins also share an environment in utero. To the extent that this environment affects the disease, heritability estimates from MZ twins raised apart may be artificially inflated.) Although more powerful than the classic twin design, few such studies have been conducted because of the scarcity of such twins.

Regardless of the method of estimation, heritability pertains to populations and not individuals. Furthermore, such estimates describe the impact of genes on specific populations exposed to a particular range of environments. Finally, twin studies alone cannot be used to determine the mode of inheritance of a disorder or the number or location of disease alleles.

Linkage and Association Studies

Linkage and association studies are used to map disease alleles to specific regions on chromosomes. These studies exploit a unique feature of the way in which alleles segregate during meiosis. During gametogenesis, diploid cells (containing 2N copies of each allele) divide to become haploid (containing only one copy of each parental allele). The probability that two alleles at different loci will recombine (termed a *recombination* or *crossover event) is* generally proportional to the distance between them. Two alleles selected at random from the genome will likely recombine, and the chance that any two maternal or paternal alleles will be transmitted together to an offspring is 50%. Alleles at nearby loci, however, tend to segregate together; that is, they are linked. By identifying genetic markers that segregate with disease, researchers can infer the location of putative disease alleles. It is not necessary for the same marker allele to be transmitted with the disease allele in all affected families, and a marker that is linked to the disease allele within a family may not be associated with disease in the population. Allelic associations (linkage disequilibrium) occur when the same marker allele is linked to disease in multiple families (Fig. 10-2).

Linkage studies use sets of families, or pedigrees, with multiple affected individuals. Genotypes are determined for affected and unaffected family members, and complex statistical models are used to determine whether the marker allele(s) and disease cosegregate in the families under a given inheritance model. Parameters that must be specified in the model include the mode of inheritance, frequency of the marker allele in the population, and disease penetrance. The summary statistic used to assess linkage is the logarithm of the odds (LOD) score, which is a measure of the likelihood that the marker and disease alleles are linked versus not linked at a given recombination rate. Although linkage analyses are typically conducted for qualitative traits or diseases, methods to evaluate linkage for quantitative traits or

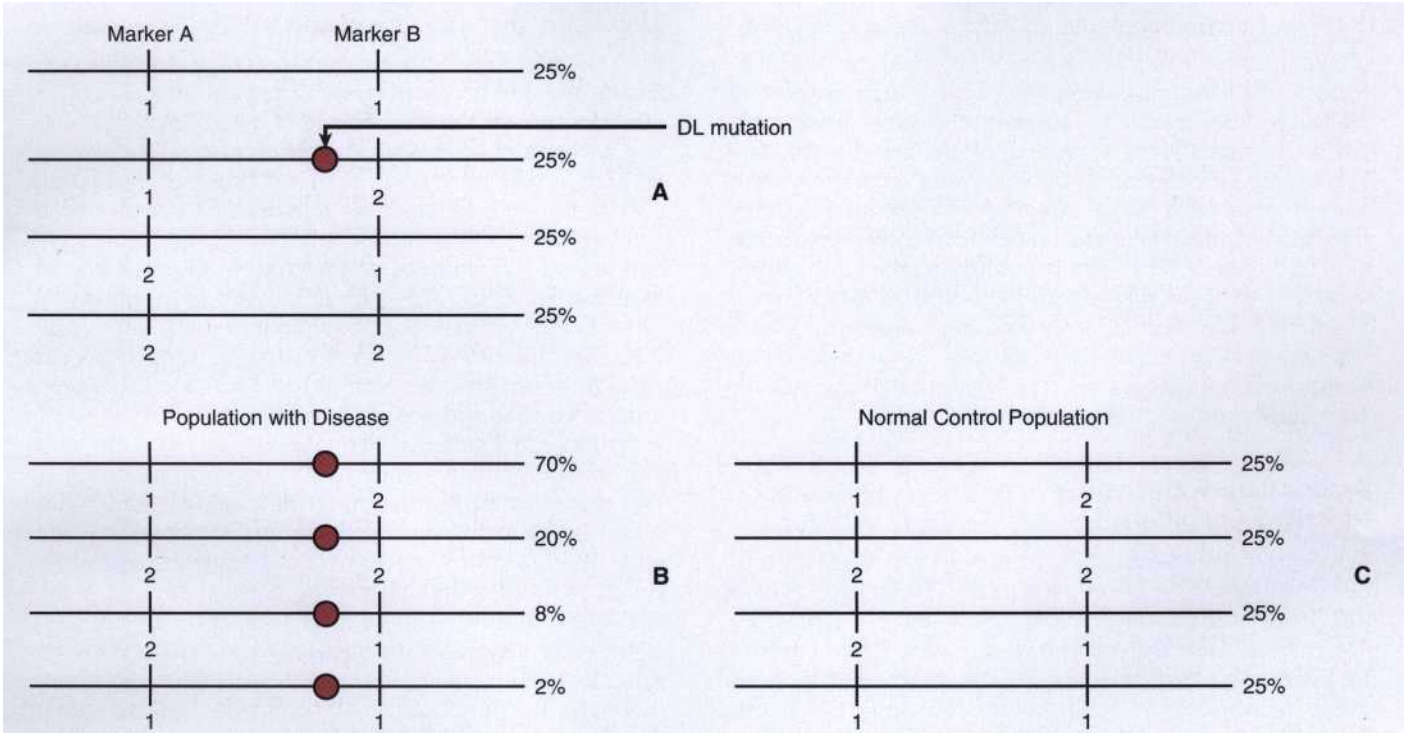

Fig. 10-2 Linkage disequilibrium between a disease locus (DL) and two linked loci, A and B. The DL mutation first arises on the chromosome with the A1 B2 haplotype. After a number of generations, most chromosomes carrying the DL mutation still have the A1 B2 haplotype, but as a result of recombination the DL mutation is also found on other haplotypes. Because the A1B2 haplotype is seen in 70% of DL chromosomes but only 25% of normal chromosomes, there is linkage disequilibrium between the DL and loci A and B. Because locus B is closer to DL, it is in greater linkage disequilibrium with DL than is locus A. (Modified from Jorde LB, Carey JC, White RL [eds]: Medical Genetics. St Louis, Mosby, 1995.)

measures have been developed. Once linkage to a particular region has been established, the task of identifying the actual disease allele or mutation is far from trivial. Linkage can be detected if the marker and disease alleles are within 20 to 30 centiMorgans (cM) of one another. In humans, 1 cM represents approximately 1 million nucleotide bases. Because sequencing 20 million to 30 million base pairs in search of mutations remains a daunting task at present, fine marker mapping is used to further refine the regions of interest. Fortunately, given the rapid progress in decoding the human genome, it will soon be possible to identify all nearby candidate genes for study once linkage is established.

To test for associations (linkage disequilibrium), the frequency of alleles at a given locus is compared between subjects with disease (cases) and healthy controls sampled from the same population. Although commonly used in genetic epidemiology, results from case-control studies should be interpreted with caution. An association does not necessarily imply a biologic link between the disease and an allele. It may be due to some environmental component causing both the marker and the disease to increase in the population, an unrecognized difference in the racial or ethnic makeup of the cases and controls, or chance alone.[13] The finding of true linkage disequilibrium in an outbred and random mating population implies that the disease and marker alleles lie very close to one another on a chromosome.

Associations (linkage disequilibrium) suggest that the presence of an allele confers risk for disease within a defined environment. This later qualification is essential when discussing common multifactorial diseases such as periodontitis. Alleles that can be used to predict disease in one population may not be useful in other populations or even in the same population when exposed to markedly different environments. For example, suppose a gene that influences the humoral response to a particular class of bacterial antigens is polymorphic in the population. Individuals with the low-response, or "disease," allele cannot effectively suppress the growth of pathogenic microorganisms that express these antigens. In the presence of the pathogens, individuals with the low-response allele develop disease. On the other hand, no relationship may exist between the disease and this allele in populations where the particular bacteria are either never or only rarely present. Therefore the notion of "high-risk" alleles may be specific to an environment.

EARLY ONSET PERIODONTAL DISEASES

The early onset periodontal diseases (EOP) are a group of diseases -prepubertal, juvenile, and rapidly progressive periodontitis-that occur in children, adolescents, and young adults. The rate of periodontal destruction is greater in EOP than in the more common adult or chronic form. Although diagnoses are based on clinical

and radiographic criteria, the immunologic and microbiologic profiles can vary substantially within the subforms. This variability complicates the search for disease alleles because multiple causes of the same phenotype (etiologic heterogeneity) and different genetic risk factors acting in different subpopulations (genetic heterogeneity) may exist. Most studies of the EOP to date have had inadequate statistical power to resolve substantial genetic heterogeneity. The variability in the clinical presentation of these diseases and the limited criteria used to establish disease diagnoses also have made the search for susceptibility genes more difficult. Nonetheless, evidence from a variety of sources suggests that the risk for EOP may be substantially heritable. [83]

Associations with Genetic and Inherited Conditions

Early onset periodontitis is a consistent feature in a number of inherited or genetic disorders (Table 10-1). These disorders, which have been discussed in detail by Soafer" and Hart, [39] demonstrate the ways in which major genes can affect risk for EOP. The disorders have been grouped according to the resultant protein or biochemical defect(s)-the mutant alleles may affect the function of phagocytic immune cells or the structure of epithelia, connective tissue, or the teeth themselves. For some conditions, the specific gene or tissue defect responsible for the condition has been identified; for others, it has not.

Hypophosphatsia is a rare disorder caused by mutations in the tissue-nonspecific alkaline phosphatase gene (1p36.1-p34).[77] These mutations lead to a deficiency in alkaline phosphatase that results in abnormal bone mineralization, skeletal anomalies, and cementum hypoplasia. Both autosomal dominant forms and recessive forms have been reported. Although the infantile form is usually fatal, milder forms can occur in children and adults. The condition leads to the premature loss of the primary and occasionally the permanent teeth. [14]

Papillon-Lefevre Syndrome (PLS) is a **rare autosomal recessive disorder characterized by palmoplantar hyperkeratosis and early onset periodontitis** (Color Fig. 10-1).[2838] Both the primary dentitions and secondary dentitions can be affected. PLS is caused by mutations in the cathepsin C gene, located on chromosome 11 (11q14-q21).[33,93]

Cathepsin C is a cysteine protease normally expressed at high levels in various tissues, including epithelium and immune cells such as polymorphonuclear leukocytes (PMNs).[75] It appears to function in protein degradation and activation of proenzymes in immune and inflammatory cells. PLS patients, who lack almost all cathepsin C activity,[93] are either mutant homozygotes (i.e., they inherited the same mutation from both parents) or compound heterozygotes (i.e., they inherited a different mutation from each parent).[32]

In some PLS patients, EOP is associated with the virulent microorganism *Actinobacillus actinomycetemcomitans*. The periodontal destruction in PLS patients can be arrested by eradicating *A. actinomycetemcomitans*," which raises the possibility that EOP is not a direct result of the genetic mutation but rather the consequence of a specific bacterial infection in a highly susceptible host.

Inherited disorders such as acatalasia, leukocyte adhesion deficiency, and the Chediak-Higashi syndrome highlight the importance of competent phagocytes in the defense against periodontal infections. Many, but not all, patients with prepubertal periodontitis also have some inherited or congenital defect in phagocytic cell function. The immunologic defects associated with these syndromes can be profound, and patients generally suffer from systemic infections in addition to periodontitis. Although the mutant alleles responsible for these syndromes may be uncommon, other, more common alleles at the same loci may serve as candidate markers for nonsyndromic forms of EOP. Very recently, nonsyndromic prepubertal periodontitis-affected individuals in a Jordanian family were found to be homozygous for a cathepsin C gene mutation (Fig. 10-3). [34]

To reach the periodontal tissues, blood-borne phagocytes must adhere to and then traverse the blood vessel wall. Surface molecules present on both the phagocyte and endothelium mediate this adhesion. Three adhesion

TABLE 10-1

Genetic and Inherited Disorders Associated with Early Onset Periodontitis

Disorder	Protein or Biochemical Defect
Leukocyte adhesion deficiency Type I	CD18 (ß-2 integrin chain of the LFA molecule)
Leukocyte adhesion deficiency Type II	CD15 (neutrophil ligand for E and P selectins); inborn error in fucose metabolism
Acatalasia	Catalase enzyme
Chronic and cyclic neutropenias	Unknown
Chediak-Higashi syndrome	Abnormal transport of vesicles to and from neutrophil lysosomes caused by mutations in the lysosomal trafficking regulator gene
Ehler-Danlos syndrome [Type IV, VIII, IX]	Type III collagen
Papillion-Lefevre syndrome	Cathepsin C (dipeptidyl aminopeptidase I)
Hypophosphatsia	Tissue-nonspecific alkaline phosphatase
Trisomy 21	Multiple; critical trisomic region is at least 5 Mb long
Prepubertal periodontitis (nonsyndromic)	Cathepsin C

molecules expressed on leukocytes are composed of a unique a subunit (CDlla, b, or c) and a common /3 subunit (CD18). When too few of these molecules are present, cells cannot adhere to endothelium and an important component of the cellular immune response is compromised. Patients with inherited deficiencies in leukocyte adhesion molecules are at high risk for EOP and especially prepubertal periodontitis in particular. Two inherited forms of leukocyte adhesion deficiency (LAD) have been described, each of which affects a different adhesion molecule. Homozygotes carrying two copies of the mutant allele experience a dramatic reduction in the number of leukocyte adhesion molecules and develop recurrent infections including periodontitis (Color Fig. 10-2). Expression is about half of normal in heterozygotes carrying one mutant and one nonmutant allele. Although cell adherence is usually normal in heterozygotes, they may be at increased risk for adult-onset disease .[96]

Segregation Analyses of Early Onset Periodontitis

It has been recognized for years that juvenile periodontitis (JP) aggregates in families.[8,12] This finding suggests but does not prove that the disease has a genetic basis. Clustering within families can occur because of shared environmental factors. Evidence for a heritable basis for JP, however, comes from a variety of sources.

In most studies of JP, the localized and generalized forms (LJP and GJP, respectively) have been considered variants of the same disorder. This theory is supported by the observation that both forms frequently occur in the same family[52,54,57]; the probability of two rare diseases occurring in the same family is exceedingly small. Prepubertal periodontitis and JP also have been observed in the same family,[88] which again suggests that these diseases have shared genetic risk factors. Also, different forms of EOP diseases have been observed to occur sequentially in the same individual.[86]

Many case reports of multiplex families (containing more than one affected member) with EOP are available. The patterns of disease in these families have led investigators to propose both dominant inheritance and recessive modes of inheritance. However, few formal segregation analyses have been conducted, and the results have been varied (Table 10-2). Melnick et all' proposed X-linked inheritance due to the preponderance of female probands (the initially identified disease-afflicted individual in the family) and affected family members. Later, this preponderance was attributed to ascertainment bias because women are more likely than men to seek dental care and participate in family studies.[37] Also, father-to-son transmissions, which were not seen in earlier studies (the lack of such transmissions suggested X-linked inheritance) were observed in later studies. The autosomal recessive mode was clearly favored in Finnish populations because parents of probands were not affected.[80,81] In the largest study conducted in the U.S. to date, the autosomal dominant mode was favored in African-American and Caucasian families.[54] The estimated frequency of the disease allele, however, was significantly higher in African-Americans and reflects the higher prevalence of EOP in this group.

Segregation analyses consistently have supported the role of a major gene in the etiology of the EOP Multifactorial or polygenic models alone cannot adequately account for the patterns of disease observed in families. Results from these studies, however, are prone to error due to the difficulty in correctly diagnosing older individuals, the variable clinical appearance of disease, and the likely etiologic and genetic heterogeneity of these diseases.[10,72] Beaty et al[5] recognized that the narrow age range in which EOP can reliably be diagnosed increases the chance that an incorrect model of inheritance is favored over the true one.

Schenkein[82] proposed a model of inheritance that distinguishes between the etiologies of localized and generalized EOP and allows for family clustering. He theorized that EOP and immunoglobulin (Ig) G2 responsiveness to bacterial lipopolysaccharides (LPS) segregate independently as dominant and codominant traits, respectively. Under this model, subjects with one EOP allele and two copies of the high IgG2 response allele would develop only localized disease. In contrast, subjects who carry the EOP allele and only one copy of the IgG2 allele would develop more widespread disease because their IgG2 response to LPS would be less robust. This model, although appealing, requires more rigorous testing, and the work needed to resolve the confounding effects of race and smoking on IgG2 levels and disease is far from trivial.

Linkage Studies of Early Onset Periodontitis

To date, few linkage studies of EOP have been performed. Boughman et a1[11] was the first to report linkage between

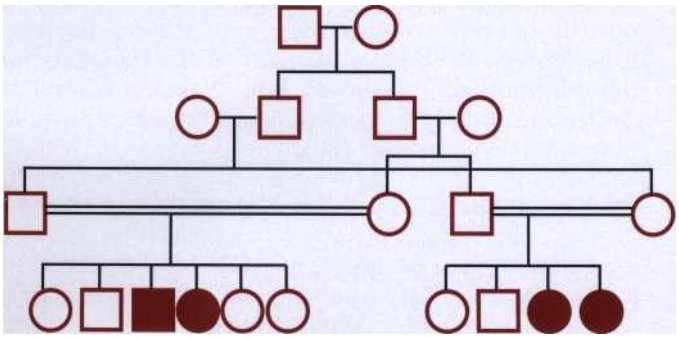

Fig. 10-3 Pedigree of a family segregating for prepubertal periodontitis. Filled squares and circles denote affected males and females, respectively. The double lines between the parents of affected individuals indicate they are blood relatives (in this case, first cousins), which is a frequent finding in rare autosomal recessive disorders. Affected individuals were homozygous by descent for a mutation in the cathepsin C gene. The four parents of the affected individuals were heterozygous for the mutation, as were the two unaffected siblings. None of these heterozygotes had clinical evidence of the disease. (From Hart TC, Hart PS, Michalec MD, et al: Localization of a gene for prepubertal periodontitis to chromosome 11q14 and identification of a cathepsin C gene mutation. J Med Genet 2000; 37:95.)

TABLE 10-2

Segregation Analyses of the Early Onset Periodontal Diseases

Racial/Ethnic Groups	Number of Families (Individuals)	Favored Model	Comments	Reference
Caucasian and African-American	19(88)	X-linked dominant	Reviewed cases in the literature plus 2 new ones. Recognized paucity of males in families. Penetrance estimated at 75%.	57
Finnish	31 (158)	Autosomal recessive	Genetic ratio 0.26 for complete and 0.17 for very incomplete ascertainment. No affected parents observed.	81
	30(142)	Autosomal recessive	Genetic ratios highly consistent with AR[1] mode. No affected parents observed.	80
Triracial isolate	1 (50)	Autosomal dominant	One five-generation family. JPZ cosegregated with dentinogenesis imperfecta. Disease allele linked to chromosome 4.	11
African-American, Caucasian, Asian	32(199)	Autosomal recessive	Tested AR, XD[3], and sporadic models. XD mode favored in 8 of 33 kindreds.	52
Not specified, US sample	28(157)	Autosomal recessive	High type II error realized for mistakenly accepting AR over AD[4] model. Tested AR, XD, and sporadic models.	5
African-American, Caucasian	100 (631)	Autosomal dominant	Evidence of racial heterogeneity. Disease allele more frequent in African-Americans than Caucasians.	54

[1] *AR,* Autosomal recessive.
[2] /P, Juvenile periodontitis.
[3] *XD,* X-linked dominant.
[4] *AD,* Autosomal dominant.

JP and a specific chromosomal region. These researchers studied an extended family in which an autosomal dominant form of JP was found to cosegregate with dentinogenesis imperfecta (DGI). A putative JP gene was localized to the long arm of chromosome 4 (4g11-13) near the gene for DGI. In the general population, however, juvenile periodontitis does not cosegregate with DGI and linkage to this same region has been excluded.[36]

Saxen and Koskimies" typed a small number of multiplex Finnish families for the HLA antigens and concluded it was unlikely that JP was linked to this region. In a Virginia family study, genome-wide searches identified two chromosomal regions suggestive of linkage but failed to identify any that were statistically significant.98 Again, disease heterogeneity appeared to be a complicating factor because this sample provided sufficient power to detect linkage to a major gene if the disease were genetically homogeneous.

Association Studies of Early Onset Periodontitis

Rather than conducting random searches of the genome for alleles associated with EOP, researchers have focused on candidate regions. These regions lie within or near genes that code for enzymes or regulatory molecules that are likely to be involved in the pathogenesis of disease. The number and variety of candidates for EOP are vast. Polymorphisms in genes encoding the immunoglobulin receptors, LPS binding proteins, prostaglandins, and cytokines are all suitable markers for study.[35,99] Polymorphisms in the vitamin D receptor[40] and mutations in the N-formyl-1-methionyl-l-leucyl-l-phenylalanine (FMLP) receptor[30] have been associated with localized forms of EOP.

The human leukocyte antigens (HLA) have been considered to be candidate markers for EOP because they are involved in regulating immune responses. More than 40 diseases, most of which are autoimmune in nature, have been associated with various HLA antigens.[92] Genes for the class I and II antigens are located on chromosome 6 in humans. Nearby genes encode for complement fragments and the proinflammatory cytokine, tumor necrosis factor-a. Currently, more than 150 HLA antigens have been defined serologically. Dissection of the coding sequences has revealed even more impressive variation at the genotype level. More than 220 alleles that code for the ß-1 molecule of the dimeric class II DR antigen (DRB1 alleles) have been identified. Although this variation is desirable for linkage studies (because most individuals will be heterozygotes for a given marker), it can hinder the search for allelic associations (linkage disequilibrium). With so many antigens and alleles, the chance of obtaining an adequate number of subjects with any particular HLA type is small except in large, homogeneous samples. Also, the possibility that an asso-

ciation will be found due to chance alone increases with the number of tests conducted. For example, consider a study that tests for associations between periodontal disease and all known HLA antigens. At a standard significance level of 5%, approximately 7 antigens (150 antigens multiplied by 0.05) would be expected to be associated with the disease by chance alone. Although statistical methods to adjust for multiple hypotheses testing are available, such corrections have not always been made.

Despite the many case-control studies of HLA antigens in the periodontal literature, few consistent findings are available (Table 10-3). This inconsistency may be due to false-positive findings, differences in the racial or ethnic makeup of the study groups, differences in the clinical criteria used to define patient groups, or true heterogeneity. Two antigens that appear to be consistently associated with EOP are HLA-A9 and 1115. The risk of disease in subjects with HLA-A9 or B15 is about 1.5 to 3.5 times greater than in those lacking these antigens." In contrast, the HLA-A2 antigen appears to be less prevalent in juvenile periodontitis patients than controls, suggesting that this antigen somehow may be protective.[42,43,91] The class II DR4 antigen has been of particular interest in periodontology because of its association with insulin-dependent diabetes mellitus (IDDM). IDDM patients with the DR4 antigen are at increased risk for diabetes-related complications,[78] including periodontitis. It has been suggested that the HLA-D antigens may mediate the association between periodontal disease and IDDM.[22] Although the number of cases was small, Katz et al[44] found the DR4 antigen to be more prevalent in EOP cases than controls. Others, however, have found no association with this antigen (see Table 10-3).

The interleukin (IL)-1 gene has been studied because of its role in the initiation and progression of the periodontal lesion. Produced primarily by activated monocytes, its actions are pleiotropic; it stimulates bone resorption, inhibits collagen synthesis, and upregulates matrix metalloproteinase activity and prostaglandin synthesis.[48-90] IL-1 exists in two forms, IL-1a and IL-1ß. An IL-1 antagonist (IL-1 ra) blocks the activity of IL-1 by competitively binding to IL-1 receptors. In humans, genes encoding IL-la, IL-1ß, and IL-1 ra are clustered on the long arm of chromosome 2.[65] Although several polymorphisms have been identified in this region, not all correlate to differences in IL-1 activity. However, one variant, due to a single nucleotide base-pair substitution in a coding region, has been associated with a four-fold increase in IL-1ß production.[35] Because the magnitude of the IL-1 response may correlate to the levels of tissue destruction, functional polymorphisms in the IL-1 gene region could influence susceptibility to periodontitis.[48]

An IL-1ß allele has been reported to be in linkage disequilibrium with generalized EOP,[21] suggesting that at least one disease allele is at or very close to this Il-1ß polymorphism (2q13). In this study, linkage disequilibrium was detected using the transmission disequilibrium test, which contrasts the number of marker alleles transmitted versus not transmitted from heterozygous parents to affected offspring. The probability that an unlinked marker allele will be transmitted is 50%. If the marker and disease allele are in linkage disequilibrium, however, the marker will be transmitted more than 50% of the time. The number of nuclear families in this report was small, however, and sibling pair analyses of the same population provided only little if any evidence of linkage to this region.[21] However, this "high-risk" Il-1ß allele may be too common in African-Americans-who are at higher risk than Caucasians for these diseases-to be of diagnostic value for JR.[97]

PERIODONTITIS IN ADULTS

Clinicians have long suspected that susceptibility to periodontitis differs among racial and ethnic groups. In the U.S., African-Americans have more severe disease than Caucasians.[7,68] Elsewhere, Sri Lankans and South Pacific islanders appear to be more prone to disease than other groups with similar environments.' Although these differences may be due to unrecognized environmental factors, they also may be the result of differences in genetic makeup.

Measures of periodontitis and gingivitis are correlated within families.[6,94] The basis of this similarity-whether it be shared environmental factors or genes-has been investigated in several large family studies. Initially, studies of Japanese and Hawaiian children suggested that gingivitis was due to recessive genes.[84] Later, correlations within families (e.g., sibling, parent-offspring) were used to estimate genetic and environmental variances for periodontitis among various racial groups in Hawaii. It was concluded that similarities within families were attributable to cultural inheritance and the common family environment, but not shared genes.[15-74] Beaty et all reported similar results in a sample primarily of African-Americans. The correlations in clinical periodontal measures were greater between mothers and offspring than between fathers and offspring. Sibling correlations in this study were generally low, and the hypothesis of no familial correlation (and hence no genetic effect) could not be rejected.

Twin Studies of Adult Periodontitis

As early as 1940, Novack[66] recognized that the periodontal conditions of identical twins were often similar. Independent twin studies in Minnesota and Virginia concluded that a significant heritable component to adult periodontitis exists. The Minnesota group 5[8,59,61,62] studied both reared-together and reared-apart adult twins. Examples of twins in this study are depicted in Color Figs. 10-3 and 10-4. Between 38% and 82% of the population variance for gingivitis, probing depth, and clinical attachment loss could be attributed to genetic variation. A significant heritable influence on radiographic crestal alveolar bone height was found in these same twins. Moreover, reared-apart MZ twins were no less similar than reared-together MZ twins, indicating that the family environment had no significant influence on clinical measures of disease. The latter finding was surprising because it is within this environment that oral hygiene behaviors are learned and pathogenic bacteria may be acquired from other family members.

TABLE 10-3

HLA Antigens and Alleles in the Periodontal Disease: Summary of Association Studies

Disease	Ages of Cases (Years)	Racial/Ethnic Group	Number of Cases	Number of Controls	Associations with Disease	Comments	References
JP and non-JP EOP	13–30	Caucasians	19 JP, 28 non-JP	41[1] 267[2]	↓ A2, A5 in non-JP	Trend for ↓ A2 in JP. No associations with ANUG.	42, 91
RPP	23–39 Median 31	Caucasians	44	2041[2]	↑ A9 (A24)	Subjects had no evidence of past JP. No significant ↑ in B15 or DR antigens although trend for DR5.	45
JP and non-JP EOP	13–30	Caucasians	33 JP, 41 Non-JP	53	↓ A2 in non-JP	Similar trend for JP. No difference in A9, A28, Bw15. Also tested ABO blood groups.	43
JP	11–29 Mode 21	Caucasians	39	1967[2]	↑ A9, A28, Bw15	No significant associations with AP. Trend for ↓ A2 in JP group.	76
JP	≤25	Caucasians & African-Americans	30	341	↑ Bw15 in blacks (Class I only)	Trend for ↑ B12 in whites. Small samples. No evidence of linkage to HLA region in collection of 8 families.	20
EOP	Mean 26.5	Japanese	24	47	None (Class II only)	Trend for ↑ DRB1 ×1401, ×1501, & DQB1 ×0503, ×0602. DR association thought to be due to linkage disequilibrium with DQ alleles.	67
JP	15–25	Afro-Caribbeans	38	42	↑ A1, B22, A28, DR7 ↓ A68 (28), B5, DR2	None remained significant following corrections for multiple comparisons.	64
RPP	21–35	Ashkenazi and non-Ashkenazi Jews	10	120	↑ DR4	Small sample size. Borderline and uncorrected P value.	44
JP	Puberty to 35	Non-Ashkenazi Jews	26	113[2]	↑ A9, B15	Associations in GJP but not LJP group. No association with DR antigens.	87
RPP	20–35	6 ethno-geographic groups	12	55	↑ DRB1 ×0401, ×0404, ×0405, or ×0408	Small sample of EOP. No significant association for all patients (n = 48) or for all DR alleles combined.	9

LJP & RPP	LJP: puberty–24; RPP: puberty–35	Turkish citizens	30 LJP, 30 RPP	3731[2]	↑ A9 (A24), DR4	↑ DR4 in both patient groups.	24

1 Resistant group.

2 Population-based controls, disease status not determined.

3 15 subjects with insulin-dependent diabetes mellitus.

EOP, Early onset periodontitis; JP, juvenile periodontitis; RPP, rapidly progressive periodontitis; AP, adult periodontitis.

Despite the usefulness of the twin study design, very large sample sizes are needed to estimate heritability precisely. For example, heritability for clinical attachment loss in the preceding study was estimated to be 48%.[58] The 90% confidence interval for this estimate was quite large, ranging from 21% to 71%.

A questionnaire survey of several thousand adult twin pairs provided further evidence of the heritable component to periodontitis.'[9] The concordance rate for disease was significantly greater in MZ twins (23%) than DZ twins (8%). Although the assessment method is questionable-twins may not be aware of their own or their twin's periodontal condition-the findings were confirmed in a more recent clinical study from the same population.60 Heritability estimates for the extent and severity of disease were approximately 50%, which were consistent with previous estimates. The heritable component for periodontitis was not associated with behaviors such as smoking, utilization of dental care, and oral hygiene habits. This implies that genes controlling biologic mechanisms, and not behaviors, mediate the genetic influence on disease.

The twin design also has been used to study whether host genes affect the composition of the oral microbiota. Oral bacteria are transmitted within families,[3] a finding that could partly explain why periodontitis can cluster in families. Although the introduction of a bacterium into the oral cavity is an environmental event, long-term colonization of the host may be determined by both host genetic factors and environmental factors. Adolescent twins have been found to be more similar in their oral microbiota than pairs of unrelated individuals.[63] In adults, however, neither host genes nor the early family environment appear to significantly influence the presence of periodontal bacteria in subgingival plaque.61 Together, these findings suggest that although host genes may influence initial colonization, this effect does not persist into adulthood.

Association Studies of Adult Periodontitis

Many of the same genes considered candidates for EOP are suitable for study in AP. The association between AP and the HLA antigens has been examined using the case-control design; however, the results of these studies have been equivocal (see Table 10-3). In one study, the HLA-B5 antigen was found to be more prevalent in adults resistant to disease.[29]

Kornman et a47 reported that a "composite" IL-1 genotype-consisting of at least one copy of the more rare allele at both an IL-la and IL-1ß loci-was associated with severe periodontitis in Northern European adults. Nonsmokers with the composite genotype were 6.8 times more likely to have severe (as opposed to mild) periodontal disease. No association in smokers was found, which supports the theory that some environmental components are such strong risk factors that they overwhelm any genetically determined susceptibility or resistance to disease. In contrast, Gore et al[27] found the more rare IL-1ß allele, but not the composite genotype, to be more prevalent in patients with advanced AP. The IL-1 and IL-1/3 sites were in linkage disequilibrium, which meant that the apparent role of the IL-1a allele could be due to its association with the IL-1ß allele and not with the disease itself. Similar evidence that risk for EOP is conferred more by the IL-1ß than IL-la allele is available.21

Galbraith et al26 found no association between AP and TNF-a polymorphisms, although one genotype was correlated with elevated TNF-a production by oral PMNs in patients with advanced disease. Similarly, Engebretson et al23 reported a difference in the amount of IL-1 in the gingival crevicular fluid of patients with periodontitis who were positive for the composite IL-1 genotype. The TNF-a and IL-1 variants are examples of functional polymorphisms. In other words, they are variations in coding sequences that affect either the structure (and hence function) or production of the final protein product. The identification of additional functional polymorphisms, especially within genes that regulate immune responsiveness, should facilitate the discovery of alleles that determine host susceptibility to periodontitis.

Patients who respond poorly to periodontal treatment by continuing to lose clinical attachment are said to have refractory periodontitis. Both EOP and AP can be refractory to treatment. Neutrophils from refractory disease patients usually display some functional defect.53.69 Kobayashi et al46 tested the association between neutrophil immunoglobulin G receptor (FcyR) polymorphisms and AP in a Japanese population. These polymorphisms, which reside in genes that encode receptors for the IgG isotypes, correlate with how efficiently PMNs are able to phagocytose opsonized antigens. The frequency of FcyR genotypes did not differ between AP patients and healthy controls. Among patients, however, one allele (FcyRIIIb-NA2) was found to be more prevalent in those who experienced recurrent disease. Others studies have not confirmed the association between FcyR genotypes and refractory disease.18

CLINICAL IMPLICATIONS OF GENETIC STUDIES

The role of host genes in the etiology and pathogenesis of the periodontal diseases is just beginning to be understood. Genetic tests may prove useful for identifying patients who are most likely to develop disease, suffer from recurrent disease, or suffer tooth loss as a result of disease. The utility of any screening tool, however, must be evaluated in diverse populations. Given the complex etiology of the periodontal diseases, it is likely that any genetic test will be useful in only a subset of patients or populations. Genetic testing to determine risk for complex diseases (e.g., cancer) is becoming increasingly more common. With the availability of such tests, practitioners have the responsibility to fully inform the demanding public what genetic tests can do, act on the results, and advise and support individuals before and after testing.71

Knowledge of specific genetic risk factors could enable clinicians to direct environmentally based prevention and treatments to individuals who are most susceptible to disease. For example, early and aggressive efforts to prevent pathogenic microorganisms from colonizing the oral cavity may be effective in preventing disease in

highly susceptible individuals. At present, however, the efficacy of specific preventive and treatment strategies in susceptible patients has yet to be clearly established.

Genetic information also may prove to be useful in predicting treatment outcomes. A retrospective cohort study of periodontal maintenance patients suggests that a patient's periodontal prognosis may depend in part on his or her IL-1 genotype.[56] In this study, the composite genotype described earlier was found to increase an individual's risk of tooth loss 2.7 times. The combined effect of a positive genotype and heavy smoking increased the risk of tooth loss nearly eightfold. Although prospective studies are needed to control for other known risk factors, this study demonstrated that a patient's Il-1 genotype might be an important factor for predicting future disease.

The identification of genetic risk factors for periodontitis in no way mitigates the importance of recognizing and controlling important environmental risk factors. For example, tobacco use is a major risk factor in AP. The risk of disease attributed to smoking appears to override any genetic susceptibility or resistance to disease.[47] For patients who smoke, preventive strategies must address the overwhelming environmental factor: tobacco use. It also is possible that new treatment strategies will be developed to directly counter the deleterious effects of certain risk allele(s). A simple theoretic example is the use of select antiinflammatory drugs in patients who are genetically programmed to be hyperresponders to bacterial antigens.

FUTURE OF GENETIC STUDIES IN PERIODONTOLOGY

At present, the search for risk alleles for periodontitis must focus on candidate gene regions. Genome-wide searches for risk alleles are not feasible due to the limited number of genetic markers currently available for typing. Single nucleotide polymorphisms (SNPs) are likely to be valuable tools in the search for disease alleles. SNPs are single base-pair substitutions that occur very frequently (i.e., every 1000 or so base pairs) throughout the genome. Few SNPs alter the amino acid sequences of proteins or even reside in exons. From an epidemiologic viewpoint, however, they are useful because they represent variation in the population. Currently, tens or even hundreds of thousands of such markers are thought to be required to detect associations for most common, complex disorders.[49] With the continual and rapid progress in the human genome project, however, it soon will become feasible to identify all alleles that confer even a moderate risk for disease. Even today, more than 800 SNPs have been identified within the 75 genes thought to be candidates for hypertension.[31] A similar number of candidate SNPs probably exists for the periodontal diseases, especially in genes whose products regulate humoral or cellular immune responses.[35]

To date, very few alleles have been consistently associated with any specific periodontal disease and the number of subjects studied has been relatively small. Therefore the risk associated with any one allele or genotype has not been precisely estimated. As the number of candidate genes available for study increases, the potentially large number of false-positive findings could lead researchers to pursue many erroneous leads. Associations between the disease and the gene(s) should be confirmed in multiple studies, and the gene(s) should have a biologically plausible relationship with the periodontal disease.

Periodontitis is clearly multifactorial, and researchers also need to design studies that examine the role of important environmental and genetic factors simultaneously. Given the large numbers of genes in the human genome and bacteria in the oral cavity, it is likely that genes and the environment interact in important yet unrecognized ways to alter disease risk. Most importantly, identifying specific genetic risk factors may be academically appealing but is of little use unless it leads to improvements in the prevention or treatment of disease.

The Role of Dental Calculus and Other Predisposing Factors

James E. Hinrichs

CHAPTER

CHAPTER OUTLINE

CALCULUS
- **Supragingival and Subgingival Calculus**
- **Prevalence**
- **Composition**
- **Attachment to the Tooth Surface**
- **Formation**
- **Etiologic Significance**
- **Materia Alba, Food Debris, and Dental Stains**

OTHER PREDISPOSING FACTORS
- **Iatrogenic Factors**
- **Malocclusion**
- **Periodontal Complications Associated with Orthodontic Therapy**
- **Extraction of Impacted Third Molars**
- **Habits and Self-Inflicted Injuries**
- **Tobacco Use**
- **Radiation Therapy**

The primary cause of gingival inflammation is bacterial plaque (see Chapters 6 and 8), along with other predisposing factors. These predisposing factors include calculus, faulty restorations, complications associated with orthodontic therapy, self-inflicted injuries, use of tobacco, and others.

CALCULUS

Calculus consists of mineralized bacterial plaque that forms on the surfaces of natural teeth and dental prostheses. Calculus is classified as supragingival or Subgingival, according to its relation to the gingival margin.

Supragingival and Subgingival Calculus

Supragingival calculus is located coronal to the gingival margin and therefore is visible in the oral cavity. It is usually white or whitish yellow in color, hard with clay-like consistency, and easily detached from the tooth surface. After removal, it may rapidly recur, especially in the lingual **area of the mandibular incisors.** The color is influenced by contact with such substances as tobacco and food pigments. It may localize on a single tooth or group of teeth, or it may be generalized throughout the mouth.

The two most common locations for supragingival calculus to develop are the buccal surfaces of the maxillary molars (Fig. 11-1) (Color Figs. 11-1 and 11-2) and the lingual surfaces of the mandibular anterior teeth.50 Saliva from the parotid gland flows over the facial surfaces of upper molars via Stensen's duct, whereas the orifices of Wharton's duct and Bartholin's duct empty onto the lingual surfaces of the lower incisors from the submaxillary and sublingual glands, respectively. In extreme cases, calculus may form a bridgelike structure over the interdental papilla of adjacent teeth or cover the occlusal surface of teeth without functional antagonists (Fig. 11-2).

Subgingival calculus is located below the crest of the marginal gingiva and therefore is not visible on routine clinical examination. The location and extent of Subgingival calculus may be evaluated by careful tactile perception with a delicate dental instrument such as an explorer. Clerehugh et al used a World Health Organization #621 probe to detect and score subgingival calculus.45 Subsequently, these teeth were extracted and visually scored for subgingival calculus. An agreement of 80% was found between these two scoring methods. Subgingival calculus is typically hard and dense and frequently

appears dark brown or greenish black in color (Fig. 11-3) while being firmly attached to the tooth surface. Supragingival calculus and subgingival calculus generally occur together, but one may be present without the other. Microscopic studies demonstrate that deposits of subgingival calculus usually extend nearly to the base of periodontal pockets in chronic periodontitis but do not reach the junctional epithelium.

When the gingival tissues recede, subgingival calculus becomes exposed and is therefore reclassified as supragingival (Fig. 11-4). Thus supragingival calculus can be composed of both supragingival calculus and previous subgingival calculus. A reduction in gingival inflammation and probing depths and a gain in clinical attachment can be observed after the removal of subgingival plaque and calculus (Fig. 11-5) (see Chapter 47).

Prevalence

Anerud and co-workers observed the periodontal status of a group of Sri Lankan tea laborers and a group of Norwegian academicians for a 15-year period.' The Norwegian population had ready access to preventive dental care throughout their lives, whereas the Sri Lankan tea laborers did not. The formation of supragingival calculus was observed early in life in the Sri Lankan individuals, probably shortly after the teeth erupted. The first areas to exhibit calculus deposits were the facial aspects of maxillary molars and the lingual surfaces of mandibular incisors. Deposition of supragingival calculus continued as individuals aged, reaching a maximal calculus score around 25 to 30 years of age. At this time, most of the teeth were covered by calculus, although the facial surfaces had less calculus than the **lingual or palatal** surfaces. Calculus accumulation appeared to be symmetric, and by age 45 only a few teeth, typically the premolars, were without calculus. Subgingival calculus appeared first either independently or on the interproximal aspects of areas where supragingival calculus already existed.' By age 30, all surfaces of all teeth had subgingival calculus without any pattern of predilection.

The Norwegian academicians received oral hygiene instructions and frequent preventive dental care throughout their lives. The Norwegians exhibited a marked reduction in the accumulation of calculus as compared with the Sri Lankan group. However, despite the fact that 80% of teenagers formed supragingival calculus on the facial surfaces of the upper molars and the lingual surfaces of lower incisors, no additional calculus formation occurred on other teeth, nor did it increase with age.'

More recently, the third National Health and Nutrition Examination Survey (NHANES III) evaluated 9689 adults in the United States between 1988 and 1994.[4] This survey revealed that 91.8% of the subjects had detectable calculus and 55.1% had subgingival calculus.

Both supragingival calculus and subgingival calculus may be seen on radiographs (see Chapter 31). Highly calcified interproximal calculus deposits are readily detectable as radioopaque projections that protrude into the interdental space (Fig. 11-6). However, the sensitivity level of calculus detection by radiographs is low.[37] The location of calculus does not indicate the bottom of the periodontal pocket because the most apical plaque is not sufficiently calcified to be visible on radiographs.

Composition

Inorganic Content. Supragingival calculus consists of inorganic (70% to 90%'[s]) and organic components. The inorganic portion consists of 75.9% calcium phosphate, $Ca_3(PO_4)_2$; 3.1% calcium carbonate, $CaCO_3$; and traces of magnesium phosphate, $Mg_3(PO_4)_2$, and other metals .214 The percentage of inorganic constituents in calculus is similar to that in other calcified tissues of the body. The principal inorganic components are calcium, 39%; phosphorus, 19%; carbon dioxide, 1.9%; magnesium, 0.8%; and trace amounts of sodium, zinc, strontium, bromine, copper, manganese, tungsten, gold, aluminum, silicon, iron, and fluorine. 140

At least two thirds of the inorganic component is

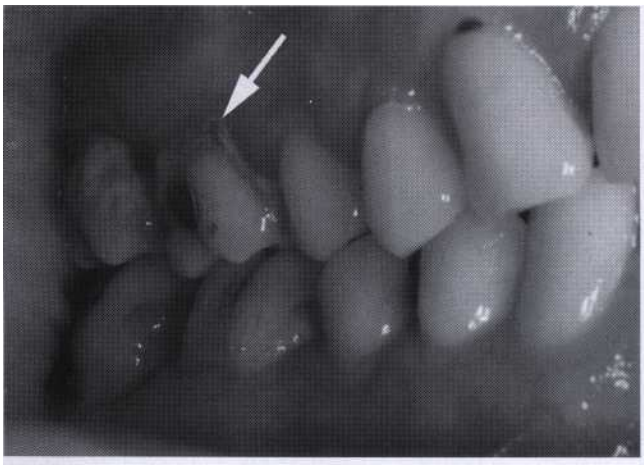

Fig. 11-1 Supragingival calculus is depicted on the buccal surfaces of maxillary molars adjacent to orifice for Stenson's duct.

Fig. 11-2 Extensive supragingival calculus is present on the lingual surfaces of lower anterior teeth.

crystalline in structure.[110] The four main crystal forms and their percentages are as follows:

Hydroxyapatite, approximately 58%
Magnesium whitlockite, approximately 21%
Octacalcium phosphate, approximately 12%
Brushite, approximately 9%

Generally, two or more crystal forms are typically found in a sample of calculus. Hydroxyapatite and octacalcium phosphate are detected most frequently (i.e., in 97% to 100% of all supragingival calculus) and constitute the bulk of the specimen. Brushite is more common in the mandibular anterior region and magnesium whitlockite in the posterior areas. The incidence of the four crystal forms varies with the age of the deposit.[26]

Organic Content. The organic component of calculus consists of a mixture of protein-polysaccharide complexes, desquamated epithelial cells, leukocytes, and various types of microorganisms.[125] Between 1.9% and 9.1% of the organic component is carbohydrate, which consists of galactose, glucose, rhamnose, mannose, glucuronic acid, galactosamine, and sometimes arabinose, galacturonic acid, and glucosamine.[114,124,195] All these organic components are present in salivary glycoprotein with the exception of arabinose and rhamnose. Salivary proteins account for 5.9% to 8.2% of the organic component of calculus and include most amino acids. Lipids account for 0.2% of the organic content in the form of neutral fats, free fatty acids, cholesterol, cholesterol esters, and phospholipids.[115]

The composition of subgingival calculus is similar to that of supragingival calculus, with some differences. It has the same hydroxyapatite content, more magnesium whitlockite, and less brushite and octacalcium phosphate.[177,201] The ratio of calcium to phosphate is higher subgingivally, and the sodium content increases with the depth of periodontal pockets.[116] Salivary proteins present in supragingival calculus are not found subgingivally.[16] Dental calculus, salivary duct calculus, and calcified dental tissues are similar in inorganic composition.

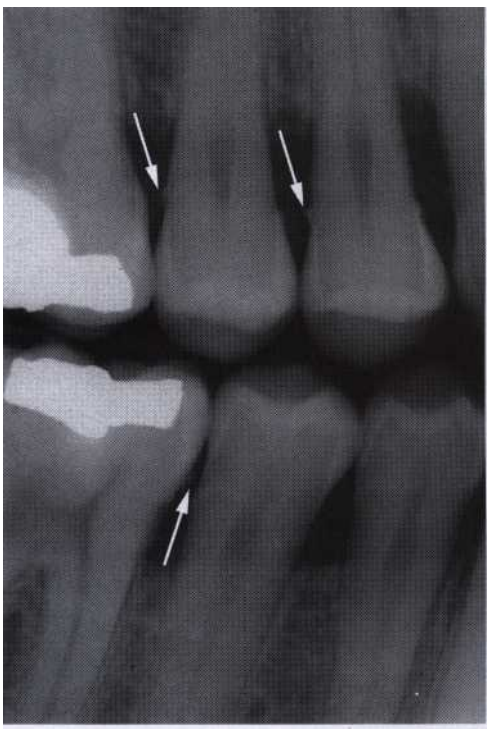

Fig. 11-6 A bitewing radiograph illustrating extensive subgingival calculus deposits that are depicted as interproximal spurs.

Attachment to the Tooth Surface

Differences in the manner in which calculus is attached to the tooth surface affect the relative ease or difficulty encountered in its removal. Four modes of attachment have been described[106,179,220:] attachment by means of an organic pellicle (Fig. 11-7, A); mechanical locking into surface irregularities such as resorption lacunae and caries (Figs. 11-7, B and 11-8); close adaptation of calculus undersurface depressions to the gently sloping mounds of the unaltered cementum surface[116] (Fig. 11-9); and penetration of calculus bacteria into cementum. However, not all investigators universally acknowledge this forth mode of attachment (Fig. 11-10).'[16] Calculus embedded deeply in cementum may appear morphologically similar to cementum and thus has been termed *calculocementum*.[186]

Formation

Calculus is dental plaque that has undergone mineralization. The soft plaque is hardened by the precipitation of mineral salts, which usually starts between the lst and 14th days of plaque formation. However, calcification has been reported to occur in as little as 4 to 8 hours.202 Calcifying plaques may become 50 ½ mineralized in 2 days and 60 ½ to 90 ½ mineralized in 12 days.[119,180,190] All plaque does not necessarily undergo calcification. Early plaque contains a small amount of inorganic material, which increases as the plaque develops into calculus. Plaque that does not develop into calculus reaches a plateau of maximal mineral content within 2 days."' Microorganisms are not always essential in calculus formation because calculus occurs readily in germ-free rodents."

Saliva is the source of mineralization for supragingival calculus, whereas the serum transudate called *gingival crevicular fluid* furnishes the minerals for subgingival calculus.[93,197] Plaque has the ability to concentrate calcium at 2 to 20 times its level in saliva .26 Early plaque of heavy calculus formers contains more calcium, three times more phosphorus, and less potassium than that of non-calculus formers, suggesting that phosphorus may be more critical than calcium in plaque mineralization.[121] Calcification entails the binding of calcium ions to the carbohydrate-protein complexes of the organic matrix and the precipitation of crystalline calcium phosphate salts.[121] Crystals form initially in the intercellular matrix and on the bacterial surfaces and finally within the bacteria.[69,221]

Calcification begins along the inner surface of the supragingival plaque and in the attached component of subgingival plaque adjacent to the tooth. Separate foci of calcification increase in size and coalesce to form solid masses of calculus (Fig. 11-11). Calcification may be accompanied by alterations in the bacterial content and staining qualities of the plaque. As calcification progresses, the number of filamentous bacteria increases and foci of calcification change from basophilic to eosinophilic. There is a reduction in the staining intensity of groups exhibiting a positive periodic acid-Schiff reaction. Sulfhydryl and amino groups also are reduced and instead stain with toluidine blue, which is initially orthochromatic but becomes metachromatic and disappears .211 Calculus is formed in layers, which are often

separated by a thin cuticle that becomes embedded in the calculus as calcification progresses .[121]

The initiation of calcification and the rate of calculus accumulation vary from person to person, for different teeth, and at different times in the same person.[140,206] On the basis of these differences, persons may be classified as heavy, moderate, or slight calculus formers or as non-calculus formers. The average daily increment in calculus formers is from 0.10% to 0.15% of dry weight.[190,206] Calculus formation continues until it reaches a maximum, after which it may be reduced in amount. The time required to reach the maximal level has been reported as 10 weeks[46] and *6* months .[208] The decline from maximal calculus accumulation, referred to as *reversal phenomenon,* may be explained by the vulnerability of bulky calculus to mechanical wear from food and from the cheeks, lips, and tongue.

Anticalculus (antitartar) dentifrices claim to reduce the quantity and quality of calculus formed, making it easier for removal by the clinician. These products appear to be helpful for some patients.

Theories Regarding the Mineralization of Calculus. The theoretic mechanisms by which plaque becomes mineralized can be stratified into two principal categories.[141]

1. *Mineral precipitation results from a local rise in the degree of saturation of calcium and phosphate ions,* which may be brought about in several ways:

   A rise in the pH o f the saliva causes precipitation of calcium phosphate salts by lowering the precipitation constant. The pH may be elevated by the loss of carbon dioxide and the formation of ammonia by dental plaque bacteria or by protein degradation during stagnation .[25,88]

   Colloidal proteins in saliva bind calcium and phosphate ions and maintain a supersaturated solution with respect to calcium phosphate salts. With stagnation of saliva, colloids settle out and the supersaturated state is no longer maintained, leading to precipitation of calcium phosphate salts.[164,183]

   Phosphatase liberated from dental plaque, desquamated epithelial cells, or bacteria precipitate calcium phosphate by hydrolyzing organic phosphates in saliva, thus

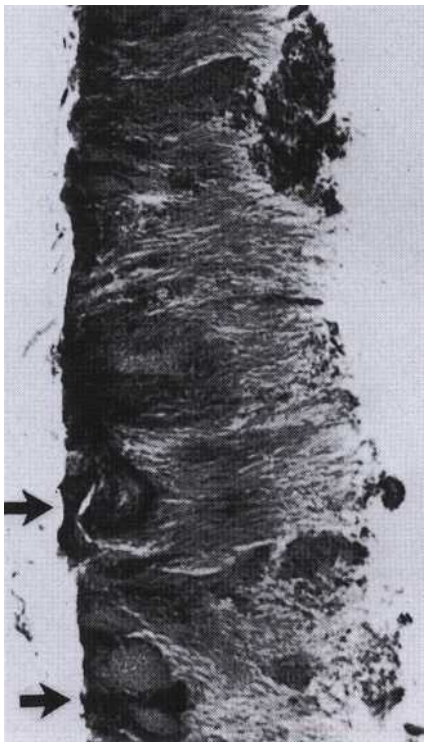

Fig. 11-11 Five-day plaque, showing spherical calcification foci (arrows) and perpendicular alignment of filamentous organisms along the inner surface and colonies of cocci on the outer surface. (From Turesky S, Renstrup G, Glickman I: Histologic and histochemical observations regarding early calculus formation in children and adults. J Periodontol 1961; 32:7.)

increasing the concentration of free phosphate ions.'" Esterase is another enzyme that is present in the cocci and filamentous organisms, leukocytes, macrophages, and desquamated epithelial cells of dental plaque." Esterase may initiate calcification by hydrolyzing fatty esters into free fatty acids. The fatty acids form soaps with calcium and magnesium that are later converted into the less-soluble calcium phosphate salts.

2. *Seeding agents induce small foci of calcification that enlarge and coalesce to form a calcified mass.* [143] This concept has been referred to as the *epitactic concept* or more appropriately, *heterogeneous nucleation.* The seeding agents in calculus formation are not known, but it is suspected that the intercellular matrix of plaque plays an active role. [126,139,221] The carbohydrate-protein complexes may initiate calcification by removing calcium from the saliva (chelation) and binding with it to form nuclei that induce subsequent deposition of minerals. [123,209]

Role of Microorganisms in the Mineralization of Calculus. Mineralization of plaque starts extracellularly around both gram-positive organisms and gram-negative organisms108; it may also start intracellularly. Filamentous organisms, diphtheroids, and *Bacterionema* and *Veillonella* species have the ability to form intracellular apatite crystals (Fig. *11-12).* Calculus formation spreads until the matrix and bacteria are calcified. [69,221]

Bacterial plaque may actively participate in the mineralization of calculus by forming phosphatases, which changes the pH of the plaque and induces mineralization, [55,123] but the prevalent opinion is that these bacteria

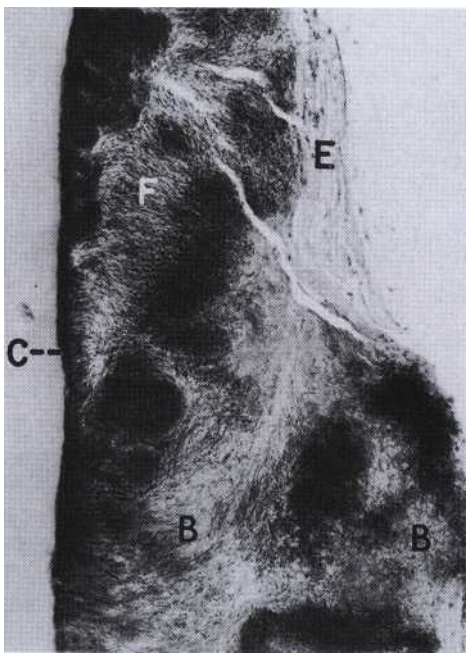

Fig. 11-12 Detailed microscopic examination of calculus showing an inner structure (C, filamentous organisms (F), other bacteria (8), and desquamated epithelial cells (E).

are only passively involved[69,113,212] and are simply calcified with other plaque components. The occurrence of calculus-like deposits in germ-free animals supports this opinion.[7a] However, other experiments suggest that transmissible factors are involved in calculus formation and that penicillin in the diets of some of these animals reduces calculus formation."

Etiologic Significance

Distinguishing between the effects of calculus and plaque on the gingiva is difficult because calculus is always covered with a nonmineralized layer of plaque.'" A positive correlation between the presence of calculus and the prevalence of gingivitis exists,[117] but this correlation is not as great as that between plaque and gingivitis.72 In young persons, periodontal condition is more closely related to plaque accumulation than to calculus, but the situation is reversed with age.72,111 The incidence of calculus, gingivitis, and periodontal disease increases with age. It is extremely rare to find periodontal pockets in adults without subgingival calculus, although subgingival calculus may be of microscopic proportion in some cases.

The nonmineralized plaque on the calculus surface is the principal irritant, but the underlying calcified portion may be a significant contributing factor (Fig. 11-13). It does not irritate the gingiva directly but provides a fixed nidus for the continued accumulation of plaque and retains it in close proximity to the gingiva. Subgingival calculus may be the product rather than the cause of periodontal pockets. Plaque initiates gingival inflammation, which starts pocket formation, and the pocket in turn provides a sheltered area for plaque and bacterial accumulation. The increased flow of gingival fluid associated with gingival inflammation provides the minerals that convert the continually accumulating plaque into subgingival calculus. Over a 6-year period, Albander et al observed 156 teenagers with histories of aggressive periodontitis.[4] They noted that areas with detectable subgingival calculus at the initiation of the study were much more likely to experience loss of periodontal attachment than sites that did not initially exhibit subgingival calculus.

While the bacterial plaque that coats the teeth is the main etiologic factor in the development of periodontal disease, the removal of subgingival plaque and calculus constitute the cornerstone of periodontal therapy. Calculus plays an important role in maintaining and accentuating periodontal disease by keeping plaque in close contact with the gingival tissue and creating areas where plaque removal is impossible. Therefore *the clinician must not only possess the clinical skill to remove the calculus and other irritants that attach to the teeth but also be very conscientious about performing this task.*

Materia Alba, Food Debris, and Dental Stains

Materia alba is a concentration of microorganisms, desquamated epithelial cells, leukocytes, and a mixture of salivary proteins and lipids, with few or no food particles, and it lacks the regular internal pattern observed in plaque.'" It is a yellow or grayish-white, soft, sticky

Fig. 11-13 Scanning electron microscope view of an extracted human tooth, fractured experimentally, showing a cross-section of subgingival calculus (C that is not firmly attached to the cemental surface (arrows). Fig. 11-14 Tobacco stains on the apical third of the clinical crown due to cigarette smoking.

deposit and is somewhat less adherent than dental plaque. The irritating effect of materia alba on the gingiva is caused by bacteria and their products.

Most food debris is rapidly liquefied by bacterial enzymes and cleared from the oral cavity by salivary flow and the mechanical action of the tongue, cheeks, and lips. The rate of clearance from the oral cavity varies with the type of food and the individual. Aqueous solutions are typically cleared within 15 minutes, whereas sticky foods may adhere for more than 1 hour. [99,207] Dental plaque is not a derivative of food debris, nor is food debris an important cause of gingivitis.54 Although the oral microflora is the main determinant of the gingival status, recent research indicates that short-chain carboxylic acids found in retained food particles may also have an impact on the periodontal status.99

Pigmented deposits on the tooth surface are called *dental stains.* Stains are primarily an aesthetic problem and do not cause inflammation of the gingiva. The use of tobacco products (Fig. 11-14), coffee, tea, certain mouthrinses, and pigments in foods can contribute to stain formation. [117]

OTHER PREDISPOSING FACTORS

Iatrogenic Factors

Deficiencies in the quality of dental restorations or prostheses are contributing factors to gingival inflammation and periodontal destruction. Inadequate dental procedures that contribute to the deterioration of the periodontal tissues are referred to as *iatrogenic factors.* Characteristics of dental restorations and removable partial dentures that are important to the maintenance of periodontal health include: the location of the gingival margin for the restoration, the space between the margin of the restoration and the unprepared tooth, the contour of restorations, the occlusion, materials used in the restoration, the restorative procedure itself, and the design of the removable partial denture. These characteristics are described in this chapter as they relate to the etiology of periodontal disease. A more comprehensive review with special emphasis on the interrelationship between restorative procedures and the periodontal status is presented in Chapter 75.

Margins of Restorations. Overhanging margins of dental restorations contribute to the development of periodontal disease by 1) changing the ecologic balance of the gingival sulcus to an area that favors the growth of disease-associated organisms (predominately gram-negative anaerobic species) at the expense of the health-associated organisms (predominately gram-positive facultative species) [109] and 2) inhibiting the patient's access to remove accumulated plaque.

The frequency of overhanging margins of proximal restorations varies in different studies from 16.5% to 75%. [28,66,92,149] A highly significant statistical relationship has been reported between marginal defects and reduced bone height. [28,83,92] Removal of overhangs permits more effective control of plaque, resulting in a reduction of gingi-

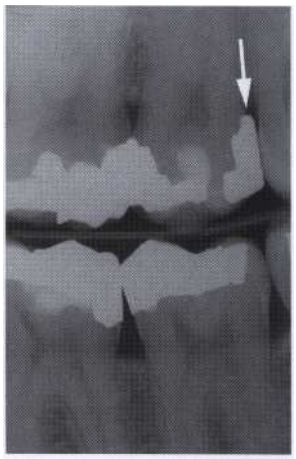

Fig. 11-15 Radiograph of amalgam overhang on the distal surface of maxillary second molar, which is a source of plaque retention and gingival irritation.

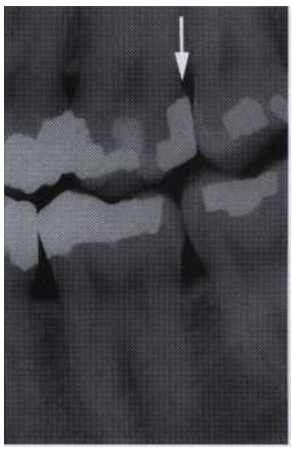

Fig. 11-16 Radiograph showing same patient as in Fig. 11-15 after the excessive amalgam has been removed.

val inflammation and a small increase in radiographic alveolar bone support[1,85,193] (Figs. 11-15 and 11-16).

The location of the gingival margin for a restoration is directly related to the health status of adjacent periodontal tissues.[191] Numerous studies[66,89,98,169,193] have shown a positive correlation between margins located apical to the marginal gingiva and the presence of gingival inflammation. Subgingival margins are associated with large amounts of plaque, more severe gingivitis, and deeper pockets. Even high-quality restorations, if placed subgingivally, will increase plaque accumulation, gingival inflammation[107,109,138,170] and the rate of gingival fluid flow.[19,71] Margins placed at the level of the gingival crest induce less severe inflammation, whereas supragingival margins are associated with a degree of periodontal health similar to that seen with non-restored interproximal surfaces.[62,191]

Roughness in the subgingival area is considered to be a major contributing factor to plaque build-up and subsequent gingival inflammation.[91] The subgingival zone is composed of the margin of the restoration, the luting material, and the prepared as well as the unprepared tooth surface. Sources of marginal roughness include"' grooves and scratches in the surface of carefully polished acrylic resin, porcelain, or gold restorations (Fig. 11-17); separation of the restoration margin and luting material from the cervical finish line, thereby exposing the rough surface of the prepared tooth (Fig. 11-18); dissolution and disintegration of the luting material between the preparation and the restoration, leaving a space (Fig. 11-19), and inadequate marginal fit of the restoration. Subgingival margins typically have a gap of 20 to 40 microns between the margin of the restoration and the unprepared tooth."' Colonization of this gap by bacterial plaque undoubtedly contributes to the detrimental effect of margins placed in a subgingival environment.

Contours/Open Contacts. Overcontoured crowns and restorations tend to accumulate plaque and possibly prevent the self-cleaning mechanisms of the adjacent cheek, lips, and tongue.[7,104,136,218] (Figs. 11-20 and 11-21) Restorations that fail to reestablish adequate interproximal embrasure spaces are associated with papillary inflammation. Undercontoured crowns that lack a protective height of contour may not be as detrimental during mastication as once thought .[218]

The contour of the occlusal surface as established by the marginal ridges and related developmental grooves normally serves to deflect food away from the interproximal spaces. The optimal cervicoocclusal location for a posterior contact is at the longest mesiodistal diameter of the tooth, which is generally just apical to the crest of the marginal ridge. The integrity and location of the proximal contacts along with the contour of the marginal ridges and developmental grooves typically prevent interproximal food impaction. *Food impaction is* the forceful wedging of food into the periodontium by occlusal forces. As the teeth wear down, their originally convex proximal surfaces become flattened and the wedging effect of the opposing cusp is exaggerated. Cusps that tend to forcibly wedge food into interproximal embrasures are known as *plunger cusps.* The interproximal plunger cusp effect may also be observed when missing teeth are not replaced and the relationship between proximal contacts of adjacent teeth is altered. An intact, firm proximal contact precludes the forceful wedging of food into the interproximal embrasure space, whereas a light or open contact is conducive to impaction.

The classic analysis of the factors leading to food impaction was made by Hirschfeld," who recognized the following factors: uneven occlusal wear, opening of the contact point as a result of loss of proximal support or from extrusion, congenital morphologic abnormalities, and improperly constructed restorations.

The presence of the previously mentioned abnormalities does not necessarily lead to food impaction and periodontal disease. A study of interproximal contacts and marginal ridge relationships109 in three groups of periodontally healthy males revealed that 0.7% to 76% of

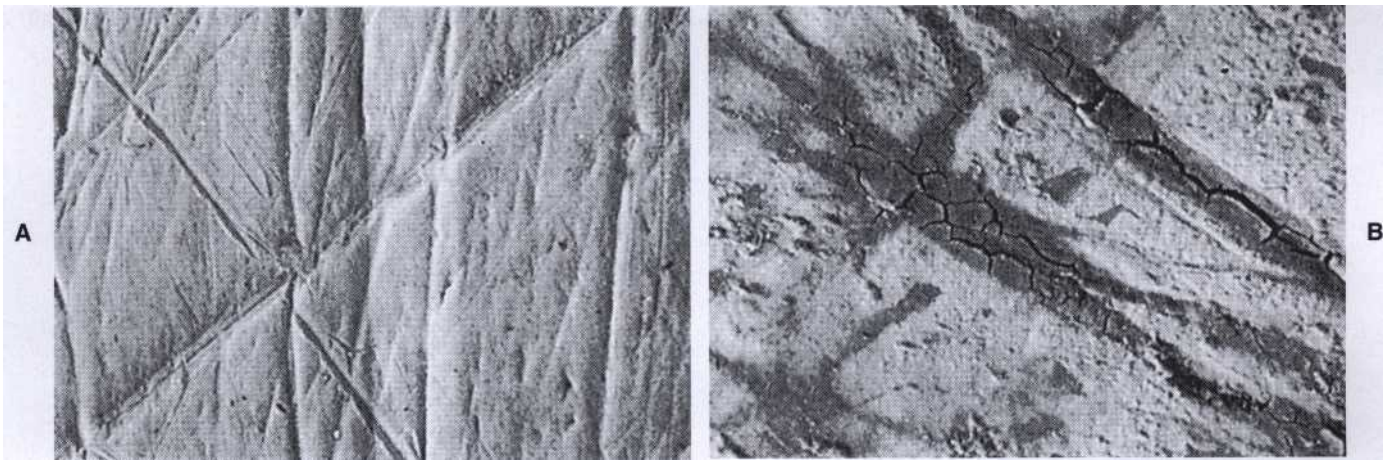

Fig. 11-17 A, A polished gold alloy crown demonstrates surface scratches. B, A gold alloy crown that had been in the mouth for several years has scratches filled with deposits. (From Silness J: Fixed prosthodontics and periodontal health. Dent Clin North Am 1980; 24:317.)

Fig. 11-18 After cementation, luting material prevents approximation of the crown margin and the finishing line, leaving part of the prepared tooth uncovered (area between arrowheads). (From Silness J: Fixed prosthodontics and periodontal health. Dent Clin North Am 1980; 24:317.)

Fig. 11-21 Radiograph of ill-fitting porcelain fused to metal crown shown in Fig. 11-20.

the proximal contacts were defective and 33.5% of adjacent marginal ridges were uneven.[148] However, greater probing depth and loss of clinical attachment have been reported for sites that exhibited both an open contact and food impaction as compared with contralateral control sites without open contacts or food impaction." Excessive anterior overbite is a common cause of food impaction on the lingual surfaces of the maxillary anterior teeth and the facial surfaces of the opposing mandibular teeth. These areas may be exemplified by attachment loss with gingival recession.

Materials. In general, restorative materials are not in themselves injurious to the periodontal tissues.[7,100] One exception to this may be self-curing acrylics[211] (Fig. 11-22).

Plaque that forms at the margins of restorations is similar to that founded on adjacent nonrestored tooth surfaces. The composition of plaque formed on all types of restorative materials is similar, with the exception of that formed on silicate.'" Although surface textures of restorative materials differ in their capacity to retain plaque,[211,215] all can be adequately cleaned if they are polished[145,178] and accessible to methods of oral hygiene. The undersurface of pontics in fixed bridges should barely touch the mucosa. Access for oral hygiene is inhibited with excessive pontic to tissue contact, thereby contributing to plaque accumulation that will cause gingival inflammation and possibly formation of pseudopockets.[61,192]

Design of Removable Partial Dentures. Several investigations have shown that after the insertion of partial dentures, the mobility of the abutment teeth, gingival inflammation, and periodontal pocket formation increases.[27,38,185] This is because partial dentures favor the accumulation of plaque, particularly if they cover the gingival tissue. Partial dentures that are worn during both night and day induce more plaque formation than those worn only during the daytime.[27] These observations emphasize the need for careful and personalized oral hygiene instruction to avoid harmful effects of partial dentures on the remaining teeth and periodontium.[19] The presence of removable partial dentures induces not only quantitative changes in dental plaque[64] but also qualitative changes, promoting the emergence of spirochetal microorganisms .[65]

Restorative Dentistry Procedures. The use of rubber dam clamps, matrix bands, and burs in such a manner as to lacerate the gingiva results in varying degrees of mechanical trauma and inflammation. Although such transient injuries generally undergo repair, they are needless sources of discomfort to the patient. Forceful packing of a gingival retraction cord into the sulcus to prepare subgingival margins on a tooth or for the purpose of obtaining an impression may mechanically injure the periodontium and leave behind impacted debris capable of causing a foreign body reaction. (See Chapter 75 for a more detailed explanation.)

Fig. 11-22 Inflamed palatal gingiva associated with a maxillary provisional acrylic partial denture. Note the substantial difference in color of the inflamed gingiva adjacent to the premolars and first molar compared with the gingiva adjacent to the second molar.

Malocclusion

Irregular alignment of teeth as found in cases of malocclusion may make plaque control more difficult. Several authors have found a positive correlation between crowding and periodontal disease[36,151,199] whereas other investigators did not find any correlation.[63] Uneven marginal ridges of contiguous posterior teeth have been found to have a low correlation with pocket depth, loss of attachment, plaque, calculus, and gingival inflammation.[103] Roots of teeth that are prominent in the arch (Figs. 11-23 and 11-24), such as in buccal or lingual version, or that are associated with a high frenal attachment and small quantities of attached gingiva frequently exhibit recession.[2,133]

Failure to replace missing posterior teeth may have adverse consequences on the periodontal support for the remaining teeth.[42] The following scenario illustrates the possible ramifications of not replacing a missing posterior tooth. When the mandibular first molar is extracted, the initial change is a mesial drifting and tilting of the mandibular second and third molars with extrusion of the maxillary first molar. As the mandibular second molar tips mesially, its distal cusps extrude and act as plungers. The distal cusps of the mandibular second molar wedge between the maxillary first and second molars and open the contact by deflecting the maxillary second molar distally. Subsequently, food impaction may occur and be accompanied by gingival inflammation with eventual loss of the interproximal bone between the maxillary first and second molars. The preceding example does not occur in all cases where mandibular first molars are not replaced. However, drifting and tilting of the remaining teeth with an accompanying alteration of the proximal contacts is generally a consequence of not replacing posterior teeth that have been extracted.

Tongue thrusting exerts excessive lateral pressure on the anterior teeth, which may result in spreading and tilting of the anterior teeth (Figs. 11-25 and 11-26). Tongue thrusting is an important contributing factor in

Fig. 11-23 A lower incisor depicting a prominent root without any attached gingiva and accompanying gingival recession.

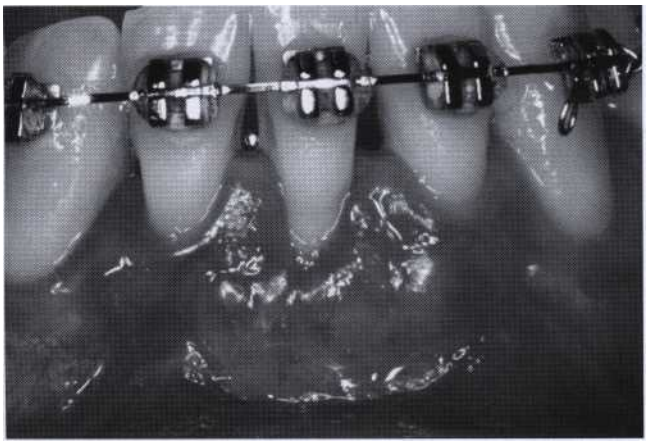

Fig. 11-24 The same patient as shown in Fig. 11-23 following the placement of a soft tissue graft to gain attached gingiva and treat the gingival recession.

pathologic tooth migration and the development of an anterior open bite.[39] Mouth breathing may be observed in association with a habit of tongue thrusting and an anterior open bite. Marginal and papillary gingivitis is frequently encountered in the maxillary anterior sextant in cases involving an anterior open bite with mouth breathing. However, the role of mouth breathing as a local etiologic factor is unclear because conflicting evidence has been reported, including the following:

1. Mouth breathing has no effect on the prevalence or extent of gingivitis, except when considerable amounts of calculus are present.[1]
2. Mouth breathers have more severe gingivitis than non-mouth breathers with similar plaque scores.[90]
3. There is no relationship between mouth breathing and prevalence of gingivitis, except a slight increase in severity.[199]
4. Crowding of teeth is associated with gingivitis only in mouth breathers.[91]

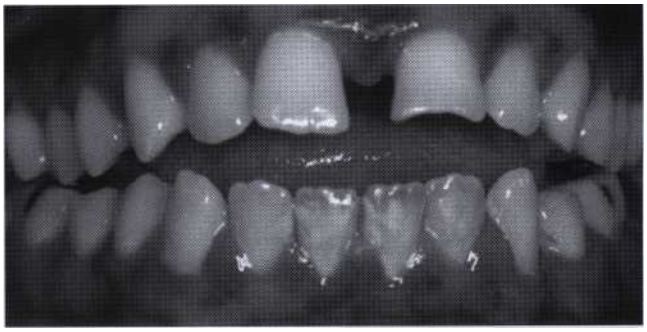

Fig. 11-25 Anterior open bite with flared incisors as observed in association with a habit of tongue thrusting.

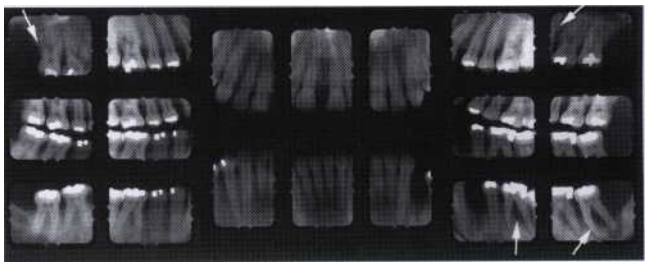

Fig. 11-26 Radiographs of patient shown in Fig. 11-25 with anterior open bite. Note severe periodontal destruction (arrows) in molar regions.

Restorations that do not conform to the occlusal pattern of the mouth result in occlusal disharmonies that may cause injury to the supporting periodontal tissues. Histologic features of the periodontium for a tooth subjected to traumatic occlusion include a widened subcrestal periodontal ligament space, a reduction in collagen content of the oblique and horizontal fibers, an increase in vascularity and leukocyte infiltration, and an increase in the number of osteoclasts on bordering alveolar bone.[24] However, these observations are generally apical and separate from the bacterial-induced inflammation that occurs at the base of the sulcus. On the basis of current human trials, it is still impossible to definitively answer the question, "Does occlusal trauma modify the progression of periodontal attachment loss associated with sulcular inflammation?"[188] (See Chapter 24 for a more detailed explanation of periodontal trauma from occlusion and the periodontal response to external forces.)

Periodontal Complications Associated with Orthodontic Therapy

Orthodontic therapy may affect the periodontium by favoring plaque retention, by directly injuring the gingiva as a result of overextended bands, and by creating excessive forces, unfavorable forces, or both on the tooth and supporting structures.

Plaque Retention and Composition. Orthodontic appliances not only tend to retain bacterial plaque and food debris, resulting in gingivitis (Fig. 11-27), but also are capable of modifying the gingival ecosystem. An increase in *Prevotella melaninogenica, Prevotella intermedia,* and *Actinomyces odontolyticus* and a decrease in the proportion of faculative microorganisms was detected in the gingival sulcus following the placement of orthodontic bands.[12] More recently, *Actinobacillus actinomycetemcomitans* was found in at least one site for 85% of children wearing orthodontic appliances compared with only 15% of the control subjects who were positive for *A. actino-*

Gingival Trauma and Alveolar Bone Height. Orthodontic treatment is often started soon after eruption of the permanent teeth, when the junctional epithelium is still adherent to the enamel surface. Orthodontic bands should not be forcefully placed beyond the level of attachment because this will detach the gingiva from the tooth and result in apical proliferation of the junctional epithelium with an increased incidence of gingival recession.[11]

The mean alveolar bone loss per patient for adolescents who underwent 2 years of orthodontic care during a 5-year observation period ranged between 0.1 and 0.5 mm.[31] This small magnitude of alveolar bone loss was also noted in the control group and therefore considered to be of little clinical significance. However, the degree of bone loss during adult orthodontic care may be higher than that observed in adolescents,[119] especially if the periodontal condition is not treated before initiating orthodontic therapy.

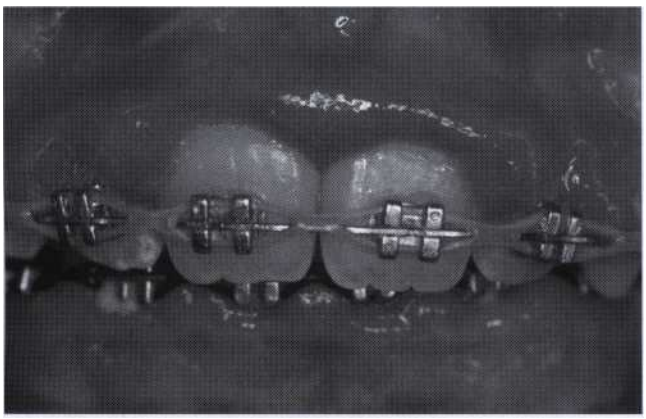

Fig. 11-27 Gingival inflammation and enlargement associated with orthodontic appliance and poor oral hygiene.

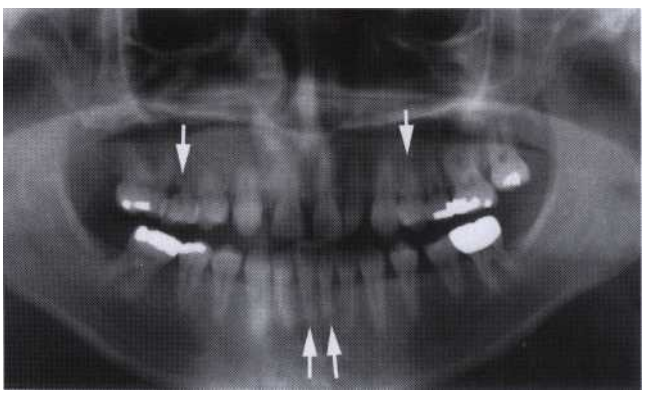

Fig. 11-28 Panoramic radiograph illustrating that a limited degree of pretreatment root resorption existed before orthodontic care was initiated.

Tissue Response to Orthodontic Forces. Orthodontic tooth movement is possible because the periodontal tissues are responsive to externally applied forces.[168,171] Alveolar bone is remodeled by osteoclasts inducing bone resorption in areas of pressure and osteoblasts forming bone in areas of tension. Although moderate orthodontic forces ordinarily result in bone remodeling and repair, excessive force may produce necrosis of the periodontal ligament and adjacent alveolar bone.[156-158] Excessive orthodontic forces also increase the risk of apical root resorption.[34,35] The prevalence of severe root resorption, as indicated by resorption of more than one third of the root length, during orthodontic therapy in adolescents has been reported at 3%.[9] The incidence of moderate to severe root resorption for incisors among adults ranging in age from 20 to 45 years has been reported as 2% pretreatment and 24.5% posttreatment[119] (Figs. 11-28 to 11-30). *It is important to avoid excessive force and too rapid tooth movement in orthodontic treatment.*

The use of elastics to close a diastema may result in severe attachment loss with possible tooth loss as the elastics migrate apically along the root (Figs. 11-31 and 11-32). Surgical exposure of impacted teeth and orthodontic-assisted eruption has the potential to compromise the periodontal attachment on adjacent teeth (Figs. 11-33 and 11-34). However, the majority of impacted teeth that are surgically exposed and aided in their eruption by orthodontic treatment subsequently exhibited >_90% of their attachment intact.[86]

It has been reported that the dentoalveolar gingival fibers that are located within the marginal and attached gingiva are stretched when teeth are rotated during orthodontic therapy.[13] Surgical severing or removal of these gingival fibers in combination with a brief period of retention may reduce the incidence of relapse after orthodontic treatment intended to realign rotated teeth.[33,135]

Extraction of Impacted Third Molars

Numerous clinical studies have reported that the extraction of impacted third molars often results in the creation of vertical defects distal to the second molars. This iatrogenic effect is unrelated to flap design[13] and appears to occur more often when third molars are extracted in individuals older than 25 years.[8,105,130] Other factors that appear to play a role in the development of lesions on the distal surface of second molars, particularly in those

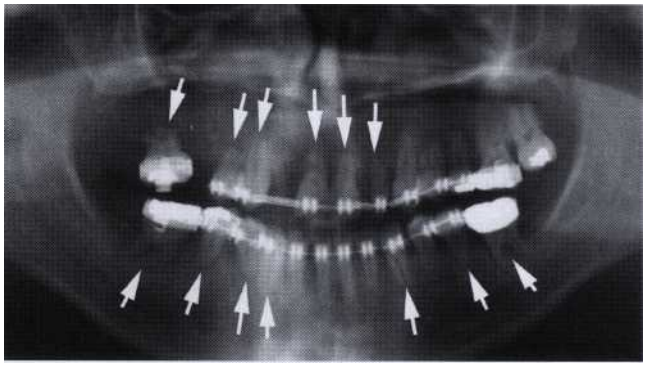

Fig. 11-29 Panoramic radiograph of the same patient as shown in Fig. 11-28 after 4 years of intermittent orthodontic treatment. Note that several roots have undergone severe resorption (see arrows) during orthodontic care.

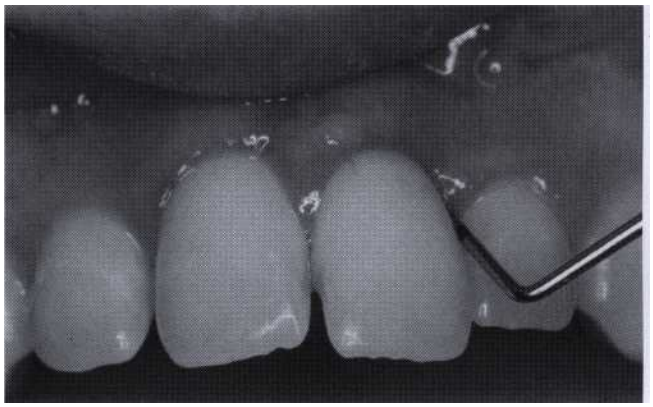

Fig. 11-31 Maxillary central incisors in which an elastic ligature was used to close a midline diastema. Note inflamed gingival and deep probing depths.

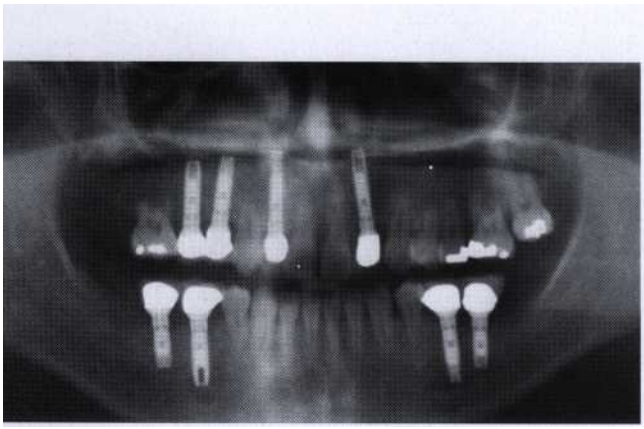

Fig. 11-30 Panoramic radiograph of the same patient as depicted in Fig. 11-29. Note the teeth that had developed extensive root resorption with accompanying hypermobility have been extracted and replaced by implant supported bridgework.

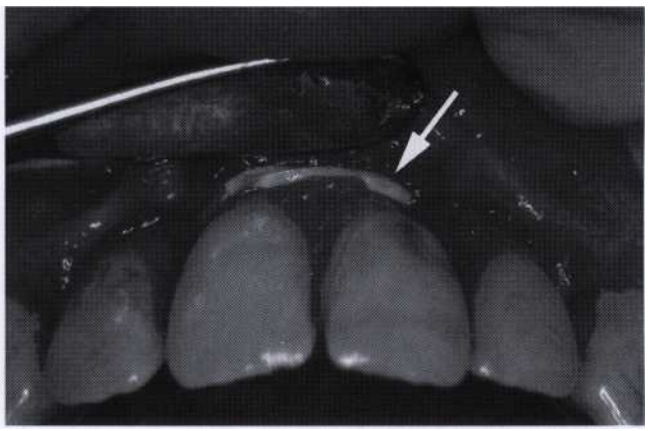

Fig. 11-32 The same patient as shown in Fig. 11-31. A full thickness mucoperiosteal flap has been reflected to expose the elastic ligature and angular intrabony defects around the central incisors.

older than 25 years, include the presence of visible plaque, bleeding on probing, root resorption in the contact area between second and third molars, presence of a pathologically widened follicle, inclination of the third molar, and close proximity of the third molar to the second molar (Fig. 11-35).[105]

Habits and Self-Inflicted Injuries

Patients might not be aware of their self-inflicted injurious habits that may be important to the initiation and progression of their periodontal disease. Mechanical forms of trauma can stem from improper use of a toothbrush, wedging of toothpicks between the teeth, application of fingernail pressure against the gingiva, pizza burns, and others[29] (Fig. 11-36). Sources of chemical irritation include topical applications of caustic medications such as aspirin or cocaine, allergic reactions to toothpaste and chewing gum, use of chewing tobacco and concentrated mouthrinses, and others.[187]

Toothbrush Trauma. Abrasions of the gingiva as well as alterations in tooth structure may result from aggressive brushing in a horizontal or rotary fashion. The deleterious effect of abusive brushing is accentuated when highly abrasive dentifrices are used. The gingival changes attributable to toothbrush trauma may be acute or chronic. The acute changes vary in their appearance and duration from scuffing of the epithelial surface to denudation of the underlying connective tissue with the formation of a painful gingival ulcer (Fig. 11-37). Diffuse erythema and denudation of the attached gingiva throughout the mouth may be a striking sequelae of overzealous brushing. Signs of acute gingival abrasion are frequently noted when the patient first uses a new brush. Puncture lesions may be produced when heavy pressure is applied to firm bristles that are aligned perpendicular to the surface of the gingiva. A forcibly embedded toothbrush bristle may be retained in the gingiva and cause an acute gingival abscess (see Chapter *19*).

Fig. 11-33 Radiograph of an impacted maxillary canine that required surgically exposed and orthodontic assistance to erupt.

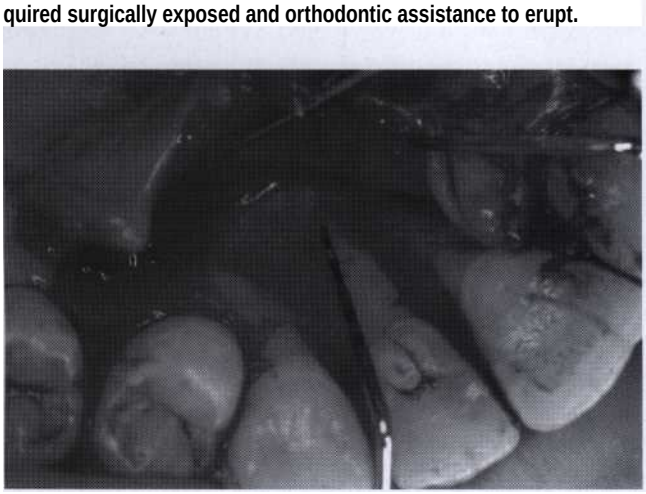

Fig. 11-34 Palatal flap reflected to reveal bony dehiscence on the maxillary lateral incisor shown in Fig. 11-33.

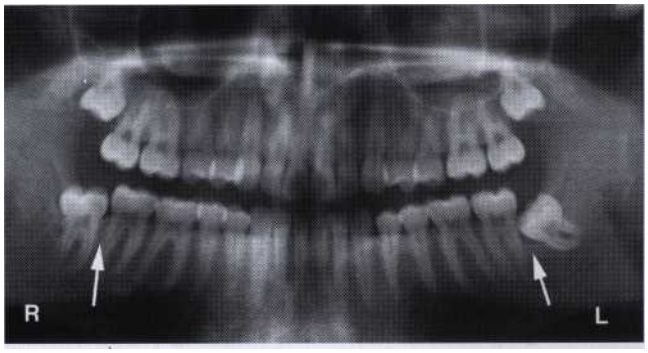

Fig. 11-35 Panoramic radiograph illustrating a mesial impacted lower left third molar with a widened follicle and no apparent bone on the distal interproximal surface of the second molar. Alternatively, the lower right third molar is vertically impacted and exhibits interproximal bone between distal to the second molar and the mesial surface of the third molar.

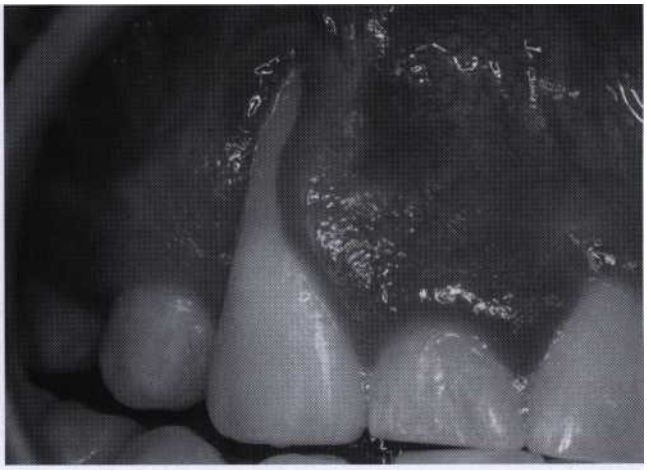

Fig. 11-36 A maxillary canine that illustrates gingival recession due to self-inflicted trauma by the patient's fingernail.

Chronic toothbrush trauma results in gingival recession with denudation of the root surface. Interproximal attachment loss is generally a consequence of bacteria-induced periodontitis, whereas buccal and lingual attachment loss is frequently the result of toothbrush abrasion.[194] Improper use of dental floss may result in lacerations of the interdental papilla.

Chemical Irritation. Acute gingival inflammation may be caused by chemical irritation resulting from either sensitivity or nonspecific tissue injury. In allergic inflammatory states, the gingival changes range from simple erythema to painful vesicle formation and ulceration. Severe reactions to ordinarily innocuous mouthwashes, dentifrices, or denture materials are often explainable on this basis.

Acute inflammation with ulceration may be produced by the nonspecific injurious effect of chemicals on the gingival tissues. The indiscriminate use of strong mouthwashes (Figs. *11-38* and *11-39),* topical application of corrosive drugs such as aspirin or cocaine, and accidental contact with drugs such as phenol or silver nitrate are common examples of chemicals that cause irritation of the gingiva.

Tobacco Use

Approximately 25% of the U.S. population smokes cigarettes,[40] and in other portions of the world the percentage of smokers appears to be even higher.[15,121] Smoking was associated with the prevalence of necrotizing ulcerative gingivitis (NUG) as early as *1947.*[154,155] In investigations in which plaque levels were kept to a minimum for both smoking and nonsmoking groups or the data were adjusted for this difference, smokers had more sites with deeper pockets[21,23,112] and greater attachment loss.[9,17,77,112] The prevalence of furcation involvement

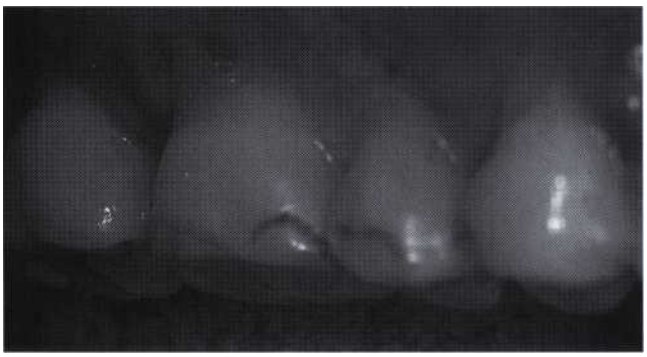

Fig. 11-37 The overzealous use of a toothbrush may denude the gingival epithelial surface, leaving the underlying connective tissue exposed as a painful ulcer.

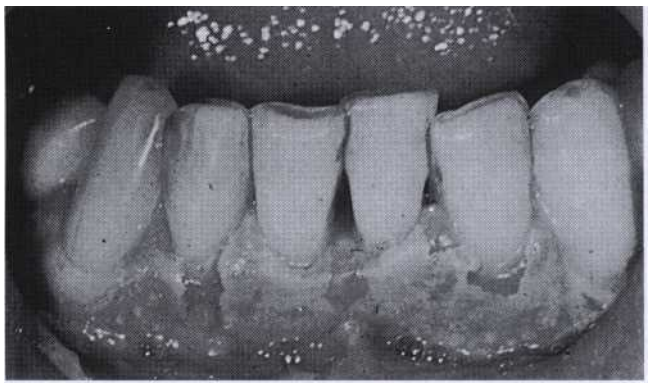

Fig. 11-38 The use of a concentrated mouthwash caused a chemical burn with accompanying necrosis and sloughing of the marginal gingiva.

among smokers was higher[9,142] as was the degree of alveolar bone loss.[20,14,216] 1t can be concluded that smokers have greater attachment loss and bone loss, an increased number of deep pockets and amount of calculus formation. However, smokers demonstrate varied levels of plaque and inflammation with a bias toward decreased inflammation.

Depending on which clinical parameters are used to assess periodontal disease, smokers are 2.6 to 6 times more likely to develop periodontal disease than nonsmokers.[18,22,77,79,198] The odds ratio for a moderate smoker (15 to 30 pack years) to have periodontal disease is 2.77 times that of a nonsmoker, and a heavy smoker (>_30 pack years) is 4.75 times more likely to have periodontal disease than a nonsmoker .[21] Pack years can be defined as the number of cigarettes smoked per day multiplied by the number of years that an individual smoked. Smoking also appears to be a contributing factor for periodontitis.[1,120,122] MacFarlane and coworkers reported that greater than 90% of their refractory periodontitis patients were smokers as compared with approximately 30% of the general population being smokers.[121] Periodontal maintenance patients who smoke are reported to be twice as likely to lose teeth over a 5-year period as compared with periodontal maintenance patients who do not smoke.[132] Smoking is one of the most significant risk factors currently available to predict the development and progression of periodontitis.[17,18,77]

Two possible explanations for smokers experiencing more prevalent and severe periodontal disease might be that they harbor more pathogenic subgingival microflora or their flora might be more virulent. However, several investigations failed to find any significant difference in the percentage of periodontal pathogens recovered from

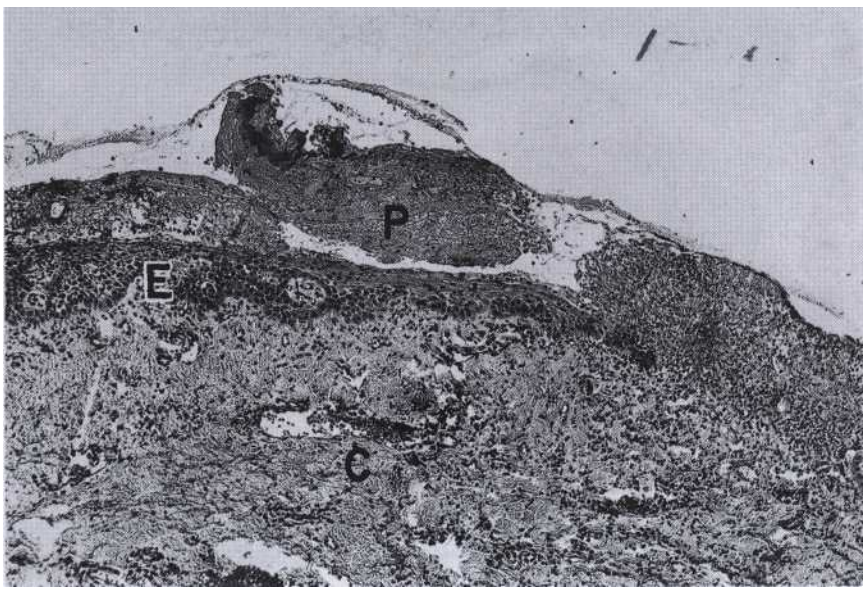

Fig. 11-39 Biopsy specimen of a necrotic area produced by chemical burn. Note the inflamed connective tissue (C) and surface pseudomembrane (P). Of particular clinical importance is the newly formed sheet of epithelial cells (E), which undermines the necrotic pseudomembrane and separates it from the underlying connective tissue. This is an important feature of the healing process.

deep pockets in smokers and nonsmokers. [160,163,198] The analysis of subgingival plaque samples collected from a large cross-sectional population in Erie County, New York[219] revealed that smokers were more likely to be infected with A. actinomycetemcomitans, Porphyromonas gingivalis, and Bacteroides forsythus than nonsmokers. However, the elevated values for these putative pathogens were not statistically higher than those found in nonsmokers. A diminished response to nonsurgical therapy has been reported for smokers. Recent research has indicated that it is more difficult to suppress certain bacteria such as A. actinomycetemcomitans,[171] p. gingivalis, [78,82] and B. forsythus[76] in smokers than in nonsmokers, which may partially explain a diminished response.

Although bacteria are the primary etiologic factors of periodontal disease, a patient's diminished host response may contribute to increased disease susceptibility. Smokers exhibit depressed numbers of helper T -lymphocytes, which are important to stimulate B-cell function for antibody production, [14,48,67] thereby reducing serum levels of IgG.[14] Smoking has been shown to decrease serum IgG2 levels in adult Caucasian subjects [165] and correlate with a dramatic reduction in levels of serum IgG2 anti-A. actinomycetemcomitans in African-American smokers with generalized, aggressive periodontitis.[20] Smokers have also been reported to exhibit reduced serum IgG antibodies to P. intermedia and F. nucleatum.[81] Neutrophils from smokers with refractory periodontitis exhibit impaired phagocytosis.[120] Neutrophils with diminished chemotaxis, phagocytosis, or both'°[2] may be a consequence of a lower antibody titer, which curtails opsonization. Nicotine has been shown to decrease gingival blood flow.[44] Periodontal wound healing may be adversely affected by exposure to tobacco or nicotine, which may impair revascularization in soft[137] and hard tissues. [172]

Smoking has been identified as a significant variable to predict the response to periodontal treatment. [132,144] Most investigations that evaluated the effect of smoking on nonsurgical therapy have demonstrated less reduction in probing depth[3,75,76,82,96,'62,171] and smaller gains in attachment levels in smokers as compared with nonsmokers.[3,82] Smokers who were treated with surgical periodontal therapy and subsequently followed with maintenance care exhibited less probing depth reduction, [3,96,161] smaller gains in clinical attachment levels [3,96] and less gain in bone height[32] than nonsmokers. Heavy cigarette smoking decreases the amount of root coverage obtainable with thick free gingival grafts,'" whereas the effect of smoking on subepithelial connective tissue grafts is not conclusive.[84,222] Gains in clinical attachment were less in smokers as compared with nonsmokers when guided tissue regenerative procedures were em-ployed.

success rates to be lower in smokers. [12,51,70,95] Implant success rate in excess of 95% have been reported among nonsmokers as compared with less than 89% in smokers during a 6-year period. [12] Patients who quit smoking 1 week before surgery and abstained for 8 weeks following the surgical placement of their implants had only one third as many failures as compared with those individuals who continued to smoke." Implant failure rates in these subjects were similar to nonsmokers. However,

Fig. 11-40 Gingival recession and hyperkeratosis of the vestibular mucosa have developed as a consequence of using chewing tobacco.

other retrospective implant studies have failed to identify smoking as a variable associated with failure. [134,213] A 15-year longitudinal study'[13] detected a slightly greater amount of marginal bone loss around implants supporting mandibular fixed prosthesis in smokers as compared with nonsmokers. In summary, smoking has a negative effect on periodontal therapy. However, periodontal therapy did result in an improvement in the periodontal condition of both smokers and nonsmokers when compared with their pretreatment status.

The prevalence and severity of periodontal disease in former smokers is between that of nonsmokers and current smokers.[30,71,11] This implies that once the patients stop smoking, additional adverse effects attributed to smoking may be minimized. However, previous damage is not reversed. Both nonsmokers and former smokers respond more favorably to periodontal therapy than current smokers, whereas no significant difference in response was noted between former smokers and nonsmokers. [78,96] The benefits of terminating smoking on periodontal treatment do not appear to be related to the number of years since smoking was halted.[76] Therefore a past history of smoking does not appear to be deleterious to the response of current periodontal treatment.

Feldman and co-workers reported that plaque, calculus, probing depth, and bone loss measurements for cigar smokers were intermediate to those for nonsmokers and cigarette smokers while exhibiting a tendency to be closer to nonsmoker values.[59]

Approximately *9%* of the U.S. high school population currently use smokeless tobacco products such as snuff and chewing tobacco.[41] The relationship between the use of smokeless tobacco and squamous cell carcinoma in the oral cavity is well established .[217] A strong relationship has been established between white oral mucosal lesions and the use of smokeless tobacco by athletes-", [114] and adolescents .[49,147,203] These white mucosal lesions occur in approximately 50% to 60% of smokeless tobacco users, whereas 25% to 30% exhibit localized attachment loss in the form of gingival recession on the facial surfaces of mandibular anterior teeth (Fig. 11-40).[73,159,174] A recent publication demonstrated that 97.5% of these

leukoplakia lesions are clinically resolved after abstaining from smokeless tobacco for 6 weeks. [131]

Radiation Therapy

Radiation therapy has cytotoxic effects on both normal cells and malignant cells. A typical total dose of radiation for head and neck tumors is in the range of 5000 to *8000* centiGrays (cGy = 1 rad).[153] The total dose of radiation is generally given in partial incremental doses referred to as *fractionation.* Fractionation helps minimize the adverse effects of the radiation while maximizing the death rate for the tumor cells.[60] Fractionated doses are typically administered in the range of 100 to 1000 cGys per week.

Radiation treatment induces an obliterative endarteritis that results in soft tissue ischemia and fibrosis while irradiated bone becomes hypovascular and hypoxic.[128] Adverse affects of head and neck radiation therapy include dermatitis and mucositis of the irradiated area as well as muscle fibrosis and trismus, which may restrict access to the oral cavity.[176] The mucositis typically develops 5 to 7 days after radiation therapy is initiated. The severity of the mucositis can be reduced by asking the patient to avoid secondary sources of irritation to the mucous membrane, such as smoking, alcohol, and spicy foods. Use of a chlorhexidine digluconate mouthrinse may help reduce the mucositis.[166] However, all chlorhexidine mouthrinses currently available in the U.S. have a high alcohol content that may act as an astringent, which dehydrates the mucosa, thereby intensifying the pain. Saliva production is permanently impaired when salivary glands that are located within the portal of radiation receive >_6000 cGy.[129] Xerostomia results in greater plaque accumulation and a reduced buffering capacity from what saliva is left. The use of effective oral hygiene, professional dental prophylactic cleanings, fluoride applications, and frequent dental examinations are essential to control caries and periodontal disease. The use of customized trays appears to be a more effective method of fluoride application as compared with the toothbrush.[101]

Periodontal attachment loss and tooth loss was greater in cancer patients who were treated with high-dose unilateral radiation as compared with the nonradiated control side of the dentition." Irradiated patients should be covered with prophylactic antibiotics before receiving appropriate nonsurgical periodontal therapy following the patient's initial recovery from radiation therapy." Dental and periodontal infections have the potential to be a severe risk to a patient who has been treated with head and neck radiation. Therefore the dental therapist may choose to consult with the patient's oncologist before initiating therapy. The risk of osteoradionecrosis must be evaluated before extracting a tooth or performing periodontal surgery in an irradiated site. Precautions must be taken regarding prophylactic antibiotics, atraumatic surgical technique, microbiologic culture and sensitivity, restricted use of local anesthetic with vasoconstrictor, and the need for hyperbaric oxygen therapy. (Refer to Chapter *38* for more detail on the periodontal management of medically compromised patients.)

Influence of Systemic Disease and Disorders on the Periodontium

Perry R. Klokkevold, Brian L. Mealey, and Fermin A. Carranza

CHAPTER OUTLINE

NUTRITIONAL INFLUENCES
- **Physical Character of the Diet**
- **Effect of Nutrition on Oral Microorganisms**
- **Fat-Soluble Vitamin Deficiency**
- **Water-Soluble Vitamin Deficiency**
- **Protein Deficiency**
- **Starvation**

ENDOCRINE DISORDERS
- **Diabetes Mellitus**
- **Oral Manifestations of Diabetes**
- **Bacterial Pathogens**
- **Polymorphonuclear Leukocyte Function**
- **Altered Collagen Metabolism**
- **Hyperparathyroidism**
- **Sex Hormones**
- **The Gingiva in Puberty**
- **Gingival Changes Associated with the Menstrual Cycle**
- **Gingival Disease in Pregnancy**
- **Hormonal Contraceptives and the Gingiva**
- **Menopausal Gingivostomatitis (Senile Atrophic Gingivitis)**
- **Corticosteroid Hormones**

HEMATOLOGIC DISORDERS
- **Leukemia**
- **The Periodontium in Leukemic Patients**
- **Chronic Leukemia**
- **Anemia**
- **Thrombocytopenia**

IMMUNODEFICIENCY DISORDERS
- **Leukocyte Disorders**
- **Antibody Deficiency Disorders**

CARDIOVASCULAR DISEASES
- **Arteriosclerosis**
- **Congenital Heart Disease**

OTHER SYSTEMIC CONDITIONS
- **Metal Intoxication**

PSYCHOSOMATIC DISORDERS

Many systemic disorders have been implicated as risk indicators or risk factors for adverse periodontal conditions. Clinical and basic science research over the past several decades has unveiled a much better understanding of the complexity and pathogenesis of periodontal diseases.[153] Clearly, there is an *essential* bacterial cause, and there are *specific* bacteria (periodontal pathogens) associated with destructive periodontal disease. These pathogens do not cause disease simply by their presence alone, but their absence appears to be consistent with periodontal health. The role of bacteria in disease etiology and pathogenesis are discussed in Chapters 6 and 8. Perhaps one of the most revealing recent discoveries about periodontitis is that the host response varies between individuals and that either an inadequate host immune response or an exaggerated host immune response to bacterial pathogens leads to more severe forms of the disease. In other words the host response to periodontal pathogens is very important and likely explains the differences in disease severity from one individual to another. Recent evidence is also beginning to shed light on the role of periodontal infections on systemic health problems such as coronary heart disease, stroke, diabetes, preterm labor, low-birth-weight delivery, and respiratory disease.[138] The potential role of periodontal infections on systemic health are discussed in Chapter 13. In addition to the interrelationships between periodontal infections and host immune response, a number of environmental, physical, and psychosocial stress factors affect periodontal tissues and

modify disease expression. In general, these disorders do not initiate chronic destructive periodontitis, but they may predispose, accelerate, or otherwise increase its progression toward periodontal tissue destruction. This chapter discusses the influence of systemic disease and disorders on the periodontium.

NUTRITIONAL INFLUENCES

Some clinicians enthusiastically adhere to the theory in periodontal disease that assigns a key role to nutritional deficiencies and imbalances. Research conducted up to the present in general does not support this view, but numerous problems in experimental design and data interpretation may render these research findings inadequate.[5] The majority of opinions and research findings on the effects of nutrition on oral and periodontal tissues point to the following:

1. *There are nutritional deficiencies that produce changes in the oral cavity*. These changes include alterations of the lips, oral mucosa, and bone, as well as the periodontal tissues. These changes are considered to be periodontal or oral manifestations of nutritional disease.
2. *There are no nutritional deficiencies that by themselves can cause gingivitis or periodontal pockets.* However, nutritional deficiencies can affect the condition of the periodontium and thereby can aggravate the injurious effects of local factors and excessive occlusal forces. Theoretically, it can be assumed that there may be a "border zone" in which local factors of insufficient severity can cause gingival and periodontal disorders, if their effect on the periodontium is aggravated by nutritional deficiencies.

This section analyzes the existing knowledge in the field of nutrition as it relates to periodontal disease, with reference also made to other oral changes of nutritional origin.

Physical Character of the Diet

Numerous experiments in animals have shown that the physical character of the diet may play some role in the accumulation of plaque and the development of gingivitis.'" Soft diets, although nutritionally adequate, may lead to plaque and calculus formation.[33,123,156] Hard, fibrous foods provide surface cleansing action and stimulation, which results in less plaque and gingivitis, even if the diet is nutritionally inadequate.[55,94,109,213]

In humans, however, studies have been unable to demonstrate reduced plaque formation when hard foods are consumed.[114] The discrepancy may be related to differences in tooth anatomy and to the fact that hard foods are fed to experimental animals as the only diet, whereas humans also consume soft foods. Human diets also have a high sucrose content, which favors the production of a thick plaque.

Effect of Nutrition on Oral Microorganisms

Although dietary intake is generally thought of in terms of sustaining the individual, it is also the source of nutrients for bacterial' Through its effects on the oral bacteria, the diet may influence relative distribution of types of organisms, their metabolic activity, and their pathogenic potential, which in turn affect the occurrence and severity of oral disease.

Sources of nutrients for the microorganisms can be endogenous and exogenous. Among the exogenous factors, the influence of the sugar content of the diet has been extensively studied, and it has been demonstrated that the amount and type of carbohydrates in the diet and the frequency of intake can influence bacterial growth.[38] Attachment and subsequent colonization of the tooth surface by certain microorganisms also may be made possible by components of the diet.

Fat-Soluble Vitamin Deficiency

Vitamins A, D, and E are fat-soluble vitamins required in the human diet. This section describes observations of deficiency of these vitamins.

Vitamin A Deficiency. A major function of vitamin A is to maintain the health of epithelial cells of the skin and mucous membranes. Deficiency of vitamin A results in dermatologic, mucosal, and ocular manifestations. In the absence of vitamin A, degenerative changes occur in epithelial tissues, resulting in a keratinizing metaplasia. Since epithelial tissues provide a primary barrier function to protect against invading microorganisms, vitamin A also plays an important role in maintaining epithelial.

Little information is available regarding the effects of vitamin A deficiency on the oral structures in humans. Several epidemiologic studies have failed to demonstrate any relation between this vitamin and periodontal disease in humans .[2,6]

In experimental animals, vitamin A deficiency results in hyperkeratosis and hyperplasia of the gingiva with a tendency for increased periodontal pocket formation. The following periodontal changes have been reported in vitamin A-deficient rats: hyperplasia and hyperkeratinization of the gingival epithelium with proliferation of the junctional epithelium and retardation of gingival wound healing.[29,64] In the presence of local factors, vitamin A-deficient rats develop periodontal pockets that are deeper than those in animals not deficient in vitamin A and exhibit associated epithelial hyperkeratosis.[28,77]

Vitamin D Deficiency. Vitamin D, or calciferol, is essential for the absorption of calcium from the gastrointestinal tract and the maintenance of the calcium-phosphorus balance. Deficiency in vitamin D and/or imbalance in calcium-phosphorus intake results in rickets in the very young and osteomalacia in adults.

The effect of such deficiency or imbalance on the periodontal tissues of young dogs results in osteoporosis of alveolar bone; osteoid that forms at a normal rate but remains uncalcified; failure of osteoid to resorb, which leads to its excessive accumulation; reduction in the width of the periodontal ligament space; a normal rate of cementum formation, but defective calcification and some cementum resorption; and distortion of the growth pattern of alveolar bone.",'"

In osteomalacic animals, there is rapid, generalized, severe osteoclastic resorption of alveolar bone, proliferation of fibroblasts that replace bone and marrow, and new bone formation around the remnants of unresorbed bony trabeculae.[53] Radiographically, there is generalized partial to complete disappearance of the lamina dura and reduced density of the supporting bone, loss of trabeculae, increased radiolucence of the trabecular interstices, and increased prominence of the remaining trabeculae. Microscopic and radiographic changes in the periodontium are almost identical with those seen in experimentally induced hyperparathyroidism.

Vitamin E Deficiency. Vitamin E serves as an antioxidant to limit free-radical reactions and to protect cells from lipid peroxidation. Cell membranes, which are high in polyunsaturated lipids, are the major site of damage in vitamin E deficiency.

No relationship has been demonstrated between deficiencies in vitamin E and oral disease, but systemic vitamin E appears to accelerate gingival wound healing in the rat. [107,144,155]

Water-Soluble Vitamin Deficiency

Vitamins B and C are water-soluble vitamins required in the human diet. The function of these vitamins and the clinical manifestations of their deficiency are described in this section.

B-Complex Deficiency. The vitamin B complex includes thiamin, riboflavin, niacin, pyridoxine (B6), biotin, folic acid, and cobalamin (B12). Oral disease is rarely due to a deficiency in just one component of the B-complex group, the deficiency is generally multiple.

Oral changes common to B-complex deficiencies are gingivitis, glossitis, glossodynia, angular cheilitis, and inflammation of the entire oral mucosa. The gingivitis in vitamin B deficiencies is nonspecific, as it is caused by bacterial plaque rather than by the deficiency, but it is subject to the modifying effect of the latter . [2]

The human manifestations of thiamin deficiency, called *beriberi,* are characterized by paralysis; cardiovascular symptoms, including edema; and loss of appetite. Frank beriberi is rare in the United States. Oral disturbances that have been attributed to thiamin deficiency include hypersensitivity of the oral mucosa; minute vesicles (simulating herpes) on the buccal mucosa, under the tongue, or on the palate; and erosion of the oral mucosa. [83,130]

The symptoms of riboflavin deficiency (ariboflavinosis) include glossitis, angular cheilitis, seborrheic dermatitis, and a superficial vascularizing keratitis. The glossitis is characterized by a magenta discoloration and atrophy of the papillae. In mild to moderate cases, the dorsum exhibits a patchy atrophy of the lingual papillae and engorged fungiform papillae, which project as pebble-like elevations. [2,99] In severe deficiency, the entire dorsum is flat, with a dry and often fissured surface.

Angular cheilitis begins as an inflammation of the commissure of the lips, followed by erosion, ulceration, and fissuring. Riboflavin deficiency is not the only cause of angular cheilitis. Loss of vertical dimension, together with drooling of saliva into the angles of the lips, may produce a condition similar to angular cheilitis. Candidiasis may develop in the commissures of debilitated persons; this lesion has been termed *perleche.*[81]

Changes observed in riboflavin-deficient animals include severe lesions of the gingivae; periodontal tissues; and oral mucosa, including noma.[41-199]

Niacin deficiency results in pellagra, which is characterized by dermatitis; gastrointestinal disturbances; neurologic and mental disturbances (dermatitis, diarrhea, and dementia); glossitis, gingivitis; and generalized stomatitis.

Glossitis and stomatitis may be the earliest clinical signs of niacin deficiency.[131] The gingiva may be involved in aniacinosis with or without tongue changes.[1°$] The most common finding is necrotizing ulcerative gingivitis, usually in areas of local irritation.

Oral manifestations of vitamin B-complex and niacin deficiency in experimental animals include black tongue and gingival inflammation with destruction of the gingiva, periodontal ligament, and alveolar bone. [2,15,50] Necrosis of the gingiva and other oral tissues, as well as leukopenia, are terminal features of niacin deficiency in experimental animals.

Folic acid deficiency results in macrocytic anemia with megaloblastic erythropoiesis, accompanied by oral changes, gastrointestinal lesions, diarrhea, and intestinal malabsorption. [52] Folic acid-deficient animals demonstrate necrosis of the gingiva, periodontal ligament, and alveolar bone without inflammation. [182] The absence of inflammation is the result of deficiency-induced granulocytopenia. In humans with sprue and other folic acid deficiency states, generalized stomatitis occurs, which may be accompanied by ulcerated glossitis and cheilitis. Ulcerative stomatitis is an early indication of the toxic effect of folic acid antagonists used in the treatment of leukemia.

In a series of human studies, a significant reduction of gingival inflammation has been reported after systemic or local use of folic acid, when compared with placebo . [203,204] This reduction occurred with no change in plaque accumulation. The same authors have postulated that the gingival changes associated with pregnancy and oral contraceptives may be partly related to suboptimal levels of folic acid in the gingiva. [202] In a clinical study of pregnant women, a reduction in gingival inflammation occurred with the use of topical folate mouth rinses; no change was found with systemic folic acid.[152] A relationship has also been assumed between phenytoin-induced gingival overgrowth and folic acid, based on the interference of folic acid absorption and utilization of phenytoin . [201]

Vitamin C (Ascorbic Acid) Deficiency. Severe vitamin C deficiency in humans results in scurvy, a disease characterized by hemorrhagic diathesis and retardation of wound healing. Vitamin C is required in the human diet but not in that of other animals except other primates, guinea pigs, and some rare flying mammals.[48] Vitamin C is abundant in fruits and vegetables. Scurvy is uncommon in countries that have adequate food

supplies, but it may appear in infants in their first year of life if formulas are not fortified with vitamins and in the very old, especially those living alone and on restricted diets.[48] Alcoholism also may predispose an individual to scurvy.

Clinical manifestations of scurvy include hemorrhagic lesions into the muscles of the extremities, the joints, and sometimes the nail beds; petechial hemorrhages, often around hair follicles; increased susceptibility to infections; and impaired wound healing.[48] Bleeding, swollen gingiva and loosened teeth are also common features of scurvy.

Vitamin C deficiency (scurvy) results in defective formation and maintenance of collagen, retardation or cessation of osteoid formation, and impaired osteoblastic function .[61,212] Vitamin C deficiency is also characterized by increased capillary permeability, susceptibility to traumatic hemorrhages, hyporeactivity of the contractile elements of the peripheral blood vessels, and sluggishness of blood flow."'

POSSIBLE ETIOLOGIC RELATIONSHIPS BETWEEN ASCORBIC ACID AND PERIODONTAL DISEASE. It has been suggested that ascorbic acid may play a role in periodontal disease by one or more of the following mechanisms[213]:

1. *Low levels of ascorbic acid influence the metabolism of collagen within the periodontium, thereby affecting the ability of the tissue to regenerate and repair itself. No* experimental evidence supports this view of the role of ascorbic acid; furthermore, it has been shown that collagen fibers in the periodontal ligament of scorbutic monkeys are the last affected before death of the animals .[2°s]
2. *Ascorbic acid deficiency interferes with bone formation, leading to loss of periodontal bone.* Changes that do occur in alveolar bone and other bones as a result of failure of the osteoblasts to form osteoid take place very late in the deficiency state. 72 Osteoporosis of alveolar bone in scorbutic monkeys occurs as a result of increased osteoclastic resorption and is not associated with periodontal pocket formation .[2°5]
3. *Ascorbic acid deficiency increases the permeability of the oral mucosa to tritiated endotoxin and tritiated inulin and of normal human crevicular epithelium to tritiated dextran.*[6,7] Optimal levels of this vitamin, therefore, would maintain the epithelium's barrier function to bacterial products.
4. *Increasing levels of ascorbic acid enhance both the chemotactic and migratory action of leukocytes without influencing their phagocytic activity.*[79] Megadoses of vitamin C seem to impair the bactericidal activity of leukocytes.[113] The significance of these findings for the pathogenesis and treatment of periodontal diseases is not understood.
5. *An optimal level of ascorbic acid is apparently required to maintain the integrity of the periodontal microvasculature, as well as the vascular response to bacterial irritation and wound healing.*[36]
6. *Depletion of vitamin C may interfere with the ecologic equilibrium of bacteria in plaque and thus increase its pathogenicity.* However, there is no evidence that demonstrates this effect.

Epidemiologic Studies. Several studies in large populations have analyzed the relationship between gingival or periodontal status and ascorbic acid levels .[2°6] These studies used different methods for the biochemical analysis of ascorbic acid and various indices for the assessment of periodontal changes; they were made in persons of different socioeconomic status, different races, and various ages. All the epidemiologic surveys failed to establish a causal relationship between the levels of vitamin C and the prevalence or severity of periodontal disease .[35,58,172] Megadoses of ascorbic acid have also been found to be unrelated to better periodontal health .[97,214]

Gingivitis. The legendary association of severe gingival disease with scurvy led to the presumption that vitamin C deficiency is an etiologic factor in gingivitis, which is common at all ages.

Gingivitis with enlarged, hemorrhagic, bluish-red gingiva is described as one of the classic signs of vitamin C deficiency, but *gingivitis is not caused by vitamin C deficiency per se.* Vitamin C- deficient patients do not necessarily have gingivitis. Acute vitamin C deficiency does not cause or increase the incidence of gingival inflammation, but it does increase its severity.[42, n,"] Gingivitis in vitamin C-deficient patients is caused by bacterial plaque. Vitamin C deficiency may aggravate the gingival response to plaque and worsen the edema, enlargement, and bleeding. In addition, although correcting the deficiency may reduce the severity of the disorder, gingivitis will remain as long as bacterial factors are present.

Periodontitis. Changes in the supporting periodontal tissues and gingiva in vitamin C deficiency have been documented extensively in experimental animals. [72,94,205] Acute vitamin C deficiency results in edema and hemorrhage in the periodontal ligament, osteoporosis of the alveolar bone, and tooth mobility; hemorrhage, edema, and degeneration of collagen fibers occur in the gingiva. Vitamin C deficiency also retards gingival healing. The periodontal fibers that are least affected by vitamin C deficiency are those just below the junctional epithelium and above the alveolar crest, which explains the infrequent apical downgrowth of the epithelium .[2°5]

Vitamin C deficiency does not cause periodontal pockets; local bacterial factors are required for pocket formation to occur. However, acute vitamin C deficiency accentuates the destructive effect of gingival inflammation on the underlying periodontal ligament and alveolar bone .[73]

The exaggerated destruction results partly from an inability to marshal a defensive delimiting connective tissue barrier reaction to the inflammation and partly from destructive tendencies caused by the deficiency itself, including inhibition of fibroblast formation and differentiation to osteoblasts, as well as impaired formation of collagen and mucopolysaccharide ground substance.

Experimental studies conducted in humans failed to show the dramatic clinical changes that have traditionally been described in scurvy.[49,93,165] A case report published by Charbeneau and Hurt showed worsening of a preexisting moderate periodontitis with the development of scurvy.[42]

In a retrospective analysis of 12,419 adults studied in the Third National Health and Nutrition Examination Survey (NHANES III), Nishida et al found that there was a weak but statistically significant dose-response relationship between the levels of dietary vitamin C intake and periodontal disease in current and former smokers as measured by clinical attachment.[146] This suggests that vitamin C deficiency has its greatest impact on periodontal disease when preexisting disease and other codestructive factors are present.

In summary, analysis of the literature indicates that the microscopic signs of vitamin C deficiency are quite different from those that occur in plaque-induced periodontal disease in humans. Patients with acute or chronic vitamin C-deficient states and no plaque accumulation show minimal, if any changes in their gingival health status.

Protein Deficiency

Protein depletion results in hypoproteinemia with many pathologic changes, including muscular atrophy, weakness, weight loss, anemia, leukopenia, edema, impaired lactation, decreased resistance to infection, slow wound healing, lymphoid depletion, and reduced ability to form certain hormones and enzyme systems.38 Protein deprivation also causes changes in the periodontium of experimental animals.43 The following observations have been made in protein-deprived animals: degeneration of the connective tissue of the gingiva and periodontal ligament, osteoporosis of alveolar bone, retardation in the deposition of cementum, delayed wound healing, and atrophy of the tongue epithelium.[39,190,191] Similar changes occur in the periosteum and bone in other non-oral areas. Osteoporosis results from reduced deposition of osteoid, reduction in the number of osteoblasts, and retardation in the morphodifferentiation of connective tissue cells to form osteoblasts, rather than from increased osteoclastic activity.

These observations are of interest in that they reveal a loss of alveolar bone that is the result of the inhibition of normal bone-forming activity rather than of the introduction of destructive factors. Protein deficiency also accentuates the destructive effects of local factors and occlusal trauma on the periodontal tissues, but the initiation of gingival inflammation and its severity depend on the local factors.[140,191] In other words, protein deprivation results in periodontal tissues that lack integrity and, as a result, are more vulnerable to breakdown when challenged by bacteria.

Starvation

Starvation is the ultimate nutritional challenge. Without any food intake, there is a total lack of nutrients, no physical stimulation and no fuel for energy. In a study of controlled semistarvation in young adults, there were no changes in the oral cavity or skeletal system, despite a 24% loss of body weight.[106] Another study, however, showed a reduction in Plaque Index scores and a considerable increase in Gingival Index scores as the fasting period lengthened.[189]

In experimental animals, acute starvation results in osteoporosis of alveolar bone and other bones, reduction in the height of alveolar bone, and accentuated bone loss associated with gingival inflammation.[74]

ENDOCRINE DISORDERS

Endocrine disorders, such as diabetes, and hormonal fluctuations that are associated with puberty and pregnancy are well known examples of systemic conditions that adversely affect the health of the periodontium. Endocrine disturbances and hormone fluctuations affect the periodontal tissues directly, modify the tissue response to local factors, and produce anatomic changes in the gingiva that may favor plaque accumulation and disease progression. This section describes the evidence supporting the relationship between endocrine disorders and periodontal disease.

Diabetes Mellitus

Diabetes mellitus is an extremely important disease from a periodontal standpoint. It is a complex metabolic disease characterized by chronic hyperglycemia. Diminished insulin production, impaired insulin action, or a combination of both result in the inability of glucose to be transported from the bloodstream into the tissues, which in turn, results in high blood glucose levels and excretion of sugar in the urine. Lipid and protein metabolism is also altered in diabetes. Uncontrolled diabetes (chronic hyperglycemia) is associated with several long-term complications, including microvascular diseases (retinopathy, nephropathy, neuropathy); macrovascular diseases (cardiovascular and cerebrovascular), an increased susceptibility to infections; and poor wound healing.

An estimated 15.7 million individuals, or 5.9% of the population in the United States, have diabetes.143 Nearly half of these individuals are unaware that they have the disease. The two major types of diabetes are types 1 and 2, with several less common secondary types of diabetes.

Type 1 diabetes mellitus, formerly insulin-dependent diabetes mellitus (IDDM), is caused by a cell-mediated autoimmune destruction of the insulin-producing beta cells of the islets of Langerhans in the pancreas, which results in insulin deficiency. Type 1 diabetes accounts for 5% to 10% of all cases of diabetes and most often occurs in children and young adults. This type of diabetes results from a lack of insulin production and is very unstable and difficult to control. It has a marked tendency toward ketosis and coma, is not preceded by obesity, and requires injected insulin to be controlled. Patients with type 1 diabetes mellitus present with the symptoms traditionally associated with diabetes, including polyphagia, polydipsia, polyuria and predisposition to infections.

Type 2 diabetes mellitus, formerly non-insulin dependent diabetes mellitus (NIDDM) is caused by peripheral resistance to insulin action, impaired insulin secretion, and increased glucose production in the liver. The insulin-producing beta cells in the pancreas are not destroyed by cell-mediated autoimmune reaction. Type 2 diabetes is the most common form of diabetes accounting for 90% to 95% of all cases. This form of the disease most often has an adult onset. Many times individuals are not aware they

have the disease until severe symptoms or complications occur. It generally occurs in obese individuals and can often be controlled by diet and/or oral hypoglycemic agents. The development of ketosis and coma is not common. Type 2 diabetes can present with the same symptoms as type 1 diabetes but typically in a less severe form.

An additional category of diabetes is hyperglycemia secondary to other diseases or conditions. A prime example of this type of hyperglycemia is gestational diabetes associated with pregnancy. Gestational diabetes develops in 2% to 5% of all pregnancies but disappears after delivery. Women who have had gestational diabetes are at increased risk of developing type 2 **diabetes later in life.** Other secondary types of diabetes are those associated with diseases that involve the pancreas and destruction of the insulin-producing cells. Endocrine diseases such as acromegaly and Cushing's syndrome, tumors, pancreatectomy, and drugs or chemicals that cause altered insulin levels are included in this group. Experimentally induced types of diabetes generally belong in this category rather than in one of the two classic categories of disease.

Oral Manifestations of Diabetes

Numerous oral changes have been described in diabetics, including cheilosis, mucosal drying and cracking, burning mouth and tongue, diminished salivary flow, and alterations in the flora of the oral cavity, with greater predominance of *Candida albicans,* hemolytic streptococci, and staphylococci.[1,23,82,133] An increased rate of dental caries has also been observed in poorly controlled diabetes.[59,67] It should be noted that these changes are not always present, are not specific, and are not pathognomonic for diabetes.[136] Furthermore, these changes are less likely to be observed in well-controlled diabetics. Individuals with controlled diabetes have a normal tissue response, a normally developed dentition, a normal defense against infections and no increase in the incidence of caries.[197]

The influence of diabetes on the periodontium has been thoroughly investigated. Although it is difficult to make definitive conclusions about the specific effects of diabetes on periodontium, a variety of changes have been described, including a tendency toward enlarged gingiva, sessile or pedunculated gingival polyps, polypoid gingival proliferations, abscess formation, periodontitis, and loosened teeth[12] (Color Fig. 12-1). Perhaps the most striking changes in uncontrolled diabetes are the reduction in defense mechanisms and the increased susceptibility to infections leading to destructive periodontal disease.

Periodontitis in type 1 diabetes appears to start after age 12.[44] The prevalence of periodontitis has been reported as being 9.8% in 13 to 18 year olds, increasing to 39% in those 19 years and older.

The extensive literature on this subject and the overall impression of clinicians point to the fact *that periodontal disease in diabetics follows no consistent or distinct pattern.* Very severe gingival inflammation, deep periodontal pockets, rapid bone loss, and frequent periodontal abscesses often occur in diabetic patients with poor oral hygiene (see Color Fig. 12-1).[3] Children with type 1 diabetes tend to have more destruction around the first molars and incisors than elsewhere, but this destruction becomes more generalized at older ages.[44] In juvenile diabetics, extensive periodontal destruction often occurs due to the age of these patients.

Other investigators have reported that the rate of periodontal destruction appears to be similar for those with diabetes and without, up to the age of 30 .[70,195] After age 30, there is a greater degree of destruction in individuals with diabetes. This may be related to disease destruction over time. Patients showing overt diabetes over a period of more than 10 years have greater loss of periodontal structures than those with a diabetic history of less than 10 years.[71] It may also be related to the diminished tissue integrity that continues to deteriorate over time. See the following description of altered collagen metabolism in diabetics.

Despite the fact that some studies have not found a correlation between the diabetic state and the periodontal condition, the majority of well-controlled studies show a higher prevalence and severity of periodontal disease in individuals with diabetes than without, with similar local factors.[10,23,37,45,89,96,145,147,149,174,209] Findings include a greater loss of attachment, increased bleeding on probing, and increased tooth mobility (Fig. 12-1). Perhaps the different degrees of diabetic involvement and control of the disease in patients examined and the diversity of indices and patient sampling are responsible for this lack of consistency.

Recent studies suggest that uncontrolled or poorly controlled diabetes is associated with an increased susceptibility and severity of infections including periodontitis.[12,174] Diabetes does not cause gingivitis or periodontal pockets, but there are indications that it alters the response of the periodontal tissues to local factors (see Color Fig. 12-1, *A, B),* hastening bone loss and retarding postsurgical healing of the periodontal tissues. Frequent periodontal abscesses appear to be an important feature of periodontal disease in diabetics.

Approximately 40% of adult Pima Indians in Arizona have type 2 diabetes. A comparison of individuals with or without diabetes in this Native American tribe has shown a clear increase in prevalence of destructive periodontitis, as well as a 15% increase in edentulousness, in individuals with diabetes.[51] The risk of developing destructive periodontitis increases threefold in these individuals.[57]

Bacterial Pathogens

The glucose content of gingival fluid and blood is higher in individuals with diabetes than without, with similar Plaque and Gingival Index scores.[60] The increased glucose in the gingival fluid and blood of individuals with diabetes could change the environment of the microflora, inducing qualitative changes in bacteria that could account for the severity of periodontal disease observed in poorly controlled individuals with diabetes.

Patients with type 1 diabetes with periodontitis have been reported to have a subgingival flora composed mainly of *Capnocytophaga,* anaerobic vibrios, and *Actinomyces* species. *Porphyromonas gingivalis, Prevotella intennedia,* and *Actinobacillus actinomycetemcomitans,* which are

common in periodontal lesions of individuals without diabetes, are present in low numbers in those with the disease.[88,134] Other studies, however, found scarce *Capnocytophaga* and abundant A. *actinomycetemcomitans* and black-pigmented *Bacteroides,* as well as P. *intermedia, P. melaninogenica,* and *Campylobacter rectus.*[133,175] Black-pigmented species, especially P. *gingivalis, P. intermedia,* and C. *rectus,* are prominent in severe periodontal lesions of Pima Indians with type 2 diabetes.[68,215] These results point to an altered flora in the periodontal pockets of patients with diabetes. The exact role of these microorganisms has not been determined.

Polymorphonuclear Leukocyte Function

The increased susceptibility of diabetics to infection has been hypothesized as being due to polymorphonuclear leukocyte deficiencies resulting in impaired chemotaxis, defective phagocytosis, or impaired adherence.[69,137,158] No alteration of immunoglobulins A, G, or M has been found in diabetics.[169]

Altered Collagen Metabolism

Increased collagenase activity and decreased collagen synthesis is found in individuals with diabetes with chronic hyperglycemia. Decreased collagen synthesis, osteoporosis, and reduction in the height of alveolar bone occur in diabetic animals, with comparable osteoporosis in other bones.[71,178] The periodontal ligament and cementum are not affected, but glycogen is depleted in the gingiva. Other investigators report that gingival inflammation and bone destruction associated with local factors are more severe in diabetic than in nondiabetic animals.[25] Generalized osteoporosis, resorption of the alveolar crest, and gingival inflammation and periodontal pocket formation associated with calculus have been described in Chinese hamsters with hereditary diabetes under insulin replacement therapy.[177]

Chronic hyperglycemia adversely affects the synthesis, maturation, and maintenance of collagen and extracellular matrix. In the hyperglycemic state, numerous proteins and matrix molecules undergo a nonenzymatic glycosylation, resulting in advanced glycation end products (AGES). The formation of AGES can occur at normal glucose levels, but in hyperglycemic environments, AGE formation is excessive. AGE formation cross-links collagen, making it less soluble and less likely to be normally repaired or replaced. As a result, collagen in the tissues of poorly controlled diabetics is aged and more susceptible to breakdown.

AGES play a central role in the classic complications of diabetes.[31] They may play a significant role in the

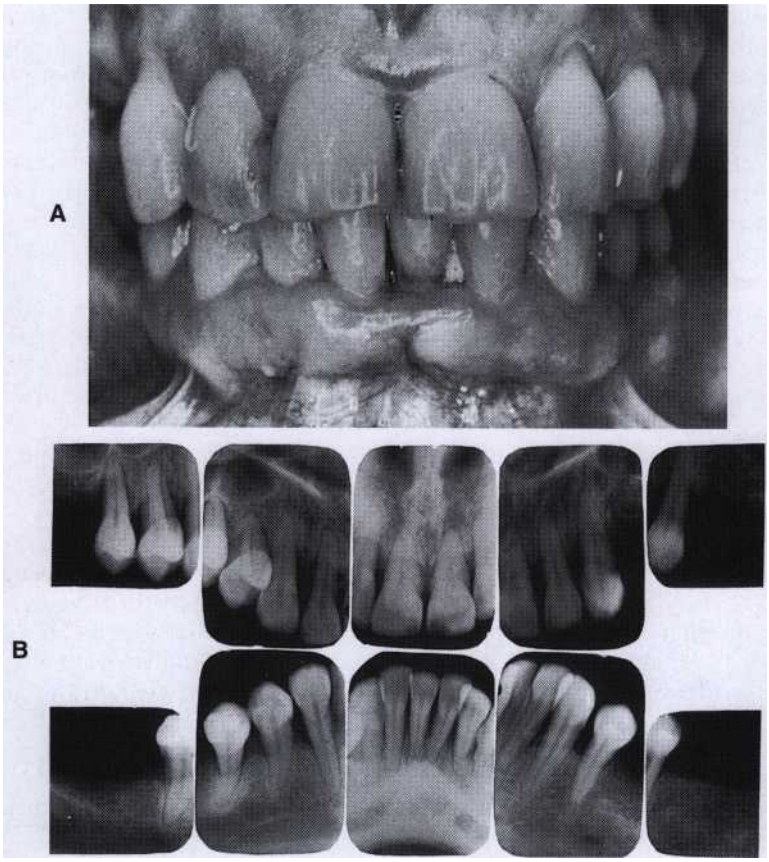

Fig. 12-1 Diabetic patient. A, Gingival inflammation and periodontal pockets in a 34-year-old patient with diabetes of long duration. B, Extensive generalized bone loss in the patient shown in A. Failure to replace posterior teeth adds to the occlusal burden of the remaining dentition.

progression of periodontal disease as well. Poor glycemic control and increased AGES render the periodontal tissues more susceptible to destruction.177 Cellular migration through cross-linked collagen is impeded and perhaps more importantly, tissue integrity is impaired as a result of damaged collagen remaining in the tissues for longer periods.

The cumulative effects of altered cellular response to local factors, impaired tissue integrity and altered collagen metabolism undoubtedly play a significant role in the susceptibility of individuals with diabetes to infections and destructive periodontal disease.

A study of risk indicators for a group of 1426 patients, ages 25 to 74, revealed that individuals who are age 45 or older, have diabetes, and smoke are at 20 times greater risk of periodontal disease than patients who do not have these indicators. If they are also infected subgingivally with *Bacteroides* forsythus or *P. gingivalis,* the risk increases to 30 to 50 times .86

Hyperparathyroidism

Parathyroid hypersecretion produces generalized demineralization of the skeleton, increased osteoclasis with proliferation of the connective tissue in the enlarged marrow spaces, and formation of bone cysts and giant cell tumors.207 The disease is called osteitis fibrosa cystica or von Recklinghausen's bone disease.

Oral changes include malocclusion and tooth mobility, radiographic evidence of alveolar osteoporosis with closely meshed trabeculae, widening of the periodontal ligament space, absence of the lamina dura, and radiolucent cystlike spaces (Figs. 12-2 and 12-3). Bone cysts become filled with fibrous tissue with abundant hemosiderin-laden macrophages and giant cells. They have been called *brown* tumors, although they are not really tumors but reparative giant cell granulomas.

Loss of the lamina dura and giant cell tumors in the jaws are late signs of hyperparathyroid bone disease, which in itself is uncommon. Complete loss of the lamina dura does not occur often, and there is a danger of attaching too much diagnostic significance to it.

Fig. 12-2 Secondary hyperparathyroidism in a 35-year-old woman with advanced kidney disease. This periapical radiograph shows ground-glass appearance of bone and loss of lamina dura. (Courtesy Dr. L. Roy Eversole, San Francisco, Calif.)

Other diseases in which it may occur are Paget's disease, fibrous dysplasia, and osteomalacia.

Different investigators report that 25%, 45%, and 50% of patients with hyperparathyroidism have associated oral changes.[110,118,192] A relationship has been suggested between periodontal disease in dogs and hyperparathyroidism secondary to calcium deficiency in the diet.90 This has not been confirmed by other studies.[194]

Sex Hormones

There are several types of gingival disease in which modification of the sex hormones is considered to be either the initiating or complicating factor; these types of gingival alterations are associated with physiologic hormonal changes and are characterized by nonspecific inflammatory changes with a predominant vascular component leading clinically to a marked hemorrhagic tendency.

Experimental Studies. Progesterone administration to female dogs produces dilation and increased permeability of the gingival microvasculature, which increases susceptibility to injury and exudation, but it does not affect the morphology of the gingival epithelium.[96]

Repeated injections of estrogen in female rats cause increased endosteal bone formation in the jaws and decreased polymerization of mucopolysaccharide protein complexes in the bone ground substance.", [148,187] Estrogen injections also counteract tendencies toward hyperkeratosis of the gingival epithelium and fibrosis of the vessel walls in ovariectomized female animals. They also stimulate bone formation and fibroplasia, which compensate for destructive changes in the periodontium induced by the systemic administration of cortisone.[76] Locally applied progesterone, estrogen, and gonadotropin appear to reduce the acute inflammatory response to chemical irritation.[122]

Elevated levels of estrogen and progesterone increase gingival exudation in female dogs with and without gingivitis, most likely because of hormone-induced increased permeability of the gingival vessels.[119]

Ovariectomy results in osteoporosis of alveolar bone, reduced cementum formation, and reduced fiber density and cellularity of the periodontal ligament in young adult mice, but not in older animals.[75-159] The gingival epithelium is atrophic in estrogen-deficient animals.[217]

Systemic administration of testosterone retards the downgrowth of sulcular epithelium over the cementum; stimulates osteoblastic activity in alveolar bone; increases the cellularity of the periodontal ligament; and restores osteoblastic activity, which is depressed by hypophysectomy.[171,184,185] The healing of oral wounds is accelerated by castration in males and is unaffected by ovariectomy in females.[34]

The Gingiva in Puberty

Puberty is often accompanied by an exaggerated response of the gingiva to local irritation.[193] Pronounced inflammation, bluish-red discoloration, edema, and enlargement result from local factors that would ordinarily elicit a comparatively mild gingival response (Fig. 12-4).

As adulthood is approached, the severity of the gingival reaction diminishes, even when local factors persist. However, complete return to normal requires removal of these factors. Although the prevalence and severity of gingival disease are increased in puberty, gingivitis is not a universal occurrence during this period; with good oral hygiene, it can be prevented (see Chapter 20).

Gingival Changes Associated with the Menstrual Cycle

As a general rule, the menstrual cycle is not accompanied by notable gingival changes, but occasional problems do occur. Gingival changes associated with menstruation have been attributed to hormonal imbalances and in some instances may be accompanied by a history of ovarian dysfunction.

During the menstrual period, the prevalence of gingivitis increases. Some patients may complain of bleeding gums or a bloated, tense feeling in the gums in the days preceding menstrual flow. The exudate from inflamed gingiva is increased during menstruation, suggesting that existent gingivitis is aggravated by menstruation, but the crevicular fluid of normal gingiva is unaffected." Tooth mobility does not change significantly during the menstrual cycle.[65] The salivary bacterial count is increased during menstruation and at ovulation to 14 days earlier.[27,160]

Gingival Disease in Pregnancy

Gingival changes in pregnancy were described as early as 1898, even before any knowledge about hormonal changes in pregnancy was available.[24]

Pregnancy itself does not cause gingivitis. Gingivitis in pregnancy is caused by bacterial plaque, just as it is in nonpregnant individuals. Pregnancy accentuates the gingival response to plaque and modifies the resultant clinical picture (Figs. 12-5 to 12-7). No notable changes occur in the gingiva during pregnancy in the absence of local factors.

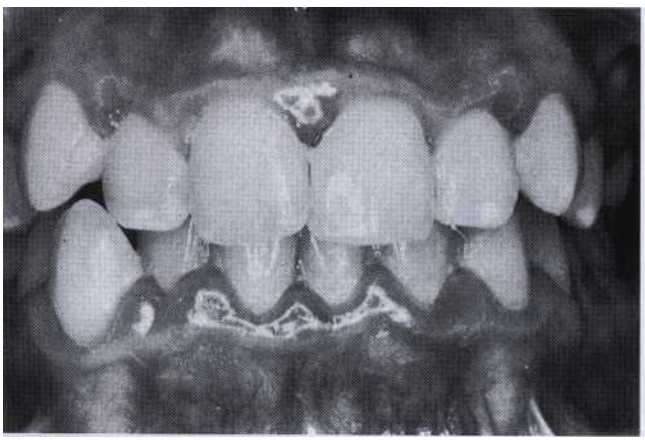

Fig. 12-4 Gingivitis in puberty, with edema, discoloration, and enlargement.

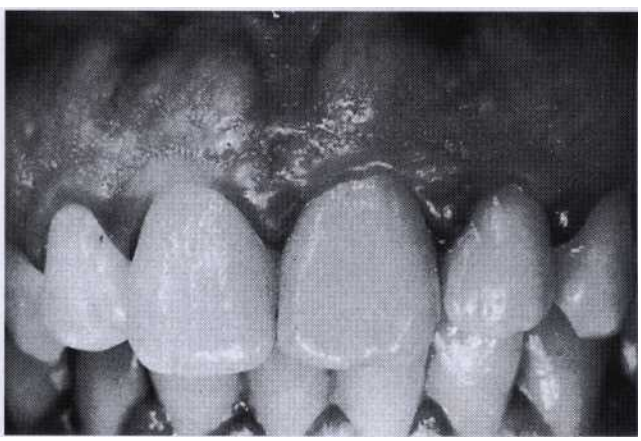

Fig. 12-5 Early changes in the interdental papillae in pregnancy.

The severity of gingivitis is increased during pregnancy beginning in the second or third month. Patients with slight chronic gingivitis that attracted no particular attention before the pregnancy become aware of the gingiva because previously inflamed areas become enlarged, edematous, and more notably discolored. Patients with a slight amount of gingival bleeding before pregnancy become concerned about an increased tendency to bleed (see Color Fig. 12-1, G).

Gingivitis becomes more severe by the eighth month and decreases during the ninth, plaque accumulation follows a similar pattern.[124] Some investigators report the greatest severity as being between the second and third trimesters .47 The correlation between gingivitis and the quantity of plaque is greater after parturition than during pregnancy, which suggests that pregnancy introduces other factors that aggravate the gingival response to local factors."'

The reported incidence of gingivitis in pregnancy in well-conducted studies varies from around 50% to 100%.'[24,28] Pregnancy affects the severity of previously inflamed areas, it does not alter healthy gingiva. Impressions of increased incidence may be created by the aggravation of previously inflamed but unnoticed areas.[161] Tooth mobility,[164] pocket depth, and gingival fluid[16,118] are also increased in pregnancy.

Partial reduction in the severity of gingivitis occurs by 2 months postpartum, and after 1 year the condition of the gingiva is comparable to that of patients who have not been pregnant .47 However, the gingiva does not return to normal as long as local factors are present. Also reduced after pregnancy is tooth mobility, pocket depth, and gingival fluid. In a longitudinal investigation of the periodontal changes during pregnancy and for 15 months postpartum, no significant loss of attachment was observed.47

Pronounced ease of bleeding is the most striking clinical feature. The gingiva is inflamed and varies in color from a bright red to bluish red.[216,218] The marginal and interdental gingivae are edematous, pit on pressure, appear smooth and shiny, are soft and pliable, and sometimes present a raspberry-like appearance. The extreme redness results from marked vascularity, and there is an increased tendency to bleed (see Color Fig. *12-1, G).* The gingival changes are usually painless unless complicated by acute infection. In some cases the inflamed gingiva forms discrete "tumorlike" masses, referred to as pregnancy tumors (see Color Fig. *12-1,* G; see Chapter 18).

The microscopic picture of gingival disease in pregnancy is one of nonspecific, vascularizing, proliferative inflammation.[128,218] Marked inflammatory cellular infiltration with edema and degeneration of the gingival epithelium and connective tissue occurs. The epithelium is hyperplastic, with accentuated rete pegs, reduced surface keratinization, and various degrees of intracellular and extracellular edema and infiltration by leukocytes.[200] Newly formed engorged capillaries are present in abundance.

The possibility that bacterial-hormonal interactions may change the composition of plaque and lead to gingival inflammation has not been extensively explored. Kornman and Loesche have reported that the subgingival flora changes to a more anaerobic flora as pregnancy progresses, the only microorganism that increases significantly during pregnancy is P. *intermedia.*[112] This increase appears to be associated with elevations in systemic levels of estradiol and progesterone and to coincide with the peak in gingival bleeding.[112] It has also been suggested that during pregnancy a depression of the maternal T-lymphocyte response may be a factor in the altered tissue response to plaque.[150]

The aggravation of gingivitis in pregnancy has been attributed principally to the increased levels of progesterone, which produce dilation and tortuosity of the gingival microvasculature, circulatory stasis, and increased susceptibility to mechanical irritation, all of which favor leakage of fluid into the perivascular tissues.[42,49] A marked increase in estrogen and progesterone occurs during pregnancy, with a reduction after parturition. The severity of gingivitis varies with the hormonal levels in pregnancy.[96]

The gingiva is a target organ for female sex hormones.

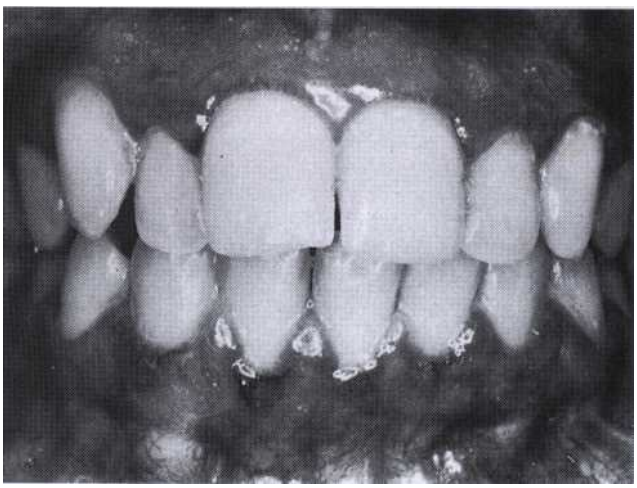

Fig. 12-6 Gingiva in pregnancy, showing edema, discoloration, and bleeding.

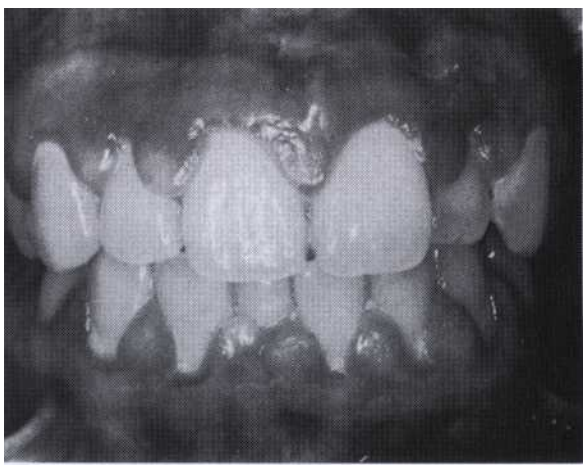

Fig. 12-7 Gingiva in pregnancy, showing edema, discoloration, and enlargement.

Formicola and colleagues have shown that radioactive estradiol injected into female rats appears not only in the genital tract but also in the gingiva.[62]

It has also been suggested that the accentuation of gingivitis in pregnancy occurs in two peaks: during the first trimester, when there is overproduction of gonadotropins, and during the third trimester, when estrogen and progesterone levels are highest.[124] Destruction of gingival mast cells by the increased sex hormones and the resultant release of histamine and proteolytic enzymes may also contribute to the exaggerated inflammatory response to local factors.[121]

Hormonal Contraceptives and the Gingiva

Hormonal contraceptives aggravate the gingival response to local factors in a manner similar to that seen in pregnancy and, when taken for a period of more than 1.5 years, increase periodontal destruction.[56,110,120]

Although some brands of oral contraceptives produce more dramatic changes than others, no correlation has been found to exist on the basis of differences in progesterone or estrogen content in various brands.[128,157] Cumulative exposure to oral contraceptives apparently has no effect on gingival inflammation or oral Debris Index scores.[101]

Menopausal Gingivostomatitis (Senile Atrophic Gingivitis)

This condition occurs during menopause or in the postmenopausal period. Mild signs and symptoms sometimes appear, associated with the earliest menopausal changes. Menopausal gingivostomatitis is not a common condition. The term used for its designation has led to the erroneous impression that it invariably occurs associated with menopause, whereas the opposite is true. Oral disturbances are not a common feature of menopause .[210]

The gingiva and remaining oral mucosa are dry and shiny, vary in color from abnormal paleness to redness, and bleed easily. Fissuring occurs in the mucobuccal fold in some cases, and comparable changes may occur in the vaginal mucosa.[166] The patient complains of a dry, burning sensation throughout the oral cavity, associated with extreme sensitivity to thermal changes; abnormal taste sensations described as "salty," "peppery" or "sour"; and difficulty with removable partial prostheses.'"

Microscopically, the gingiva exhibits atrophy of the germinal and prickle cell layers of the epithelium and, in some instances, areas of ulceration.

The signs and symptoms of menopausal gingivostomatitis are in some degree comparable to those of chronic desquamative gingivitis (see Chapter 39). Signs and symptoms similar to those of menopausal gingivostomatitis occasionally occur after ovariectomy or sterilization by radiation in the treatment of malignant neoplasms.

Corticosteroid Hormones

In humans, systemic administration of cortisone and adrenocorticotropic hormone (ACTH) appears to have no effect on the incidence and severity of gingival and periodontal disease."-' However, renal transplant patients who are receiving immunosuppressive therapy (prednisone or methylprednisone and azathioprine or cyclophosphamide) have significantly less gingival inflammation than control subjects with similar amounts of plaque.[16,103,151,198]

The systemic administration of cortisone in experimental animals results in osteoporosis of alveolar bone; capillary dilation and engorgement, with hemorrhage in the periodontal ligament and gingival connective tissue; degeneration and reduction in the number of collagen fibers of the periodontal ligament, and increased destruction of the periodontal tissues associated with inflammation caused by local irritation."

HEMATOLOGIC DISORDERS

All blood cells play a role in the maintenance of a healthy periodontium. White blood cells (WBCs) are involved in peripheral and inflammatory reactions. Red blood cells (RBCs) are responsible for gas exchange and nutrient supply to the periodontal tissues and platelets and are required for normal hemostasis. Disorders of the blood or blood-forming organs can have a profound effect on the periodontium. Certain oral changes such as hemorrhage may suggest the existence of a blood disturbance; specific diagnosis, however, requires a complete physical examination and a thorough hematologic study. Comparable oral changes occur in more than one form of blood dyscrasia, and secondary inflammatory changes produce a wide range of variation in the oral signs.

Gingival and periodontal disturbances associated with blood dyscrasias must be thought of in terms of fundamental interrelationships between the oral tissues and the blood and blood-forming organs rather than in terms of a simple association of dramatic oral changes with hematologic disease. Ecchymosis and petechiae observed most often in the soft palate area is a sign of an underlying bleeding disorder (Figs. 12-8 and 12-9). Abnormal bleeding from the gingiva or other areas of the oral mucosa that is difficult to control is an important clinical sign suggesting a hematologic disorder. Hemorrhagic tendencies occur when the normal hemostatic mechanisms are disturbed.

Leukemia

The leukemias are "malignant neoplasias of WBC precursors, characterized by (1) diffuse replacement of the bone marrow with proliferating leukemic cells; (2) abnormal numbers and forms of immature WBCs in the circulating blood; and (3) widespread infiltrates in the liver, spleen, lymph nodes, and other sites throughout the body.""'

According to the type of WBC involved, leukemias are classified as *lymphocytic* or *myelocytic;* a subgroup of the myelocytic leukemias is monocytic leukemia. According to their evolution, leukemias can be *acute,* which is rapidly fatal, *subacute;* or *chronic.* In acute leukemia, the primitive "blast" cells are released into the peripheral circulation, whereas in chronic leukemia, the abnormal cells tend to be more mature with normal morphologic characteristics when released into the circulation.

In all leukemias, the replacement of the bone marrow elements by leukemic cells reduces normal production of

RBCs, WBCs, and platelets, leading to anemia, a reduction in the number of nonmalignant WBCs, and thrombocytopenia. Anemia results in poorer tissue oxygenation, making tissues more friable and susceptible to breakdown. A reduction of normal WBCs in the circulation leads to an increased susceptibility to infections. Thrombocytopenia (low platelet counts) leads to bleeding tendency, which can occur in any tissue but has a propensity to occur in the mouth, especially the gingival sulcus (Fig. 12-10). Some patients may have normal blood counts while leukemic cells are present in the bone marrow, this type of disease is called *aleukemic leukemia."*

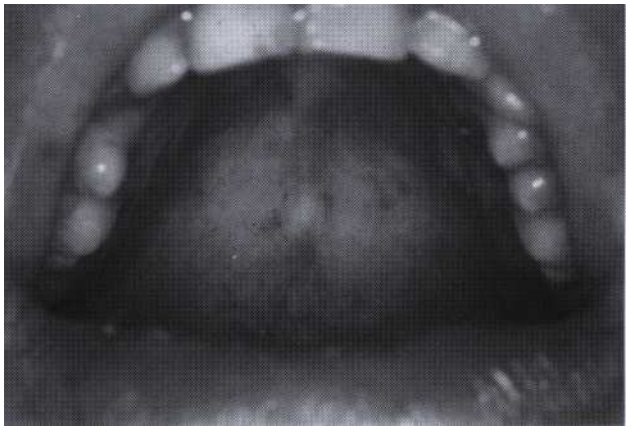

Fig. 12-8 Petechiae evident on the soft palate of patient with underlying bleeding disorder.

The Periodontium in Leukemic Patients

Oral and periodontal manifestations of leukemia consist of leukemic infiltration, bleeding, oral ulcerations, and infections.

Leukemic Infiltration of the Periodontium. Leukemic **cells can infiltrate** the gingiva and, less frequently, the alveolar bone. Gingival infiltration often results in leukemic gingival enlargement (see Chapter 18).

A study of 1076 adult patients with leukemia showed that 3.6% of the patients with teeth had leukemic gingival proliferative lesions, with the highest incidence in patients with acute monocytic leukemia (66.7%), followed by acute myelocytic-monocytic leukemia (18.7%) and acute myelocytic leukemia (3.7%).[54] It should be pointed out, however, that monocytic leukemia is an extremely rare form of the disease. Leukemic gingival enlargement is not found in edentulous patients or in patients with chronic leukemia. Leukemic gingival enlargement consists of a basic infiltration of the gingival corium by leukemic cells that creates gingival pockets where bacterial plaque accumulates, initiating a secondary inflammatory lesion that contributes also to the enlargement of the gingiva.

Fig. 12-9 Ecchymosis evident on the lateral aspects of the soft palate and tonsillar pillars of patient with chemotherapy induced thrombocytopenia.

Clinically, the gingiva appears initially bluish red and cyanotic, with a rounding and tenseness of the gingival margin; then it increases in size, most often in the interdental papilla and partially covering the crowns of the teeth (Figs. 12-11, 12-12, and 12-13).

Microscopically, the gingiva exhibits a dense, diffuse infiltration of predominantly immature leukocytes in the attached and marginal gingiva. Occasional mitotic figures indicative of ectopic hematopoiesis may be seen. The normal connective tissue components of the gingiva are displaced by the leukemic cells (Fig. 12-14, A). The nature of the cells depends on the type of leukemia. The cellular accumulation is denser in the entire reticular connective tissue layer. In almost all cases, the papillary layer contains comparatively few leukocytes. The blood vessels are distended and contain predominantly leukemic cells, and the RBCs are reduced in number. The epithelium presents a variety of changes. It may be thinned or hyperplastic. Common findings include degeneration associated with intercellular and intracellular edema and leukocytic infiltration with diminished surface keratinization.

The microscopic picture of the marginal gingiva differs from that of the remainder of the gingiva in that it usually exhibits a notable inflammatory component, in

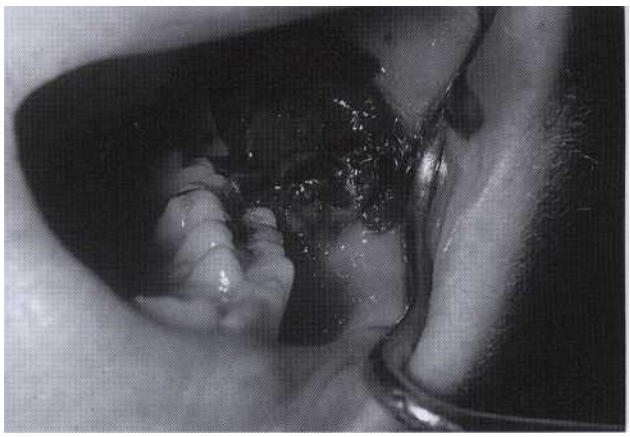

Fig. 12-10 Spontaneous bleeding from the gingival sulcus in a patient with thrombocytopenia. Normal coagulation is evident by the large clot that forms in the mouth. However, platelets are inadequate to establish hemostasis.

Fig. 12-11 Leukemic infiltration causing localized gingival swelling of the interdental papilla.

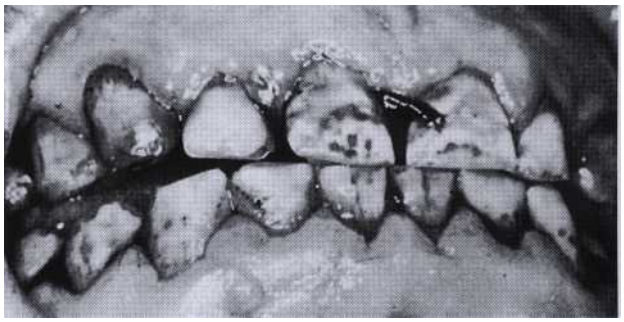

Fig. 12-12 Acute lymphocytic leukemia. The gingiva is inflamed, edematous, and discolored and bleeds spontaneously.

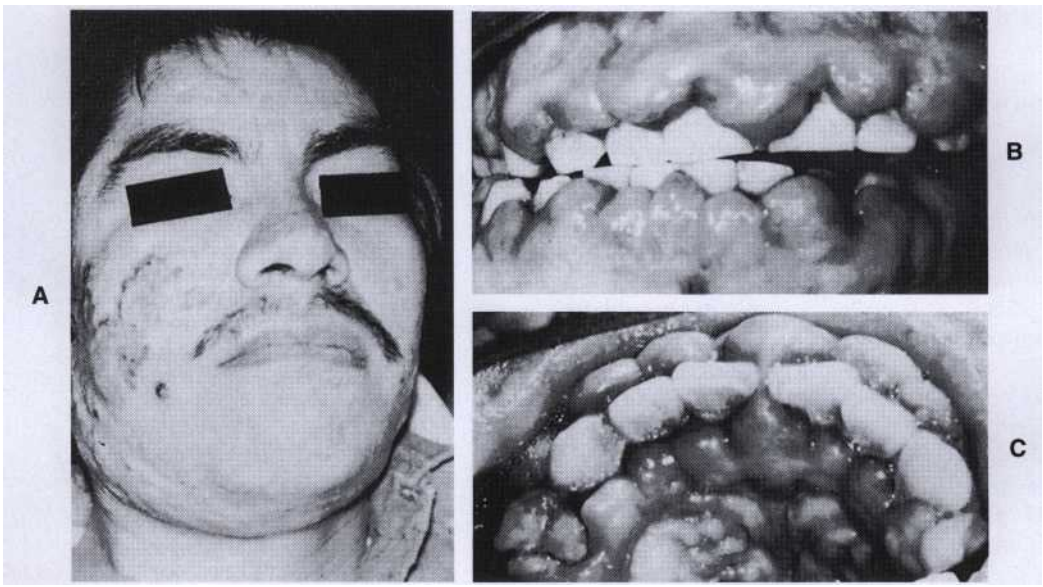

Fig. 12-13 Acute myelocytic leukemia. A, View of patient's face. Note the elevated flat macules and papules (leukemia cutis) on the right cheek. B, Intraoral view showing the pronounced gingival enlargement. C, Occlusal view of upper anterior teeth. Note the marked enlargement in both the facial and the palatal aspects. (Courtesy Dr. Spencer Woolfe, Dublin, Ireland.)

addition to the leukemic cells. Scattered foci of plasma cells and lymphocytes with edema and degeneration are common findings. The inner aspect of the marginal gingiva is usually ulcerated, and marginal necrosis with pseudomembrane formation may also be seen.

The periodontal ligament and alveolar bone may also be involved in acute and subacute leukemia (see Fig. 12-14, B). The periodontal ligament may be infiltrated with mature and immature leukocytes. The marrow of the alveolar bone exhibits a variety of changes, such as localized areas of necrosis, thrombosis of the blood vessels, infiltration with mature and immature leukocytes, occasional RBCs, and replacement of the fatty marrow by fibrous tissue.

In leukemic mice, the presence of infiltrate in marrow spaces and the periodontal ligament results in osteoporosis of the alveolar bone with destruction of the supporting bone and disappearance of the periodontal fibers (Fig. 12-15).[30,40]

The abnormal accumulation of leukemic cells in the dermal and subcutaneous connective tissue is called *leukemia cutis* and forms elevated flat macules and papules (see Fig. 12-13, A).[54,168]

Bleeding. Gingival hemorrhage is a common finding in leukemic patients (see Fig. 12-10), even in the absence of clinically detectable gingivitis. Bleeding gingiva can be an early sign of leukemia.[180] It is due to the thrombocytopenia that results from replacement of the bone marrow cells by leukemic cells and also from the inhibition of normal stem cell function by leukemic cells or their products.[161]

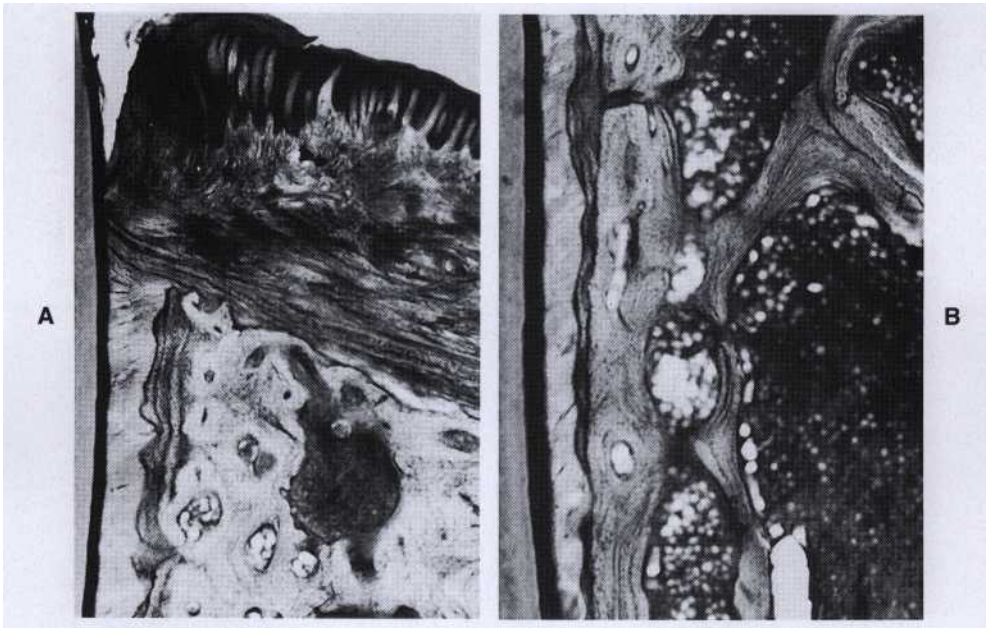

Fig. 12-14 A, Leukemic infiltrate in gingiva and bone in a human autopsy specimen. B, Same case as in A. Note the dense infiltrate in marrow spaces and the lack of extension to the periodontal ligament.

This bleeding tendency can also manifest itself in the skin and throughout the oral mucosa, where petechiae are often found, with or without leukemic infiltrates. Oral bleeding has been reported as a presenting sign in 17.7% of patients with acute leukemia and in 4.4% of patients with chronic leukemia.'" This symptom can also result from the chemotherapeutic agents used.

Oral Ulceration and Infection. The granulocytopenia resulting from the replacement of bone marrow cells by leukemic cells reduces the tissue resistance to opportunistic microorganisms and leads to ulcerations and infections. Discrete, punched-out ulcers penetrating deeply into the submucosa and covered by a firmly attached white slough can be found in the oral mucosa.11 These lesions occur in sites of trauma such as the buccal mucosa in relation to the line of occlusion or the palate. Patients with past history of herpes infection may develop herpetic oral ulcers, often in multiple sites and large atypical forms and after chemotherapy is instituted" (Fig. 12-16).

Gingival bacterial infection in leukemic patients can be a primary bacterial infection or result from an increased severity of existing gingival or periodontal disease. Acute gingivitis and lesions of necrotizing ulcerative gingivitis are more frequent and severe in terminal cases of acute leukemia19 (Figs. 12-17 and 12-18).

In leukemia, the response to irritation is altered so that the cellular component of the inflammatory exudate differs both quantitatively and qualitatively from that which occurs in nonleukemic individuals. There is pronounced infiltration of immature leukemic cells in addition to the usual inflammatory cells.

The inflamed gingiva differs clinically from inflamed gingiva in nonleukemic individuals. It is a peculiar bluish red, is markedly spongelike and friable, and bleeds

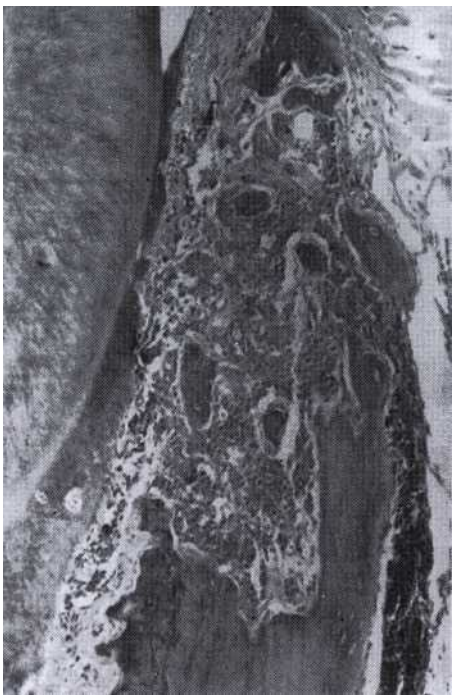

Fig. 12-15 Leukemic infiltrate in alveolar bone in leukemic mouse. Note the leukemic infiltrate producing destruction of bone and loss of periodontal ligament.

persistently on the slightest provocation or even spontaneously. This markedly altered and degenerated tissue is extremely susceptible to bacterial infection, which can be so severe as to cause acute gingival necrosis and pseudomembrane formation (Figs. 12-19 and 12-20). These are secondary oral changes superimposed on the

Fig. 12-16 Large ulcerations on the palate of patient with granulocytopenia secondary to leukemia. These atypical ulcerations are caused by herpes virus opportunistic infection. Notice the smaller, discrete round ulcerations that have coalesced into the larger lesion.

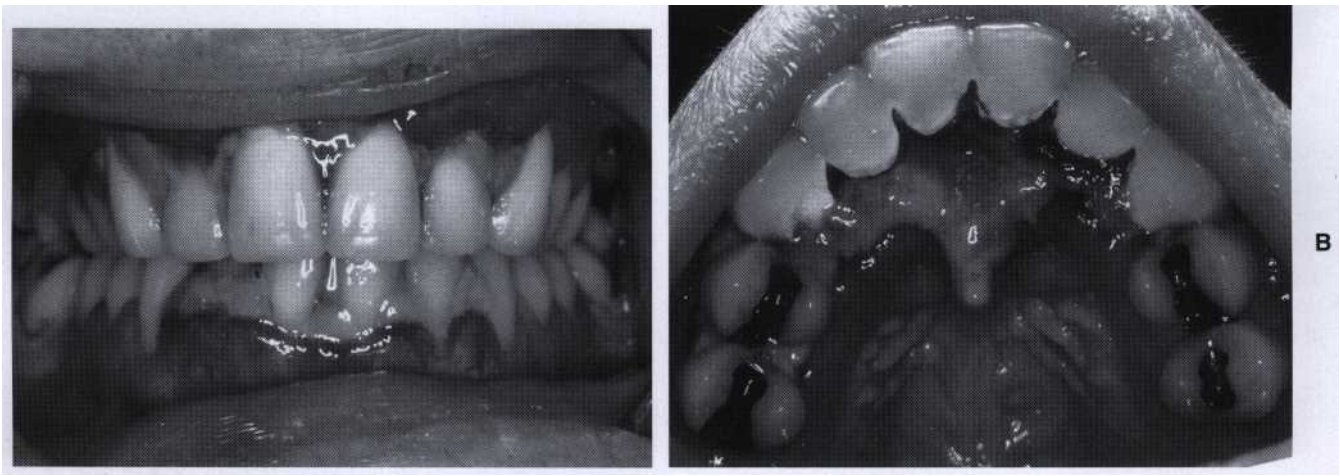

Fig. 12-17 A, Anterior view of patient with acute myelocytic leukemia. Interdental papilla are necrotic with a highly inflamed and swollen base. B, Palatal view demonstrating extensive necrosis of interdental and palatal tissue.

Fig. 12-18 Same patient as in Fig. 12-17 following chemotherapy and initial induction of remission. A, Anterior view reveals that although the tissue health has dramatically improved, the interdental papilla have been lost. B, Palatal view shows extensive loss of gingival tissue around maxillary incisors.

oral tissues altered by the blood disturbance. They produce associated disturbances that may be a source of considerable difficulty to the patient, such as systemic toxic effects, loss of appetite, nausea, blood loss from persistent gingival bleeding, and constant gnawing pain. By eliminating local factors, it is possible to alleviate severe oral changes in leukemia.

Chronic Leukemia

In chronic leukemia, clinical oral changes suggesting a hematologic disturbance are very rare. The microscopic changes in chronic leukemia may consist of replacing the normal fatty marrow of the jaws with islands of mature lymphocytes or lymphocytec infiltration of the marginal gingiva without dramatic clinical manifestations.

The existence of leukemia is sometimes revealed by a gingival biopsy performed to clarify the nature of a troublesome gingival condition. In such cases, the gingival findings must be corroborated by medical examination and hematologic study. The absence of leukemic involvement in a gingival biopsy specimen does not rule out the possibility of leukemia. In chronic leukemia, the gingiva may simply present inflammatory changes, with no suggestion of a hematologic disturbance. In patients with recognized leukemia, the gingival biopsy indicates the extent to which leukemic infiltration is responsible for the altered clinical appearance of the gingiva. Al*though such findings are of interest, their benefit to the patient is insufficient to warrant routine gingival biopsy studies inpatients with leukemia.*

Anemia

Anemia is a deficiency in the quantity or quality of the blood as manifested by a reduction in the number of erythrocytes and in the amount of hemoglobin. Anemia may be the result of blood loss, defective blood formation, or increased blood destruction.

Anemias are classified according to cellular morphology and hemoglobin content as 1) macrocytic hyperchromic anemia (pernicious anemia); 2) microcytic hypochromic anemia (iron deficiency anemia); 3) sickle cell anemia; or 4) normocytic-normochromic anemia (hemolytic or aplastic anemia).

Pernicious anemia results in tongue changes in 75% of cases. The tongue appears red, smooth, and shiny, owing to atrophy of the papillae. There is also marked pallor of the gingiva (Figs. 12-21 and 12-22).

Iron deficiency anemia induces similar tongue and gingival changes. A syndrome consisting of glossitis and ulceration of the oral mucosa and oropharynx, inducing dysphagia (Plummer-Vinson syndrome), has been described in patients with iron deficiency anemia.

Sickle cell anemia is a hereditary form of chronic hemolytic anemia that occurs almost exclusively in blacks. It is characterized by pallor, jaundice, weakness, rheumatoid manifestations, and leg ulcers. Oral changes include generalized osteoporosis of the jaws, with a peculiar stepladder alignment of the trabeculae of the interdental septa, along with pallor and yellowish discoloration of the oral mucosa. Periodontal infections may precipitate sickle cell crisis.162

Fig. 12-20 The opportunistic bacterial infection in this immunosuppressed patient caused complete destruction of the gingiva exposing the underlying alveolar bone.

Fig. 12-19 Opportunistic bacterial infection of the gingiva in a patient with leukemia. Gingival tissue is highly inflamed, bleeding and necrotic with pseudomembrane formation.

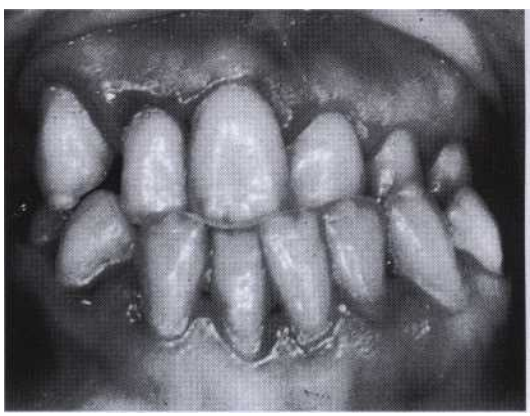

Fig. 12-21 Diffuse pallor of the gingiva in a patient with anemia. The discolored, inflamed gingival margin stands out in sharp contrast to the adjacent pale, attached gingiva.

Aplastic anemias result from a failure of the bone marrow to produce erythrocytes. Their etiology is usually the effect of toxic drugs on the marrow. Oral changes include pale discoloration of the oral mucosa and increased susceptibility to infection, owing to the concomitant neutropenia.

Thrombocytopenia

Thrombocytopenic purpura may be idiopathic (i.e., of unknown etiology, as in Werlhof's disease), or it may occur secondary to some known etiologic factor responsible for a reduction in the amount of functioning marrow and a resultant reduction in the number of circulating platelets. Such etiologic factors include aplasia of the marrow; crowding out of the megakaryocytes in the marrow, as in leukemia, replacement of the marrow by tumor; and destruction of the marrow by irradiation or radium or by drugs such as benzene, aminopyrine, and arsenical agents.

Thrombocytopenic purpura is characterized by a low platelet count, a prolonged clot retraction and bleeding time, and a normal or slightly prolonged clotting time. There is spontaneous bleeding into the skin or from mucous membranes. Petechiae and hemorrhagic vesicles occur in the oral cavity, particularly in the palate, tonsillar pillars, and the buccal mucosa (see Figs. 12-8 and 12-9). *The gingivae are swollen, soft, and friable. Bleeding occurs spontaneously or on the slightest provocation and is difficult to control. Gingival changes represent an abnormal response to local irritation;* the severity of the gingival condition is dramatically alleviated by removal of the local factors (Fig. 12-23).

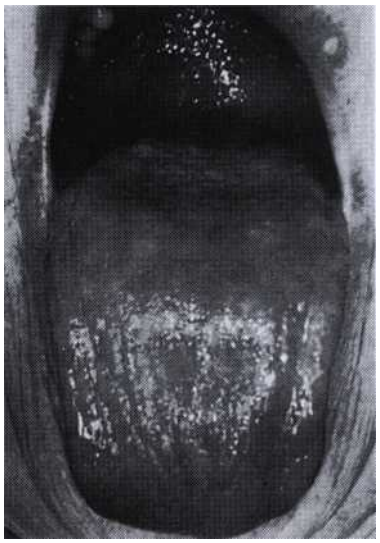

Fig. 12-22 Smooth tongue in a patient with pernicious anemia.

IMMUNODEFICIENCY DISORDERS

Deficiencies in host defense mechanisms may lead to severely destructive periodontal lesions. These deficiencies may be primary, or inherited; or secondary, caused by immunosuppressive drug therapy or pathologic destruction of the lymphoid system. Leukemia, Hodgkin's disease, lymphomas, and multiple myeloma all may result in secondary immunodeficiency disorders.

Leukocyte Disorders

Disorders that affect production or function of leukocytes may result in severe periodontal destruction (see also Chapters 8 and 10).

Agranulocytosis. *Agranulocytosis is characterized by a reduction in the number of circulating granulocytes and results in severe infections, including ulcerative necrotizing lesions of the oral mucosa, skin, and gastrointestinal and genitourinary tracts.* Less severe forms of the disease are called *neutropenia* or *granulocytopenia.*

Drug idiosyncrasy is the most common cause of agranulocytosis, but in some instances, its cause cannot be explained. Agranulocytosis has been reported after the administration of drugs such as aminopyrine, barbiturates and their derivatives, benzene ring derivatives, sulfonamides, gold salts, or arsenical agents. [113,127,139,163] It generally occurs as an acute disease, but it sometimes reappears in cyclic episodes (cyclic neutropenia). It may be periodic with recurring neutropenic cycles.[196]

The onset of the disease is accompanied by fever, malaise, general weakness, and sore throat. Ulceration in

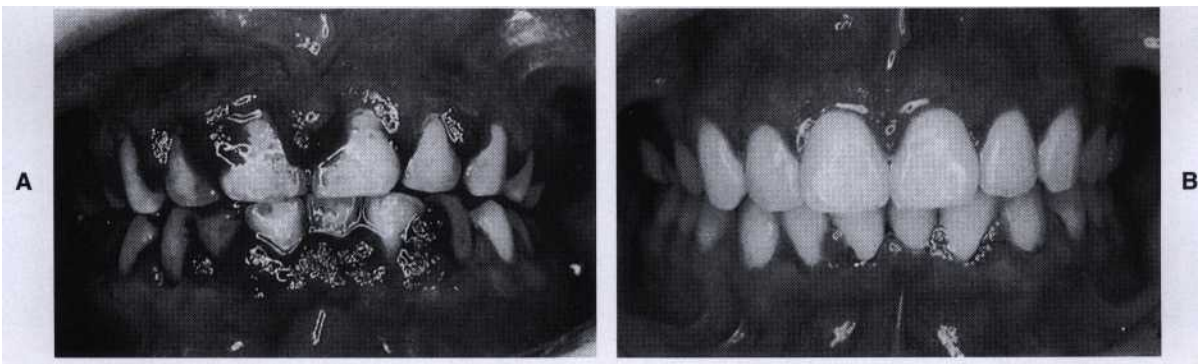

Fig. 12-23 Thrombocytopenic purpura. A, Hemorrhagic gingivitis in patient with thrombocytopenic purpura. B, Marked reduction in severity of gingival disease after removal of surface debris and careful scaling.

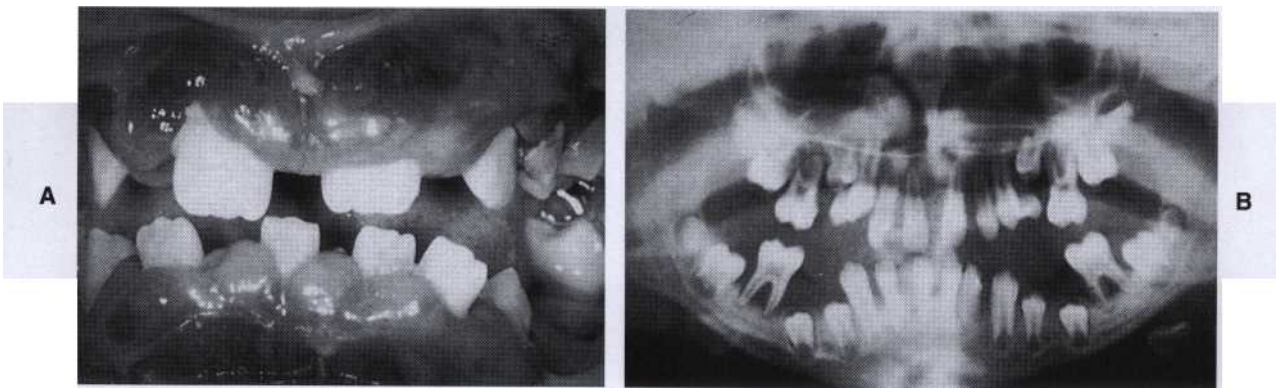

Fig. 12-24 Prepubertal periodontitis (A), clinical picture and panoramic radiograph (B). The patient is a 10-year-old boy with cyclic neutropenia and agammaglobulinemia.

the oral cavity, oropharynx, and throat is characteristic. The mucosa exhibits isolated necrotic patches that are black and gray and are sharply demarcated from the adjacent uninvolved areas.[104,132] *The absence of a notable inflammatory reaction due to lack of granulocytes is a striking feature.* The gingival margin may or may not be involved. Gingival hemorrhage, necrosis, increased salivation, and fetid odor are accompanying clinical features. The occurrence of rapidly destructive periodontitis has been described in cyclic neutropenia (Fig. 12-24).[181]

The following microscopic changes have been described in the periodontium[13]:

- Hemorrhage into the periodontal ligament with destruction of the principal fibers
- Osteoporosis of the cancellous bone with osteoclastic resorption
- Small fragments of necrotic bone in the hemorrhagic periodontal ligament
- Hemorrhage in the marrow adjacent to the teeth, areas in which the periodontal ligament is widened and consists of dense fibrous tissue with fibers parallel to the tooth surface
- Formation of new bony trabeculae

In cyclic neutropenia the gingival changes recur with recurrent exacerbation of the disease.[46]

Experimentally, neutropenia has been produced in dogs with heterologous antineutrophil serum. Neutrophilic granulocytes disappeared from the tissues, but ulcerative lesions and bacterial invasion were not observed, probably owing to the short duration of the experiment (4 days).[173]

Because infection is a common feature of agranulocytosis, differential diagnosis involves consideration of such conditions as acute necrotizing ulcerative gingivitis, diphtheria, noma, and acute necrotizing inflammation of the tonsils. Definitive diagnosis depends on the hematologic findings of pronounced leukopenia and almost complete absence of neutrophils.

Chediak-Higashi Syndrome. Chediak-Higashi syndrome is a rare disease that affects the production of organelles found in almost every cell. It affects mostly the melanocytes, platelets, and phagocytes and produces partial albinism, mild bleeding disorders, and recurrent bacterial infections, including rapidly destructive periodontitis. It has been described as a genetically transmitted disease in ranch-raised mink (see Chapter 10).[8,154]

Antibody Deficiency Disorders

Agammaglobulinemia. Agammaglobulinemia results from a deficiency in B cells; T-cell function remains normal. It can be congenital (X-linked or Bruton's agammaglobulinemia) or acquired. The disease is characterized by recurrent infections, including destructive periodontitis in children (see Fig. 12-24).

Acquired Immunodeficiency Syndrome. Acquired immunodeficiency syndrome (AIDS) is caused by the human immunodeficiency virus (HIV) and is characterized by destruction of lymphocytes, rendering the patient susceptible to opportunistic infections, including destructive periodontal lesions and malignancies (see Chapter 29).

CARDIOVASCULAR DISEASES

Arteriosclerosis

In aged individuals, arteriosclerosic changes characterized by intimal thickening, narrowing of the lumen, thickening of the media, and hyalinization of the media and adventitia, with or without calcification, are common in vessels throughout the jaws, as well as in areas of periodontal inflammation (Fig. 12-25).[84,161,211] Both periodontal disease and arteriosclerosis increase with age, and it has been hypothesized that the circulatory impairment induced by vascular changes may increase the patient's susceptibility to periodontal disease.[11,20,22] Conversely, there is recent evidence to suggest that individuals with periodontal disease may be at greater risk for heart disease as a result of chronic periodontal infections and inflammation. See Chapter 13 for a detailed discussion of the relationship between periodontal inflammatory disease and the risk for systemic diseases.

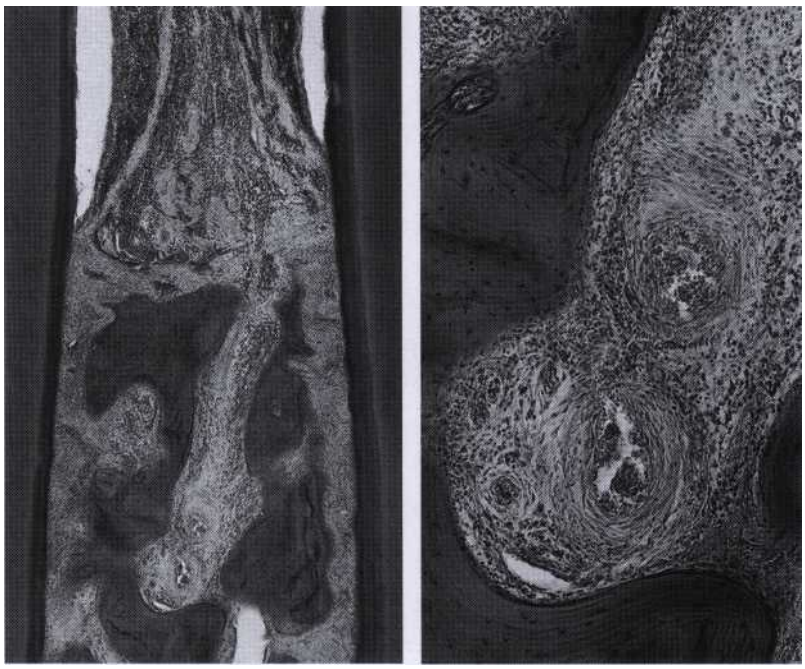

Fig. 12-25 Vascular changes in an aged individual with periodontal disease. A, periodontitis, showing inflammation extending from the gingiva into the interdental septum. B, Detailed view, showing arterioles with thickened walls in the marrow space of the interdental septum.

In experimental animals, partial ischemia of more than 10 hours' duration created by arteriolar occlusion produces changes in the oxidative enzymes and acid phosphatase activity and in the glycogen and lipid content of the gingival epithelium.98 Focal necrosis, followed by ulceration, occurs in the epithelium, with the junctional epithelium least affected.'" DNA duplication is depressed. Changes typical of periodontal disease do not occur. Ischemia is followed by hyperemia, which is accompanied by metabolic changes and increased DNA synthesis in the epithelium. The gingival response to arteriolar occlusion is epithelial proliferation and thickening.

Congenital Heart Disease

Gingival disease and other oral symptoms may occur in children with congenital heart disease.[26,102] In cases of tetralogy of Fallot, which is characterized by pulmonary stenosis, right ventricular enlargement, a defect in the interventricular septum, and malposition of the aorta to the right, the oral changes include a purplish-red discoloration of the lips and gingiva and sometimes severe marginal gingivitis and periodontal destruction (Figs. 12-26 and 12-27). The discoloration of the lips and gingivae corresponds to the general degree of cyanosis and returns to normal after corrective heart surgery. The tongue appears coated, fissured, and edematous, and there is extreme reddening of the fungiform and filiform papillae. The number of subepithelial capillaries is increased but will return to normal after heart surgery.[63]

In cases of tetralogy of Eisenmenger, there is pulmonary insufficiency and a diastolic murmur; the lips, cheeks, and buccal mucous membranes are cyanotic, but markedly less so than in tetralogy of Fallot. Severe generalized marginal gingivitis may be found. In cases in which there is *transposition of the aorta and superior vena cava,* cyanotic discoloration and marginal gingivitis of a lesser degree are noted. In coarctation of the aorta, there is narrowing of the vessel in the region where it is joined by the ductus arteriosus. Patients with this problem show marked inflammation of the gingiva in the anterior part of the mouth.

OTHER SYSTEMIC CONDITIONS

Metal Intoxication

The ingestion of metals such as mercury, lead, and bismuth in medicinal compounds and through industrial contact may result in oral manifestations owing to either intoxication or absorption without evidence of toxicity.

Bismuth Intoxication. Chronic bismuth intoxication is characterized by gastrointestinal disturbances, nausea, vomiting, and jaundice, as well as by an ulcerative gingivostomatitis, generally with pigmentation and accompanied by a metallic taste and burning sensation of the oral mucoua. The tongue may be sore and inflamed. Urticaria, exanthematous eruptions of different types, bullous and purpuric lesions, and herpes zoster-like eruptions and pigmentation of the skin and mucous membranes are among the dermatologic lesions attributed to bismuth intoxication. Acute bismuth intoxication, which is less commonly seen, is accompanied by methemoglobin formation, cyanosis, and dyspnea.[91]

Bismuth pigmentation in the oral cavity usually appears

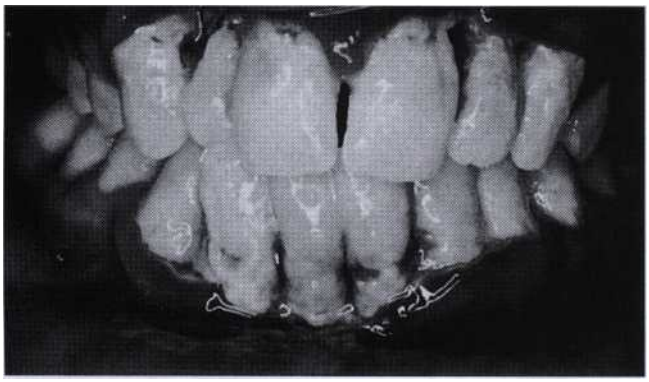

Fig. 12-26 Extensive marginal inflammation with ulceronecrotic lesions and periodontal destruction in an adolescent with tetralogy of Fallot.

Fig. 12-27 Characteristic clubbing of the fingers in the patient shown in Fig. 12-26, consistent with untreated congenital cyanotic heart disease.

as a narrow, bluish-black discoloration of the gingival margin in areas of preexistent gingival inflammation (see Chapter 17 and Fig. 17-11). Such pigmentation results from the precipitation of particles of bismuth sulfide associated with vascular changes in inflammation. It is not evidence of intoxication but simply indicates the presence of bismuth in the bloodstream. Bismuth pigmentation in the oral cavity also occurs in cases of intoxication. It assumes a linear form if the marginal gingiva is inflamed.

Lead Intoxication. Lead is slowly absorbed, and toxic symptoms are not particularly definitive when they do occur.loo There is pallor of the face and lips and gastrointestinal symptoms consisting of nausea, vomiting, loss of appetite, and abdominal colic. Peripheral neuritis, psychologic disorders, and encephalitis have been reported. Among the oral signs are salivation, coated tongue, a peculiar sweetish taste, gingival pigmentation, and ulceration. *The pigmentation of the gingiva is linear (burtonian line), steel gray, and associated with local irritation. Oral signs may occur without toxic symptoms.*

Mercury Intoxication. Mercury intoxication is characterized by headache, insomnia, cardiovascular symptoms, pronounced salivation (ptyalism), and a metallic taste .4 *Gingival pigmentation in linear form results from the deposition of mercuric sulfide. The chemical also acts as an irritant, which accentuates the preexistent inflammation and commonly leads to notable ulceration of the gingiva and adjacent mucosa and destruction of the underlying bone.* Mercurial pigmentation of the gingiva also occurs in areas of local irritation in patients without symptoms of intoxication.

Other Chemicals. Other chemicals, such as phosphorus, arsenic, and chromium, may cause necrosis of the alveolar bone with loosening and exfoliation of the teeth. [117,179] Inflammation and ulceration of the gingiva are usually associated with destruction of the underlying tissues. Benzene intoxication is accompanied by gingival bleeding and ulceration with destruction of the underlying bone.' 79

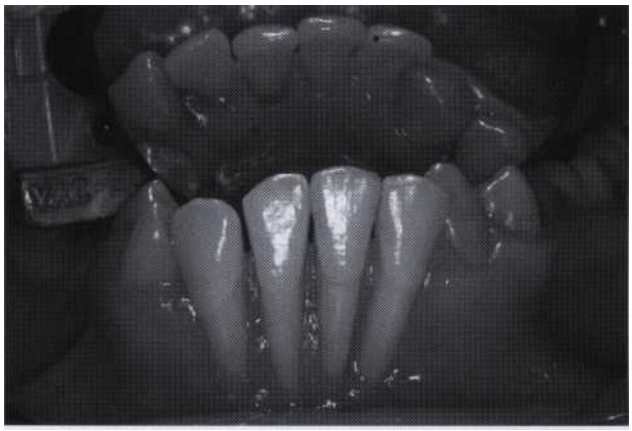

Fig. 12-28 Severe gingival recession of all lower incisors, which was discovered under general anesthestic in an uncooperative, institutionalized adult with mental disorders. The patient was known to habitually pace around the home with all four fingers inside his lower lip.

PSYCHOSOMATIC DISORDERS

Harmful effects that result from psychic influences on the organic control of tissues are known as psychosomatic disorders." The two ways in which psychosomatic disorders may be induced in the oral cavity are 1) through the development of habits that are injurious to the periodontium and 2) by the direct effect of the autonomic nervous system on the physiologic tissue balance.

Psychologically, the oral cavity is related directly or symbolically to the major human instincts and passions. In the infant, many oral drives find direct expression as oral receptive and aggressive trends and oral eroticism."' In the adult, most of the instinctive drives are normally suppressed by education and are satisfied in substitutive ways, or are taken over by organs more appropriate than the mouth. *However, under conditions of mental and emotional duress, the mouth may subconsciously become an outlet for the gratification of basic drives in the adult.*

Gratification may be derived from neurotic habits, such as grinding or clenching the teeth; nibbling on

foreign objects (e.g., pencils or pipes); nail biting; or excessive use of tobacco, which are all potentially injurious to the periodontium.[32,66,176] Self-inflicted gingival injuries such as gingival recession have been described in both children and adults. Correlation between psychiatric and anxiety states and the occurrence of periodontal disease have been reported, but these reports have been questioned by some investigators.',[18,129,141] Psychologic factors in the cause of necrotizing ulcerative gingivitis are discussed in Chapter 19.

Advances in science and technology over the last century have greatly expanded our knowledge of the pathogenesis of periodontal diseases. Periodontal disease is an infectious disease. However, environmental, physical, social, and host stresses may affect and modify disease expression. It is clear that certain systemic conditions may affect the initiation and progression of gingivitis and periodontitis. Many of these are discussed in Chapters 10 and 12. Systemic disorders affecting neutrophil, monocyte/macrophage, and lymphocyte function result in altered production or activity of host inflammatory. mediators.53 These alterations may manifest clinically as early onset of periodontal destruction or a more rapid rate of destruction than would occur in the absence of such disorders.

Evidence emerging in the last decade has shed light on the converse side of the relationship between systemic health and oral health-that is, the potential effects of periodontal disease on a wide range of organ systems. This field of periodontal medicine addresses the important questions: Can bacterial infection of the periodontium, commonly known as *periodontitis,* have an effect remote from the oral cavity? Is periodontal infection a risk factor for systemic diseases or conditions that affect human health?

PATHOBIOLOGY OF PERIODONTITIS

Our understanding of the pathogenesis of periodontitis has changed remarkably over the last 30 years.57 Nonspecific accumulation of bacterial plaque was once thought to be the cause of periodontal destruction, but it is now

Respiratory System
Chronic obstructive pulmonary disease
Acute bacterial pneumonia

recognized that periodontitis is an infectious disease associated with a small number of predominantly gram-negative microorganisms. Furthermore, the importance of the host in disease initiation and progression is clearly recognized. Although pathogenic bacteria are necessary for **periodontal disease, they are** not in and of themselves sufficient to cause the disease. A susceptible host is also imperative. In a host who is not susceptible to disease, pathogenic bacteria may have no clinical effect. Conversely, the susceptible host experiences clinical signs of periodontitis in the presence of pathogenic bacteria.

Recognition of the importance of host susceptibility opens a door to understanding the differences in the onset, natural history, and progression of periodontitis seen throughout the scientific literature. Due to differences in host susceptibility, not all individuals are equally vulnerable to the destructive effects of periodontal pathogens. Thus patients may not necessarily have similar disease expression in spite of the presence of similar bacteria. Likewise, the response to periodontal treatment may vary depending on the wound healing capacity and susceptibility of the host to further disease progression. The importance of host susceptibility is clearly evident in the medical literature. For example, respiratory tract pathogens may have minimal effect on many individuals; yet, in a susceptible host such as an elderly patient, these same pathogens may cause life-threatening respiratory tract illnesses.

Many of the systemic conditions discussed in Chapters 10 and 12 serve to modify the susceptibility of the host to periodontitis. For example, patients with immune suppression may not be able to mount an effective host response to subgingival microorganisms, resulting in more rapid and severe periodontal destruction. Although the potential impact of many systemic disorders on the periodontium is well-documented, recent evidence suggests that periodontal infection may significantly enhance the risk for **certain systemic diseases or alter the natural course** of systemic conditions.46 Conditions in which the influences of periodontal infection are documented include coronary heart disease (CHD) and CHD-related events such as angina and infarction, atherosclerosis, stroke, diabetes mellitus, preterm labor, low birth-weight delivery, and respiratory conditions such as chronic obstructive pulmonary disease (COPD) (Box 13-1).[4658]

FOCAL INFECTION THEORY REVISITED

Recent research in the area of periodontal medicine marks a resurgence in the concept of focal infection. In 1900, William Hunter, a British physician, first developed the idea that oral microorganisms were responsible for a wide range of systemic conditions that were not easily recognized as being infectious in nature[6,51] and claimed that restoration of carious teeth rather than extraction resulted in trapping of infectious agents under restorations. In addition to caries, pulpal necrosis, and periapical abscesses, Hunter also identified gingivitis and periodontitis as foci of infection. He advocated extraction of teeth with these conditions to eliminate the source of sepsis. Hunter believed that teeth were liable to septic infection primarily due to their structure and their relationship to alveolar bone. He stated that the degree of systemic effect produced by oral sepsis depended on the virulence of the oral infection and the degree of resistance of the individual. He also felt that oral organisms had specific actions on different tissues and that these organisms acted by producing toxins, resulting in low-grade "subinfection," which produced systemic effects over prolonged periods. Finally, Hunter believed that the connection between oral sepsis and resulting systemic conditions could be shown by removal of the causative sepsis via tooth extraction and observation of the improvement in systemic health. Since it explained a wide range of disorders for which there was no known explanation at the time, Hunter's theory became widely accepted in Britain and eventually the United States, leading to wholesale extraction of teeth.

The focal infection theory fell into disrepute in the 1940s and 1950s when widespread extraction, often of the entire dentition, failed to reduce or eliminate the systemic conditions to which the supposedly infected dentition had been linked. The theory, while offering a possible explanation for perplexing systemic disorders, had been based on very little, if any, scientific evidence. Hunter and other advocates of the theory were unable to explain how focal oral sepsis produced these systemic maladies. They were unable to elucidate possible interactive mechanisms between oral and systemic health. Furthermore, the suggested intervention of tooth extraction often had no effect on the systemic conditions for which patients sought relief. However, Hunter's ideas did encourage extensive research in microbiology and immunology.

EVIDENCE-BASED CLINICAL PRACTICE

Many of the precepts of the focal infection theory are being revived today in light of recent research demonstrating links between oral and systemic health. Yet, in order

for the "hypothesis not to fall into disrepute for a second time, there must be no unsubstantiated attributions, no theories without evidence."" Today's era of evidence-based medicine and dentistry provides an excellent environment in which to examine the possible relationships between oral infection and systemic disorders."

To establish a relationship between conditions A and B, different levels of evidence must be examined. All scientific evidence is not given the same weight .[32,52] The stronger the evidence, the more likely it is that a true relationship exists between the conditions. Table 13-1 describes these various levels of evidence.

For example, in examining the relationship between elevated cholesterol levels and CHD-related events, the literature might initially consist entirely of case reports or similar anecdotal information in which individual patients with recent myocardial infarction are found to have elevated cholesterol levels. These anecdotal reports suggest a possible relationship between elevated cholesterol and myocardial infarction, but the evidence is weak. These case reports may lead to cross-sectional studies in which a large subject population is examined to determine whether those individual who have had a myocardial infarction have higher cholesterol levels than other individuals (control subjects) who have not had an infarction. Ideally, these cross-sectional studies are controlled for other potential causes or factors associated with myocardial infarction such as age, gender, and smoking history. In other words, the subjects who had a previous myocardial infarction would be retrospectively "matched" with subjects of similar age, gender, and smoking history. Then their cholesterol levels would be examined for similarities or differences. Significantly higher cholesterol levels in those subjects with a previous infarction compared with those without infarction offers stronger evidence than case reports and further substantiates a possible link between elevated cholesterol and myocardial infarction.

Even stronger evidence is provided by longitudinal studies in which subject populations are examined over time. For example, a group of subjects might periodically have cholesterol levels evaluated over several years. If those individuals with elevated cholesterol levels have a significantly higher rate of myocardial infarction over time compared with those subjects with normal cholesterol levels, even stronger evidence is available to substantiate the link between cholesterol and infarction. Finally, intervention trials may be designed to alter the potentially causative condition and to determine the effect of this change on the resultant condition. For example, patients with elevated cholesterol may be divided into two groups: a group that uses a cholesterol-lowering drug or diet and a control group that has no intervention. These two groups might also be compared with a third group with normal cholesterol levels. Over time, the rate of myocardial infarction in each group would be determined. If the group on the cholesterol-lowering regimen has a significantly lower rate of infarction than the group with continued elevations in cholesterol, strong evidence of a link between cholesterol and myocardial infarction would be established.

At each level of evidence, it is important to determine whether there is a biologically plausible link between conditions A and B. For example, if case reports, cross-sectional studies, longitudinal studies, and intervention trials all support the link between cholesterol levels and

TABLE 13-1

Evaluation of Evidence

Type of Study	Strength of Evidence	Comments
Case report		Provides relatively weak retrospective anecdotal evidence • May suggest further study needed
Cross-sectional study	+	• Compares groups of subjects at a single point in time • Stronger than case report • Fairly easy to conduct • Relatively inexpensive to conduct
Longitudinal study	++	• Follows groups of subjects over time • Stronger than cross-sectional study • Studies with control group much stronger than studies without controls • More difficult and expensive to conduct
Intervention trial	+++	• Examines effects of some intervention • Studies with control group (i.e., placebo) much stronger than studies without controls • Strongest form of evidence is randomized controlled intervention trial • Difficult and expensive to conduct

myocardial infarction, the following question remains: How is cholesterol related to infarction? What are the mechanisms by which cholesterol affects the cardiovascular system and thus increases the risk for myocardial infarction? These studies provide explanatory data that further substantiate the link between the two conditions.

The focal infection theory, as proposed and defended in the early part of the 20th century, was based on almost no evidence. Only the occasional case report and other anecdotes were available to substantiate the theory. Although explanatory mechanisms were proposed, none were validated with scientific research. Unfortunately, this theory predated current concepts of evidence-based clinical practice, leading to unnecessary extraction of millions of teeth. Today, in reexamining the potential associations between oral infections and systemic conditions, it is important to determine what evidence is available, is still needed to substantiate the associations, and validates the possible mechanisms of association. This chapter reviews current knowledge relating periodontal infection to overall systemic health.

THE SUBGINGIVAL ENVIRONMENT AS A RESERVOIR OF BACTERIA

The subgingival microbiota in patients with periodontitis provides a significant and persistent gram-negative bacterial challenge to the host (see Chapters 6 and 8). These organisms and their products, such as lipopolysaccharide (LPS), have ready access to the periodontal tissues and to the circulation via the sulcular epithelium, which is frequently ulcerated and discontinuous. Even with treatment, complete eradication of these organisms is difficult, and their reemergence is often rapid. The total surface area of pocket epithelium in contact with subgingival bacteria and their products in a patient with generalized moderate periodontitis has been estimated to be approximately the size of the palm of an adult hand, with even larger areas of exposure in cases of more advanced periodontal destruction.57 Bacteremias are common after mechanical periodontal therapy and also occur frequently during normal daily function and oral hygiene procedures. [25,45,74] just as the periodontal tissues mount an immunoinflammatory response to bacteria and their products, systemic challenge with these agents also induces a major vascular response. This host response may offer explanatory mechanisms for the interactions between periodontal infection and a variety of systemic disorders.

PERIODONTAL DISEASE AND MORTALITY

The ultimate medical outcome measure is mortality. In the 1960s a prospective study known as the Normative Aging Study was begun. The study enrolled 2280 healthy men, each of whom received baseline clinical, radiographic, laboratory, and electrocardiographic examinations. Subjects have been seen every 3 years for the past 30 years, and received their medical and dental care in the private sector. The Veterans Affairs (VA) Dental Longitudinal Study began in 1968, using a subset of patients from the Normative Aging Study to examine age-related changes in the oral cavity and to identify risk factors for oral disease." Clinical examinations were performed and alveolar bone level measurements were determined from full-mouth radiographs. The mean percentage of alveolar bone loss and the mean probing depth were determined for each subject. A recent study of data from this subject population sought to determine whether periodontal disease status was a significant predictor of mortality independent of other baseline characteristics within the population.[19] From the original sample of 804 dentate, medically healthy subjects, a total of 166 died during the study. Periodontal status at the baseline examination was a significant predictor of mortality independent of other factors such as smoking, alcohol use, cholesterol levels, blood pressure, family history of heart disease, education level, and body mass. For those subjects with the most alveolar bone loss, having an average of greater than 21% alveolar bone loss at baseline, the risk of dying during the follow-up period was 70% higher than for all other subjects. Interestingly, alveolar bone loss increased the risk of mortality to a greater extent than smoking (52% increased risk), a well-known risk factor for mortality.

In the study described above, periodontitis preceded and increased the risk of mortality. Yet this only establishes an association, not causation. It is possible that periodontal disease reflects other health behaviors not evaluated in this study, rather than acting as a specific cause of mortality. In other words, patients with poor periodontal health may also have other risk factors that increase mortality rate (e.g., smoking).

In examining research that suggests oral health status as a possible risk factor for systemic conditions, it is important to recognize when other known risk factors for those systemic conditions have been accounted for in the analysis. Host susceptibility factors that place individuals at risk for periodontitis may also place them at risk for systemic diseases such as cardiovascular disease. In that case, the association may actually be between the risk factors, rather than between the diseases themselves. For example, periodontitis and cardiovascular disease share risk factors like smoking, age, race, male gender, and stress. Genetic risk factors may also be shared.[57] In the VA Dental Longitudinal Study, smoking was an independent risk factor for mortality. When examining the data to determine if periodontal status was a risk factor, smoking status and other known risk factors for mortality were removed from the equation to allow independent evaluation of periodontal status.

PERIODONTAL DISEASE AND CORONARY HEART DISEASE/ATHEROSCLEROSIS

To further explore the periodontal disease and coronary heart disease/atherosclerosis association, investigators have studied specific systemic disorders and medical outcomes to determine their relationship to periodontal status. CHD-related events are a major cause of death. Myocardial infarction has been associated with acute systemic bacterial and viral infections, and infarction is sometimes preceded by influenza-like symptoms.[38,67] Is it possible that oral infection is similarly related to myocardial infarction? Traditional risk factors such as smoking,

dyslipidemia, hypertension, and diabetes mellitus do not explain the presence of coronary atherosclerosis in a large number of patients. Localized infection resulting in a chronic inflammatory reaction has been suggested as a mechanism underlying coronary heart disease in these individuals.[48]

In cross-sectional studies of patients with acute myocardial infarction or confirmed CHD compared with age- and gender-matched control patients, myocardial infarction patients had significantly worse dental health (periodontitis, periapical lesions, caries, and pericoronitis) than did controls.[39,40] This association between poor dental health and myocardial infarction was independent of known risk factors for heart disease such as age, cholesterol levels, hypertension, diabetes, and smoking. Because atherosclerosis is a major determinant of CHD-related events, dental health has also been related to coronary atheromatosis. Mattila and colleagues performed oral radiographic examinations and diagnostic coronary angiography on men with known CHD.[41] There was a significant correlation between the severity of dental disease and the degree of coronary atheromatosis. This relationship remained significant after accounting for other known risk factors for coronary artery disease. Cross-sectional studies thus suggest a link between oral health and CHD; however, such studies cannot determine causality in this relationship. Rather, dental diseases may be indicators of general health practices. For example, periodontal disease and CHD are both related to lifestyle and share numerous risk factors such as smoking, diabetes, and low socioeconomic status. Bacterial infections have significant effects on endothelial cells, blood coagulation, lipid metabolism, and monocytes/macrophages. The research of Mattila and colleagues showed that dental infections were the only factors, other than the classic and well-recognized coronary risk factors, that were associated independently with the severity of coronary atherosclerosis.

Longitudinal studies provide compelling data on this relationship. In a 7-year follow-up study of the patients from the study of Mattila and colleagues, dental disease was significantly related to the incidence of new fatal and nonfatal coronary events, as well as to overall mortality." In a prospective study of a national sample of adults, 9760 subjects were followed for 14 years following baseline dental and medical evaluation.[14] The main outcome measures were incidence of mortality or hospital admission due to CHD. Subjects with periodontitis had a 25% increase in the risk for CHD compared with those with no or minimal periodontal disease after adjusting for other known risk factors. Among younger males (ages 25 to 49), periodontitis increased the risk of CHD by 70%. The level of oral hygiene was also associated with heart disease. Patients with poor oral hygiene, as indicated by higher debris and calculus scores, had a two-fold increased risk for coronary heart disease.

In another large prospective study, 1147 men were followed for 18 years.' During that time, 207 men (18%) developed CHD. When periodontal status at baseline was related to the presence or absence of CHD-related events during follow-up, a significant relationship was found. Subjects with greater than 20% mean bone loss had a 50% increased risk of CHD compared with those with 0 to 20% bone loss. The extent of sites with probing depth greater than 3 mm was strongly related to the incidence of CHD. Subjects with probing depths greater than 3 mm on at least half of their teeth had a two-fold increased risk, whereas those with probing depths greater than 3 mm on all teeth had more than a three-fold increased risk on CHD. This study and others in which the periodontal condition is known to have preceded the CHD-related events, support the concept that periodontal disease is a risk factor for CHD, independent of other classic risk factors.

The Effect of Periodontal Infection

Periodontal infection may affect the onset or progression of atherosclerosis and CHD through certain mechanisms. Periodontitis and atherosclerosis both have complex etiologic factors, combining genetic and environmental influences. The diseases share many risk factors and have distinct similarities in basic pathogenic mechanisms.

Ischemic Heart Disease. Ischemic heart disease is associated with the processes of atherogenesis and thrombogenesis (Fig. 13-1). Increased viscosity of blood may promote major ischemic heart disease and stroke by increasing the risk of thrombus formation.[36] Fibrinogen is probably the most important factor in promoting this hypercoagulable state. Fibrinogen is the precursor to fibrin, and increased fibrinogen levels increase blood viscosity. Increased plasma fibrinogen is a recognized risk factor for cardiovascular events and peripheral vascular

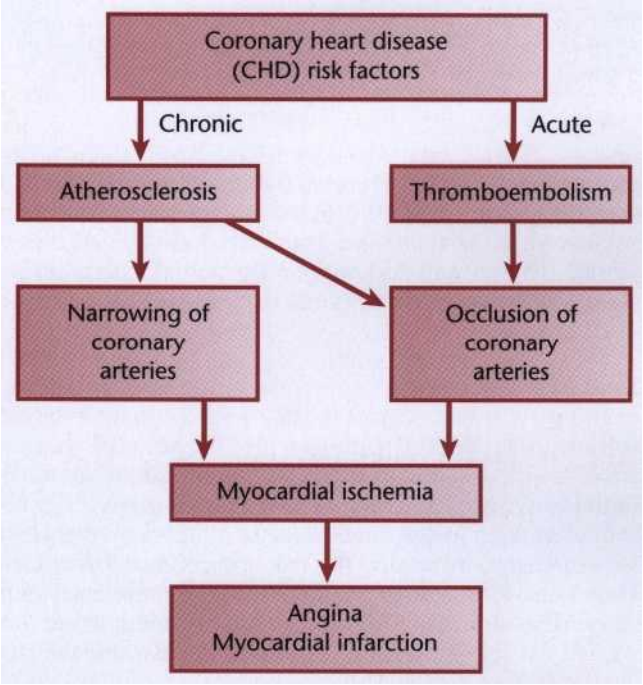

Fig. 13-1 Acute and chronic pathways to ischemic heart disease. CHD-related events such as angina or myocardial infarction may be precipitated by either one or both pathways.

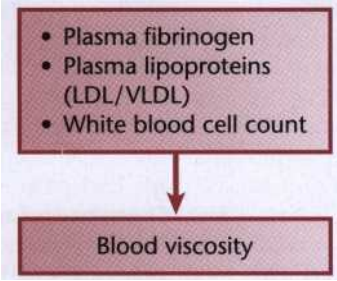

Fig. 13-2 Factors affecting blood viscosity in health

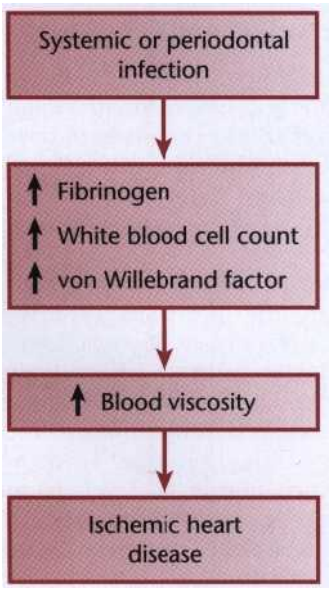

Fig. 13-3 Effect of infection on blood viscosity. Increased plasma fibrinogen and von Willebrand factor cause hypercoagulability. When combined with increased WBC count, blood viscosity increases, increasing the risk of coronary ischemia.

disease (Fig. 13-2).[37] Elevated white blood cell (WBC) count is also a predictor of heart disease and stroke, and circulating leukocytes may promote occlusion of blood vessels. The coagulation factor VIII: von Willebrand factor has likewise been associated with the risk of ischemic heart disease.[61]

Systemic Infections. Systemic infections are known to induce a hypercoagulable state and to increase blood viscosity (Fig. 13-3). Fibrinogen levels and WBC counts are often increased in patients with periodontal disease.[34] Individuals with poor oral health may also have significant elevations in coagulation factor VIII: von Willebrand factor antigen, increasing the risk of thrombus formation. Thus periodontal infection may also promote increased blood viscosity and thrombogenesis, leading to an increased risk for central and peripheral vascular disease.

Daily Activity. Routine daily activities such as mastication and oral hygiene procedures result in frequent bacteremia with oral organisms. The exposure time to bacteremias from routine daily chewing and tooth brushing is much greater than from dental procedures.[25] Periodontal disease may predispose the patient to an increased incidence of bacteremia, including the presence of virulent gram-negative organisms associated with periodontitis. It has been estimated that about 8% of all cases of infective endocarditis are associated with periodontal or dental disease without any preceding dental procedure." Recognition of this fact is implicit in the American Heart Association recommendations on prevention of bacterial endocarditis, which stress the importance of establishing and maintaining "the best possible oral health to reduce potential sources of bacterial seeding. "[12]

Thrombogenesis. Platelet aggregation plays a major role in thrombogenesis, and most cases of acute myocardial infarction are precipitated by thromboembolism. Oral organisms may be involved in coronary thrombogenesis. Platelets selectively bind some strains of Streptococcus sanguis, a common component of supragingival plaque, and Porphyromonas gingivalis, a pathogen closely associated with periodontitis.[28] Aggregation of platelets is induced by the platelet aggregation-associated protein (PAAP) expressed on some strains of these bacteria.[27] In animal models, intravenous infusion of PAAP-positive bacterial strains resulted in alterations of heart rate, blood pressure, cardiac contractility, and electrocardiogram (ECG) consistent with myocardial infarction. Platelet accumulation also occurred in the lungs, leading to tachypnea. No such changes were seen with infusion of PAAP-negative strains. PAAP-positive bacteria caused aggregation of circulating platelets, resulting in formation of thromboemboli and the resultant cardiac and pulmonary changes. Thus it is possible that periodontitis-associated bacteremia with certain strains of S. sanguis and P. gingivalis may promote acute thromboembolic events via interaction with circulating platelets.

Atherosclerosis. Atherosclerosis is a focal thickening of the arterial intima, the innermost layer lining the vessel lumen, and the media, the thick layer under the intima consisting of smooth muscle, collagen, and elastic fibers (Fig. 13-4). Early in the formation of atherosclerotic plaques, circulating monocytes adhere to the vascular endothelium. This adherence is mediated through several adhesion molecules on the endothelial cell surface, including intercellular adhesion molecule-1 (ICAM-1), endothelial leukocyte adhesion molecule-1 (ELAM-1), and vascular cell adhesion molecule-1 (VCAM-1).[33] These adhesion molecules are up-regulated by a number of factors including bacterial LPS, prostaglandins and pro-inflammatory cytokines. After binding to the endothelial cell lining, monocytes penetrate the endothelium and migrate under the arterial intima. The monocytes ingest circulating low-density lipoprotein (LDL) in its oxidized state and become engorged, forming foam cells characteristic of atheromatous plaques.

Once within the arterial media, monocytes may also transform to macrophages. A host of pro-inflammatory cytokines such as interleukin-1 (IL-1), tumor necrosis factor-alpha (TNF-a), and prostaglandin E2 (PGE2) are then produced, which propagate the atheromatous

lesion. Mitogenic factors such as fibroblast growth factor and platelet-derived growth factor stimulate smooth muscle and collagen proliferation within the media, thickening the arterial wal1.37 Atheromatous plaque formation and thickening of the vessel wall narrow the lumen and dramatically decrease blood flow through the vessel. Arterial thrombosis often occurs after an atheromatous plaque ruptures. Plaque rupture exposes circulating blood to arterial collagen and tissue factor from monocytes/macrophages that activate platelets and the coagulation pathway. Platelet and fibrin accumulation forms a thrombus that may occlude the vessel, resulting in ischemic events such as angina or myocardial infarction. The thrombus may separate from the vessel wall and form an embolus, which may also occlude vessels, again leading to acute events such as myocardial or cerebral infarction (stroke).

The Role of Periodontal Disease in Myocardial or Cerebral Infarction

In animal models, gram-negative bacteria and the associated LPS cause infiltration of inflammatory cells into the arterial wall, proliferation of arterial smooth muscle, and intravascular coagulation. These changes are identical to those seen in naturally occurring atheromatosis. In a study of eight atherorrias obtained from humans during endarterectomy, three contained periodonta pathogens."

Periodontal diseases result in chronic systemic exposure to products of these organisms. Low-level bacteremia may initiate host responses that alter coagulability, endothelial and vessel wall integrity, and platelet function, resulting in atherogenic changes and possible thromboembolic events (Fig. 13-5).

Research has clearly shown a wide variation in host response to bacterial challenge between patients. Some individuals with heavy plaque accumulation and high proportions of pathogenic organisms appear relatively resistant to bone and attachment loss. Others develop extensive periodontal destruction in the presence of small amounts of plaque and low proportions of putative pathogens. Those patients with abnormally exuberant inflammatory responses often have a hyperinflammatory monocyte/macrophage phenotype (M0+). Monocytes/macrophages from these individuals secrete significantly increased levels of pro-inflammatory mediators like IL-1, TNF-a, and PGE_2 in response to bacterial LPS than do monocytes/macrophages from patients with a normal monocyte/macrophage phenotype. Patients with aggressive periodontitis, refractory periodontitis, and type 1 diabetes mellitus often possess the M0+ phenotype.'

This monocyte/macrophage phenotype appears to be under both genetic and environmental control.' The monocyte/macrophage cell line is intimately involved in the pathogenesis of both periodontal disease and atherosclerosis. Diet-induced elevations in serum LDL levels

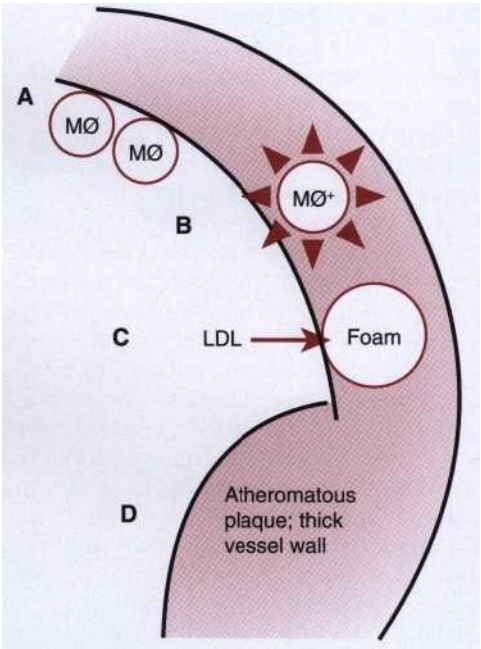

Fig. 13-4 Pathogenesis of **atherosclerosis.** A, **Monocytes/macrophages adhere to vascular endothelium. B, Monocytes/macrophages penetrate into arterial media, producing pro-inflammatory cytokines and growth factors. G, Ingestion of oxidized LDL enlarges monocytes to form foam cells. D, Smooth muscle proliferation and plaque formation thicken vessel wall and narrow lumen.**

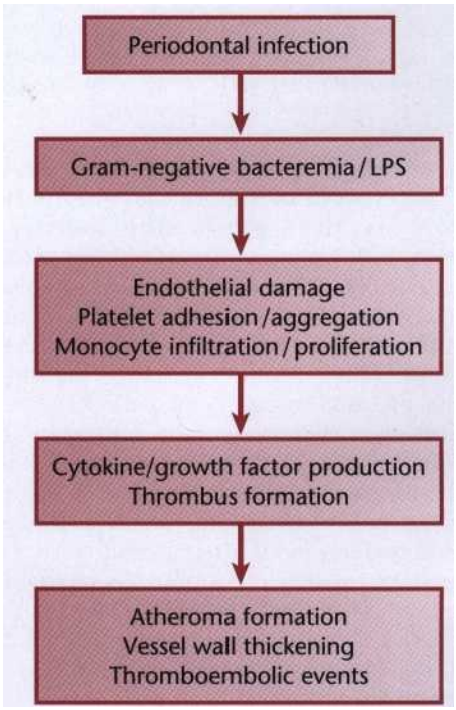

Fig. 13-5 Influence of periodontal infection on atherosclerosis. Periodontal pathogens and their products result in damage to vascular endothelium. Monocytes/macrophages enter vessel wall, producing cytokines that further increase inflammatory response and propagate the atheromatous lesion. Growth factor production leads to smooth muscle proliferation in the vessel wall. Damaged endothelium also activates platelets, resulting in platelet aggregation, and potentiating thromboembolic events.

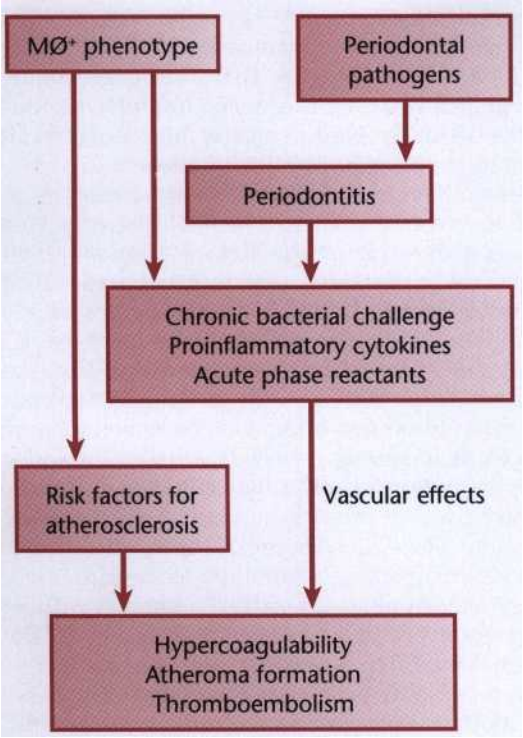

Fig. 13-6 Cardiovascular and periodontal consequences of hyperresponsive monocyte/macrophage phenotype. In combination with other risk factors, the Mo+ phenotype predisposes to both atherosclerosis and periodontitis. Bacterial products and inflammatory mediators associated with periodontitis affect vascular endothelium, monocytes/macrophages, platelets, and smooth muscle; and, may increase blood coagulability. This may further atherosclerosis and result in thromboembolism and ischemic events.

up-regulate monocyte/macrophage responsiveness to bacterial LPS. Thus elevated LDL levels, a known risk factor for atherosclerosis and CHD, may increase secretion of destructive and inflammatory cytokines by monocytes/macrophages. This may result not only in propagation of atheromatous lesions, but also in enhanced periodontal destruction in the presence of pathogenic organisms. This is one example of a potential shared mechanism in the pathogenesis of cardiovascular and periodontal diseases. The presence of a M0+ phenotype may place patients at risk for both CHD and periodontitis (Fig. 13-6). Periodontal infections may contribute to atherosclerosis and thromboembolic events by repeatedly challenging the vascular endothelium and arterial wall with bacterial LPS and proinflammatory cytokines. Vascularmonocytes/macrophages in patients with a MO+ phenotype meet this challenge with an abnormally elevated inflammatory response that may directly contribute to atherosclerosis and may precipitate thromboembolic events.46

PERIODONTAL DISEASE AND STROKE

Ischemic cerebral infarction, or stroke, is often preceded by systemic bacterial or viral infection.[69] In one study, patients with cerebral ischemia were five times more likely to have had a systemic infection within 1 week before the ischemic event than were nonischemic control subjects. Recent infection was a significant risk factor for cerebral ischemia and was independent of other known risk factors such as hypertension, history of a previous stroke, diabetes, smoking and coronary heart disease.20 Interestingly, the presence of systemic infection before the stroke resulted in significantly greater ischemia and a more severe post-ischemic neurologic defect than did stroke that was not preceded by infection.[21] Stroke patients with a preceding infection had slightly higher levels of plasma fibrinogen and significantly higher levels of C-reactive protein than did those without infection. C-reactive protein is an acute phase reactant that increases rapidly in inflammatory conditions and infection. C-reactive protein induces monocytes/macrophages to produce tissue factor, which stimulates the coagulation pathway and increases blood coagulability. Increased fibrinogen levels may contribute to this process.

Periodontal Infection Associated with Stroke

In case-control studies, poor dental health was a significant risk factor for cerebrovascular ischemia. In one study, bleeding on probing, suppuration, subgingival calculus, and the number of periodontal or periapical lesions were significantly greater in male stroke patients than in controls.70 Overall, 25% of all stroke patients had significant dental infections compared with only 2.5% of controls. This study supports an association between poor oral health and stroke in men under age 50. In the other study, men and women age 50 and older who had a stroke had significantly more severe periodontitis and more periapical lesions than did nonstroke control subjects.[22] Poor dental health was an independent risk factor for stroke. In a longitudinal study over 18 years, subjects with greater than 20% mean radiographic bone loss at baseline were almost three times as likely to have a stroke than were subjects with less than 20% bone loss. Periodontitis was a greater risk factor for stroke than was smoking and was independent of other known risk factors.

Most cases of stroke are caused by thromboembolic events, whereas others are related to cerebrovascular atherosclerosis. As discussed in the previous section, periodontal infection may contribute to the pathogenesis of atherosclerosis by providing a persistent bacterial challenge to arterial endothelium, contributing to the monocyte/macrophage-driven inflammatory process that results in atheromatosis and narrowing of the vessel lumen (see Figs. 13-5 and 13-6). Furthermore, periodontal infection is associated with increased plasma fibrinogen and C-reactive protein levels, which contribute to hypercoagulability. Finally, bacteremia with PAAP-positive bacterial strains from the supra- and subgingival plaque can increase platelet aggregation, contributing to thrombus formation and subsequent thromboembolism, the leading cause of stroke.[46]

PERIODONTAL DISEASE AND DIABETES MELLITUS

The relationship between diabetes mellitus and periodontal disease has been extensively examined. It is clear from epidemiologic research that diabetes increases

the risk for and severity of periodontal diseases.[59] The biologic mechanisms through which diabetes influences the periodontium are discussed in Chapter 12. The increased prevalence and severity of periodontitis commonly seen in patients with diabetes, especially those with poor metabolic control, led to the designation of periodontal disease as the "sixth complication of diabetes."[1] In addition to the five "classic" complications of diabetes (Box 13-2), the American Diabetes Association has officially recognized that periodontal disease is common in patients with diabetes, and its Standards of Care include taking a history of current or past dental infections as part of the physician's examination.[2,3]

Although many studies have examined the effects of diabetes on the periodontium, fewer have endeavored to examine the effect of periodontal infection on control of diabetes. The following questions remain:

- Does the presence or severity of periodontal disease affect the metabolic state in diabetic patients?
- Does periodontal treatment aimed at reducing the bacterial challenge and minimizing inflammation have a measurable effect on glycemic (blood glucose) control?

In a longitudinal study of patients with type 2 (non-insulin-dependent) diabetes, severe periodontitis was associated with significant worsening of glycemic control over time.[71] Individuals with severe periodontitis at the baseline examination had a greater incidence of worsening glycemic control over a 2- to 4-year period than did those without periodontitis at baseline. In this study, periodontitis is known to have preceded the worsening of glycemic control. Periodontitis has also been associated with the classic complications of diabetes. Diabetic adults with severe periodontitis at baseline had a significantly greater incidence of kidney and macrovascular complications over the subsequent 1 to 11 years than did diabetic adults with only gingivitis or mild periodontitis.[72] This was true despite the fact that both groups had similar glycemic control. One or more cardiovascular complications occurred in 82% of patients with severe periodontitis compared with only 21% of patients without severe periodontitis. Again, severe periodontitis preceded the onset of clinical diabetic complications in these subjects.

Loe H: Periodontal disease: The sixth complication of diabetes mellitus. Diabetes Care 1993; 16(suppl 1):329.

In diabetic patients with periodontitis, periodontal therapy may have beneficial effects on glycemic control.[46,47] This may be especially true for patients with relatively poor glycemic control and more advanced periodontal destruction prior to treatment.[24] Forty years ago, the potential benefits of periodontal therapy were first described in young adults with diabetes and severe periodontitis.[75] Treatment with mechanical debridement, surgery, selected tooth extraction, and systemic antibiotics resulted in decreased insulin demand. In a more recent evaluation of scaling and root planing combined with systemic doxycycline therapy for 2 weeks, type 1 (insulin-dependent) diabetic patients with improved periodontal health also had significant improvement in glycemic control (Fig. 13-7).[49] Conversely, those individuals who demonstrated little beneficial clinical effect from periodontal treatment had no change in glycemic control.

In a placebo-controlled study of poorly controlled individuals with type 2 diabetes and severe periodontitis, nonsurgical mechanical debridement combined with systemic doxycycline for 14 days was compared with similar mechanical treatment combined with systemic placebo.[23] All patient groups had significant improvements in periodontal status, with reduced probing depths and bleeding on probing. Those treated with doxycycline had a greater reduction in the prevalence of *P. gingivalis*, which was more sustained over time. The

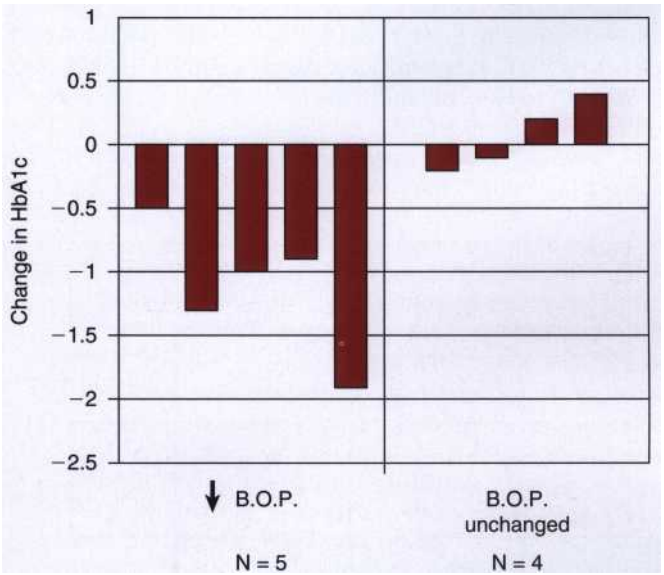

Fig. 13-7 Periodontal treatment: effects on glycemic control. In five patients, reductions in periodontal inflammation after mechanical therapy combined with systemic doxycycline antibiotic were accompanied by improved glycemic control (decreased glycated hemoglobin values HbAl c). In four patients with no improvement in periodontal health, no improvement in glycemic control occurred. (From Miller LS, Manwell MA, Newbold D, et al: The relationship between reduction in periodontal inflammation and diabetes control: A report of 9 cases. J Periodontol 1992; 63:843.)

doxycycline-treated patients also demonstrated significant improvement in glycemic control 3 months after treatment, which gradually reverted to baseline levels at 6 months. Placebo-treated subjects had no significant improvement in glycemic control. These studies suggest that the combination of subgingival mechanical debridement and systemic doxycycline may result in short-term improvement in glycemia in diabetic patients with severe periodontitis and poor metabolic control.

Conversely, moderately or well-controlled individuals with diabetes and periodontitis who are treated by mechanical therapy alone may demonstrate no significant changes in glycemic control, despite improvement in their periodontal condition. In **studies of subjects treated by mechanical therapy without adjunctive use of antibiotics**, significant changes in glycemic control are less common.[1,8,23,66] Many of the **patients in these studies had relatively** good glycemic control before treatment, so less benefit on metabolic control might be expected. Although routine use of systemic antibiotics in treatment of chronic periodontitis is not justified, patients with poorly controlled diabetes and severe periodontitis may constitute one patient group for whom such therapy is appropriate. Of course, antibiotics remain an adjunct to the necessary mechanical removal of plaque and calculus.

The mechanisms by which adjunctive antibiotics may induce positive changes in glycemic control when combined with mechanical debridement are unknown at this time. Systemic antibiotics may eliminate residual bacteria following scaling and root planing, further decreasing the bacterial challenge to the host. Tetracyclines are also known to suppress glycation of proteins and to decrease activity of tissue-degrading enzymes such as matrix metalloproteinases. These changes may contribute to improvement in metabolic control of diabetes.

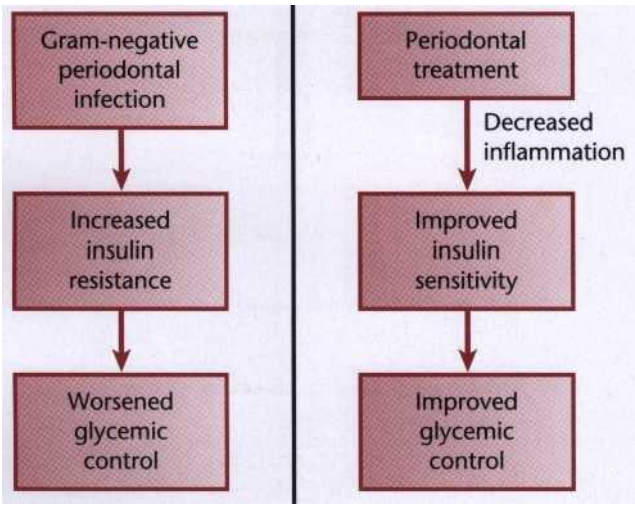

Fig. 13-8 Potential effects of periodontal infection and periodontal therapy on glycemia in patients with diabetes.

Periodontal Infection Associated with Glycemic Control in Diabetes

An **understanding of the effects of other infections is useful in delineating the mechanisms** by which periodontal infection influences glycemia. Acute bacterial and viral infections have been shown to increase insulin resistance and aggravate glycemic control.[62,76] This occurs in individuals with diabetes and without. Systemic infections increase tissue resistance to insulin, preventing glucose from **entering target cells, causing elevated** blood glucose levels, and requiring increased pancreatic insulin production to maintain normoglycemia. Insulin resistance may persist for weeks or even months after the patient has recovered clinically from their illness. In the individual with type 2 diabetes, who already has significant insulin resistance, further tissue resistance to insulin induced by infection may considerably exacerbate poor glycemic control. In type 1 patients, normal insulin doses may be inadequate to maintain good glycemic control in the presence of infection-induced tissue resistance. It is possible that chronic gram-negative periodontal infections may also result in increased insulin resistance and poor glycemic control.[24] In patients with periodontitis, persistent systemic challenge with periodontopathic bacteria and their products may act in a way similar to well-recognized systemic infections (Fig. 13-8). This mechanism would explain the worsening of glycemic control associated with severe periodontitis. Periodontal treatment designed to decrease the bacterial insult and reduce inflammation might restore insulin sensitivity over time, resulting in improved metabolic control. The improved glycemic control seen in several studies of periodontal therapy would support such a hypothesis.

PERIODONTAL DISEASE AND PREGNANCY OUTCOME

Low-birth-weight (LBW) infants (those weighing less than 2500 g at birth) are 40 times more likely to die in the neonatal period than normal-birth-weight (NBW) infants." Although about 7% of all infants weigh less than 2500 g at birth, they account for two thirds of neonatal deaths. LBW infants who survive the neonatal period are at increased risk for congenital anomalies, respiratory disorders and neurodevelopmental disabilities. The social and financial costs of LBW infants are enormous, and an emphasis on prevention of low-weight births is preferred to the high-cost intensive care often required to allow survival of LBW infants.

The primary cause of LBW infant deliveries is preterm labor or premature rupture of membranes. Factors such as smoking, alcohol or drug use during pregnancy, inadequate prenatal care, race, low socioeconomic status, hypertension, high or low maternal age, diabetes, and genitourinary tract infections increase the risk of preterm LBW. However, these risk factors are not present in approximately one fourth of preterm LBW cases, leading to a continued search for other causes.55

Research has examined the relationship between maternal infection and preterm labor, premature rupture of membranes, and LBW delivery. The true extent of this

relationship is difficult to determine, since the majority of maternal infections may be subclinical. Genitourinary tract infections have been associated with adverse pregnancy outcomes. Women with bacteriuria have increased rates of preterm delivery, and antibiotic treatment of bacteriuria has resulted in a significant decrease in preterm delivery rates compared with placebo treatment.[31,66] Vaginal colonization with group-B streptococci or *Bacteroides* species increases the risk of premature rupture of membranes, preterm delivery, and LBW.[44]

Bacterial Vaginosis

Bacterial vaginosis is the most common vaginal disorder in women of reproductive age. It is caused by changes in the vaginal microflora in which normally predominant facultative lactobacilli are replaced by *Gardnerella vaginalis;* anaerobic organisms, including species of the genera *Prevotella, Bacteroides, Peptostreptococcus, Porphyromonas, Mobiluncus;* and others.[29] Bacterial vaginosis is a known risk factor for preterm labor, premature rupture of membranes, and LBW.[31] In fact, treatment of bacterial vaginosis with metronidazole in pregnant women resulted in decreased preterm birth rates compared with placebo treatment.[50]

The exact mechanism by which vaginal colonization or genitourinary tract infection may cause premature rupture of membranes and preterm labor is not known. The primary mechanism has traditionally been thought to be ascending infection from the vagina and endocervix. Endotoxin (LPS) and bioactive enzymes produced by many organisms associated with vaginosis may directly injure tissue, as well as induce release of pro-inflammatory cytokines and prostaglandins. Throughout normal gestation, amniotic prostaglandin levels rise steadily until a sufficient threshold is reached that induces labor and delivery. Maternal infection may cause increased prostaglandin production and may result in labor-inducing levels being achieved before full gestation. In addition to prostaglandins, various pro-inflammatory cytokines such as IL-1, IL-6, and TNF have been found in the amniotic fluid of women with preterm labor.

Women with preterm labor often have culture-positive amniotic fluid, even in the absence of clinical infection. Of culture-positive patients, the most commonly isolated species is *Fusobacterium nucleatum*.[31] Although *F. nucleatum is* occasionally isolated from the vaginal flora in bacterial vaginosis, its prevalence in women with preterm labor is much greater than in vaginosis. *F. nucleatum is* even less frequently isolated from the vaginal flora of women without bacterial vaginosis. This organism is certainly not the only one isolated from amniotic fluid in women with preterm labor. Many of the isolated species are those commonly found in bacterial vaginosis. Thus an ascending route of infection is supported by the presence of these bacterial vaginosis-associated species. However, the frequency of *F. nucleatum* detection suggests other possible routes of infection. Some investigators have suggested the possibility of infection via a hematogenous route from a location in which the organism is commonly detected.[31] *F. nucleatum is* a common oral species and is highly prevalent in patients with periodontitis. It is possible that this organism reaches the amniotic fluid by hematogenous spread from the oral cavity. This route is also suggested by the occasional isolation of *Capnocytophaga* species in the amniotic fluid of women with preterm labor, an organism rarely isolated from the vagina but common in the oral cavity. Hill found that the species and subspecies of *F. nucleatum* isolated from amniotic fluid cultures in women with preterm labor more closely matched those found in subgingival plaque than strains identified from the lower genital tract.[30] In addition to hematogenous spread, another possible route of infection is by oral-genital contact, with transfer of oral organisms to the vagina.[31]

Although direct effects of microorganisms may play an important role in many cases of preterm labor, premature rupture of membranes, and LBW, indirect mechanisms may also be operative.[46,55] Bacterial infection of the chorioamnion, or extraplacental membrane, may lead to chorioamnionitis, a condition strongly associated with premature membrane rupture and preterm delivery. However, many cases of histologic chorioamnionitis demonstrate negative bacterial cultures, indicating that infection is not the sole cause of this condition.

How might this occur? It is likely that an indirect mechanism may be active in which the cascade of host products produced in response to infection is often responsible for preterm labor. Maternal infection may lead to the presence of amnionic bacterial products, such as LPS from gram-negative organisms, which stimulate production of host-derived cytokines in the amnion and decidua (Fig. 13-9). These cytokines, including IL-1, TNF-a, and IL-6 stimulate increased prostaglandin production

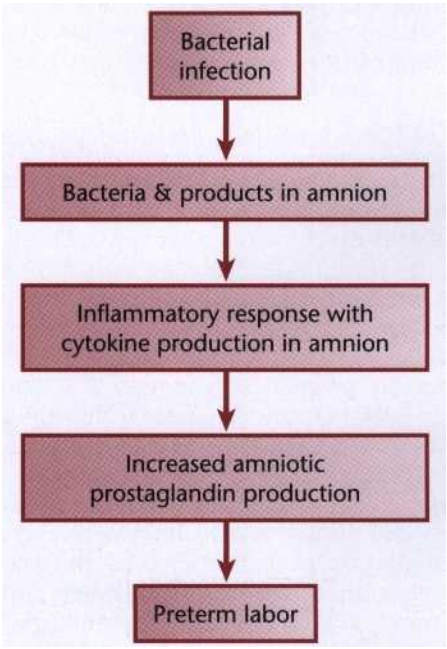

Fig. 13-9 Mechanisms by which infection may induce preterm labor.

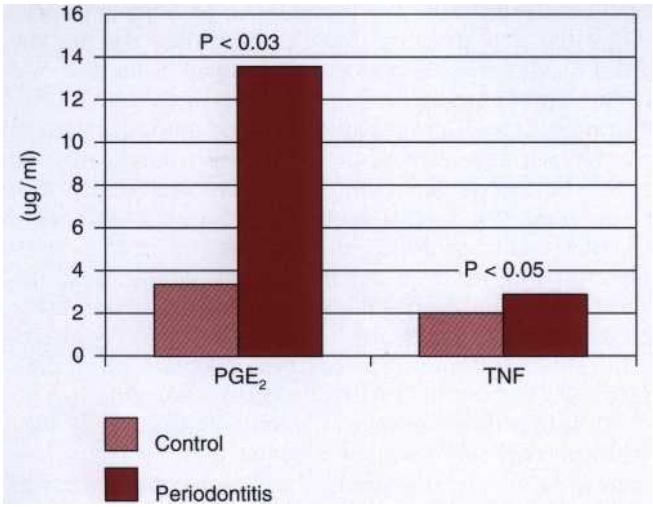

Fig. 13-10 Amniotic fluid levels in experimental periodontitis. Experimental periodontitis resulted in increased amniotic fluid levels of TNF-a and PGE in the pregnant hamster model, providing evidence that periodontal infection can affect the fetal environment. (From Offenbacher S, Jarad HL, O'Reilly PG, et al: Potential pathogenic mechanisms of periodontitis-associated pregnancy complications. Ann Periodontol 1998; 3:233.)

from the amnion and decidua, leading to onset of preterm labor. A premature rise in PGE2 and PGF2a is characteristic of preterm labor, regardless of whether clinical or subclinical maternal genitourinary tract infection is detected. The question then arises as to what stimulates the increased cytokine levels and resultant increased prostaglandin levels seen in preterm delivery in patients with no evidence of genitourinary infection. Some have suggested that many cases of preterm LBW are a result of infections of unknown origin-that is, infections originating in areas other than the genitourinary tract.

The Role of Periodontitis in Pregnancy Outcome

Periodontitis is a remote gram-negative infection that may play a role in LBW. As discussed previously, periodontopathic organisms and their products may have wide-ranging effects, most likely mediated through stimulation of host cytokine production in target tissues. Animal studies suggest that remote reservoirs of gram-negative organisms and their products may have a negative impact on pregnancy outcome. P. gingivalis implanted in subcutaneous chambers during gestation caused significant increases in TNF-a and PGE2 levels.' This localized subcutaneous infection resulted in a significant increase in fetal death and a decrease in fetal birth weight for those that remained viable, when compared with control animals that were not inoculated. There was a significant correlation between both TNF-a and PGE2 levels, as well as fetal death and growth retardation. These data suggest that a remote, nondisseminated infection with P. gingivalis may result in abnormal pregnancy outcomes in this model.

Decreased fetal birth-weight and increased fetal death were also seen after intravenous injections with LPS derived from P. gingivalis.[10] This effect was greatly increased when P. gingivalis LPS was administered before mating and during gestation, indicating that repeated immunization with P. gingivalis LPS does not provide protection during pregnancy, but potentiates the negative effects of LPS exposure during gestation. P. gingivalis-induced experimental periodontitis in animal models resulted in decreased fetal birth-weight and increased amniotic fluid levels of TNF-a and PGE2 (Fig. 13-10).[55] This provides direct evidence that periodontal infection can affect the fetal environment and pregnancy outcome.

These animal studies have led to examination of the potential effects of periodontitis on pregnancy outcome in humans. In a case control study of 124 women (93 cases with at least one LBW delivery and 31 controls with at least one normal birth weight delivery), Offenbacher and coworkers found that women having LBW infants had greater clinical attachment loss than women having NBW infants.[54] After adjusting for known risk factors for LBW, women with periodontitis resulting in greater than 3 mm of attachment loss in at least 60% of sites had a 7.5-fold increased risk of having a LBW infant. In fact, periodontitis contributed to more preterm LBW cases than did smoking or alcohol use during pregnancy. This study indicated a strong association between periodontal infection and adverse pregnancy outcomes. Other studies have demonstrated significantly fewer periodontally healthy sextants and greater gingival bleeding in women having LBW infants.[13]

In a cross-sectional study, women having LBW infants had significantly higher levels of Actinobacillus *actinomycetemcomitans, Bacteroides forsythus, P.* gingivalis, and *Treponema denticola* in their subgingival plaque than did the control women having NBW infants.[55] Women having LBW infants also had higher levels of gingival crevicular fluid PGE2 and IL-1. In primiparous women (those experiencing a first birth), the gingival crevicular fluid levels of PGE2 were inversely related to their infants' birth-weight. Women with higher PGE2 levels in the gingival crevicular fluid had smaller and more premature infants. Gingival crevicular fluid levels of IL-1 and PGE2 have been shown to correlate highly with intraamniotic IL-1 and PGE2 levels. In fact, measuring crevicular fluid levels of these inflammatory mediators has been suggested as a less invasive means of screening expectant mothers for elevated amniotic IL-1 and PGE2 levels than amniocentesis.[55] Thus women having LBW infants have a higher prevalence and severity of periodontitis, more gingival inflammation, higher levels of putative periodontal pathogens, and an elevated subgingival inflammatory response compared with women having NBW infants. When combined with animal studies showing adverse effects of experimental periodontitis on the fetus and data supporting biologically plausible interactive mechanisms, the evidence strongly suggests that periodontal infection may have significant negative impact on pregnancy outcome in some women. To date, however, no longitudinal human studies or intervention trials have been published that examine the potential

effects of periodontal treatment or lack of treatment on pregnancy outcome in women with periodontitis.

PERIODONTAL DISEASE AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is a disease state characterized by airflow obstruction due to chronic bronchitis or emphysema. Bronchial mucous glands enlarge, and an inflammatory process occurs in which neutrophils and mononuclear inflammatory cells accumulate within the lung tissue.[26,73] About 14 million Americans have COPD, and tobacco smoking is the primary risk factor.

COPD shares similar pathogenic mechanisms with periodontal disease. In both diseases, a host inflammatory response is mounted in response to chronic challenge: by bacteria in periodontal disease and by factors such as cigarette smoke in COPD. The resulting neutrophil influx leads to release of oxidative and hydrolytic enzymes that cause tissue destruction directly. Recruitment of monocytes and macrophages leads to further release of pro-inflammatory mediators.

Less is known about the clinical relationship between periodontal disease and COPD compared with CHD and other systemic conditions. In analyzing data from a longitudinal study of more than 1100 men, alveolar bone loss was associated with the risk for COPD.[26] Over a 25-year period, 23% of subjects were diagnosed with COPD. Subjects with more severe bone loss at the baseline dental examination had a significantly increased risk of subsequently developing COPD compared with subjects with less bone loss. The increase in risk was independent of age, smoking status, and other known risk factors for COPD. Individuals with poor oral hygiene have also been found to be at increased risk for chronic respiratory diseases such as bronchitis and emphysema.[64] These associations remain to be confirmed by further research.

PERIODONTAL DISEASE AND ACUTE RESPIRATORY INFECTIONS

The upper respiratory passages are often contaminated with organisms derived from the oral, nasal, and pharyngeal regions. Conversely, the lower airways in which gas exchange occurs are generally maintained free of microorganisms by a combination of host immune factors and mechanical clearance through the cough reflex, ciliary transport of aspirated contaminants, and movement of secretions from the lower airways into the trachea.[46] Pneumonia is an infection of the lungs caused by bacteria, viruses, fungi, or mycoplasma and is broadly categorized as either community-acquired or hospital-acquired. A wide variety of bacteria may cause pneumonia, and the spectrum of offending organisms differs markedly between community-acquired and hospital-acquired infections.

Community-acquired bacterial pneumonia is caused primarily by inhalation of infectious aerosols or by aspiration of oropharyngeal organisms. S. *pneumoniae* and *Haemophilus influenzae* are most common, although numerous other species may occur, including anaerobic bacteria.[56] Antibiotic therapy is highly successful in resolution of most cases of community-acquired bacterial pneumonia. To date, no associations have been found between oral hygiene or periodontal disease and the risk for acute respiratory conditions such as pneumonia in community-dwelling individuals.[64]

The same cannot be said for individuals in the hospital setting. Hospital-acquired (nosocomial) bacterial pneumonia has a very high morbidity and mortality rate. Approximately 20% to 50% of patients with nosocomial pneumonia die.[11] The incidence of nosocomial pneumonia is highest in severely ill patients such as those in intensive care units or on ventilatory support. More than half of patients on mechanical ventilation for several days or more acquire pneumonia. Although nosocomial pneumonia is most commonly caused by gram-negative aerobic organisms, many cases are the result of infection by anaerobic bacteria, including those commonly found in the subgingival environment.

Hospital-acquired pneumonia is usually caused by aspiration of oropharyngeal contents. Oropharyngeal colonization with potential respiratory pathogens (PRPs) increases during hospitalization, and the longer the hospital stay the greater the prevalence of PRPs.[46] PRPs are found predominantly in the gastrointestinal tract and may be passed through esophageal reflux into the oropharynx where they colonize. Subsequent aspiration may lead to pneumonia. Patients whose posterior oropharynx becomes colonized with PRPs have a significantly increased risk of developing nosocomial pneumonia compared with those without oropharyngeal colonization by PRPs.

Selective decontamination is a technique that combines systemic antibiotics with orally administered nonabsorbable antibiotics in an attempt to eradicate PRPs from the digestive tract and oropharynx and to thereby minimize the risk of nosocomial respiratory infections. The technique is used primarily in patients who are intubated and on mechanical ventilators. Selective decontamination significantly decreases the incidence of nosocomial pneumonia.[6s] Decontamination of only the digestive tract does not reduce the incidence of pneumonia, but decontamination of the oropharynx alone does.[60,68] This provides further evidence that the oropharynx is the primary site of PRP colonization, with subsequent aspiration of causative organisms leading to pneumonia.

PRPs may also originate in the oral cavity, with dental plaque serving as a reservoir of these organisms. Poor oral hygiene is common in the hospital and nursing home settings, especially in severely ill patients.[6] PRPs are more commonly isolated from supragingival plaque and buccal mucosa of patients in intensive care units than in outpatient settings.[63] Thus organisms that are not routinely found in dental plaque become plaque colonizers after prolonged hospitalization. Subgingival plaque may also harbor PRPs, and putative periodontal pathogens have been associated with nosocomial pneumonia. Furthermore, anaerobic organisms from periodontal pockets may serve as the primary inoculum for suppurative respiratory diseases such as pulmonary

abscesses that have significant morbidity and mortality. 4 Although considerable circumstantial evidence suggests that periodontal pathogens may cause acute nosocomial pulmonary infections, currently no published studies specifically demonstrate an increased risk of such infections in patients with periodontal disease. Likewise, there is no research evaluating the effects of periodontal treatment on the incidence of bacterial pneumonia.

PERIODONTAL MEDICINE IN CLINICAL PRACTICE

The concept of periodontal diseases as localized entities affecting only the teeth and supporting apparatus is over simplified and in need of revision. Rather than being confined to the periodontium, periodontal diseases may have wide-ranging systemic effects. In most persons, these effects may be relatively inconsequential or at least not clinically evident. However, in susceptible individuals, periodontal infection may act as an independent risk factor for systemic disease and may be involved in the basic pathogenic mechanisms of these conditions. Furthermore, periodontal infection may exacerbate existing systemic disorders.

Periodontal Disease and Systemic Health in the Clinical Practice of Dentistry

Proper use of the knowledge of potential relationships between periodontal disease and systemic health requires the dental professional to expand his or her horizons, to step back from the technically demanding aspects of the dental art, and to recognize the oral cavity as one of many interrelated organ systems. An infection the size of one's palm on the leg of a pregnant woman would be a major concern to the patient and her health care provider, given the potential negative consequences of this localized infection on fetal and maternal health. A similar suppurating infection on the foot of a person with diabetes would be cause for immediate evaluation and aggressive treatment, knowing the effects of such infections on metabolic control of diabetes. Periodontal infection must be viewed in a similar fashion. Periodontitis is a gram-negative infection resulting in severe inflammation, with potential intravascular dissemination of microorganisms and their products throughout the body. However, periodontitis tends to be a "silent" disease, until destruction results in acute symptoms. Most patients, and many medical professionals, do not recognize the potential infection that may exist within the oral cavity.

Patient Education

Patient education is a priority. Only 30 years ago, the factors involved in CHD were unclear. Yet today, it would be difficult to find an individual who was unfamiliar with the link between cholesterol and heart disease. This change was precipitated by research clearly demonstrating the increased risk for heart disease in individuals with high cholesterol levels, followed by intensive education efforts to spread the message from the scientific community to the wider citizenry. It is important to recognize that high cholesterol levels have not been shown to cause heart disease in all individuals, but rather to significantly increase the risk of disease. Cholesterol has also been demonstrated to have a biologically plausible role in the pathogenesis of CHD. Similarly, patient education efforts in the realm of periodontal medicine must emphasize the nature of periodontal infections, the increased risk for systemic disease associated with the infection, and the biologically plausible role periodontal infection may play in systemic disease. Few individuals had their cholesterol levels evaluated until the knowledge of the link between cholesterol and heart disease became widespread. Likewise, increased appreciation of the potential effects of periodontal infection on systemic health may result in increased patient demand for periodontal evaluation.

Enhanced community awareness may be derived from newspapers, magazines, and other lay sources. However, the most reliable origin of information should be the dental and medical professions through daily contact with patients. The pregnant woman usually knows that infections may adversely affect her pregnancy. Persons with diabetes generally know that infections make glycemic control worse. However, many of these patients do not know that occult periodontal infections can have the same effect as more clinically evident infections. It is up to the dentist to diagnose periodontal infections, provide appropriate treatment, and prevent disease recurrence or progression. Since many medical professionals are unfamiliar with the oral cavity and oral health research, dentists must reach out to the medical community in an effort to improve patient care through education and communication. Likewise, patients must be educated in disease prevention. Just as patients know that lowering cholesterol levels may decrease their risk for heart disease, prevention of periodontal infection should be emphasized. A physician would be remiss if he or she did not provide education on decreasing cholesterol, losing weight, and ceasing a smoking habit to a patient at risk for CHD. Likewise, controlling the risk factor of periodontal infection requires the dentist to emphasize personal and professional preventive measures focused on thorough oral hygiene and regular recall.

Periodontal Disease, CHD, COPD, and Pregnancy

Does periodontal disease cause coronary heart disease, COPD, or adverse pregnancy *outcomes?* The question may only be answered based on the evidence available today, with the full knowledge that conclusions may change as future evidence dictates. Periodontal disease may increase the risk for many systemic disorders. Biologically plausible mechanisms support the role of periodontal infection in these conditions, but periodontal infection should not be presented as the cause of such systemic diseases any more than cholesterol is said to cause heart disease. Periodontal infection is one of many potential risk factors for a number of systemic conditions. Fortunately, it is a readily modifiable risk factor, unlike age, gender, and genetic influences.

The focal infection theory of the early 20th century was widely and appropriately discredited when treatment

based on the theory, namely tooth extraction, had no effect on the underlying diseases that oral sepsis supposedly caused. Similarly, the clinical utility of our current knowledge base is only now evolving. Future research will further delineate the role of periodontal infection in systemic health. It is possible that the associations between periodontal infection and conditions such as LBW delivery, diabetes, cardiovascular and cerebrovascular diseases, and respiratory diseases will be further substantiated. Longitudinal studies and intervention trials are needed before any causative role can be assigned.

The emerging field of periodontal medicine offers new insights into the concept of the oral cavity as one system interconnected with the whole of the human body. For many years, the dental profession has recognized the effects of systemic conditions on the oral cavity. Only now are we coming to more fully understand the impact of the periodontium on systemic health.

CHAPTER OUTLINE

EFFECTS OF SMOKING ON THE PREVALENCE AND SEVERITY OF PERIODONTAL DISEASE
- **Gingivitis**
- **Periodontitis**

EFFECTS OF SMOKING ON THE ETIOLOGY AND PATHOGENESIS OF PERIODONTAL DISEASE
- **Microbiology**
- **Immunology**
- **Physiology**

EFFECTS OF SMOKING ON THE RESPONSE TO PERIODONTAL THERAPY
- **Nonsurgical Therapy**
- **Surgical Therapy and Implants**
- **Maintenance Therapy**
- **Recurrent (Refractory) Disease**

A old estimated 27.9% of dentate U.S. adults are current smokers and 23.3% are former smokers. The prevalence of smoking is higher in individuals er than 34 years of age when compared with older age groups and in males (30.9%) compared with females (25.1%), with the highest prevalence seen in non-Hispanic black men (38.6%). Current smoking is more common among low-income adults (37.1%) compared with medium or high-income earners and increases with decreasing years of education. [69] Increasing evidence points to smoking as a major risk factor for periodontitis, affecting the prevalence, extent, and severity of disease. In addition, smoking may influence the clinical outcome of nonsurgical and surgical therapy as well as the long-term success of implant placement. With 41.9% of periodontitis cases in the U.S. being associated with smoking, it has become increasingly important to understand its impact on the initiation, progression, and management of the disease in patients who smoke. This chapter discusses the effects of smoking on the prevalence, severity, etiology, and pathogenesis of periodontal disease as well as the impact on treatment. The reader is referred to several excellent reviews on the topic for the detailed results of studies. [34,49,50,53,71]

EFFECTS OF SMOKING ON THE PREVALENCE AND SEVERITY OF PERIODONTAL DISEASE

Gingivitis

Controlled clinical studies have demonstrated that in human models of experimental gingivitis, the development of inflammation in response to plaque accumulation is reduced in smokers compared with nonsmokers (Table 14-1). [6,16] In addition, cross-sectional studies have consistently demonstrated that smokers present with less gingival inflammation than nonsmokers. [5,8,9,54,55] These data suggest that smokers have a decreased expression of clinical inflammation in the presence of plaque accumulation when compared with nonsmokers. The microbiologic, immunologic, and physiologic factors that might account for this observation are discussed in detail later.

Periodontitis

Although gingival inflammation in smokers appears to be reduced in response to plaque accumulation when compared with nonsmokers, an overwhelming body of data

TABLE 14-1

Effects of Smoking on the Prevalence and Severity of Periodontal Disease

Periodontal Disease	Impact of Smoking
Gingivitis	↓ Gingival inflammation and bleeding on probing
Periodontitis	↑ Prevalence and severity of periodontal destruction
	↑ Pocket depth, attachment loss, and bone loss
	↑ Rate of periodontal destruction
	↑ Prevalence of severe periodontitis
	↑ Tooth loss
	↑ Prevalence with increased number of cigarettes smoked per day
	↓ Prevalence and severity with smoking cessation

, **Decreased; T, increased.**

points to **smoking as a major risk factor for increasing the prevalence and severity of periodontal** destruction. Multiple cross-sectional and longitudinal studies have demonstrated that pocket depth, attachment loss, and alveolar bone loss are more prevalent and severe in patients who smoke compared with nonsmokers.[34,49,50,53,71] An assessment of the relationship between cigarette smoking and periodontitis was performed in more than *12,000* dentate individuals over the age of *18* years as part of the National Health and Nutrition Examination Survey (NHANES III).[69] Periodontitis was defined as >_ 1 site with clinical attachment loss of >_4 mm and pocket depth of >4 mm. Using criteria established by the Centers for Disease Control and Prevention (CDC), current smokers were defined as those that had smoked >_ 100 cigarettes over their lifetime and smoked at the time of the interview; former smokers had smoked >100 cigarettes in their lifetime but were not currently smoking, and nonsmokers had not smoked >_100 cigarettes in their lifetime. Of the *12,000* individuals studied, *9.2%* had periodontitis. This represented approximately 15 million cases of periodontitis in the U.S. On average, smokers were *4* times as likely to have periodontitis as persons who had never smoked after adjusting for age, gender, race/ethnicity, education, and income/poverty ratio. Former smokers were *1.68* times more likely to have periodontitis than persons who had never smoked. This study also demonstrated a dose-response relationship between cigarettes smoked per day and the odds of having periodontitis. In subjects smoking <_*9* cigarettes per day, the odds for having periodontitis was *2.79* whereas subjects smoking >_*31* cigarettes per day were nearly *6* times more likely to have periodontitis. With former smokers, the odds of having periodontitis declined with the number of years since quitting. These data indicated that approximately *42%* of periodontitis cases *(6.4* million cases) in the U.S. adult population were attributable to current smoking and approximately *11% (1.7* million cases) were attributable to former smoking.

These data are consistent with the findings of other cross-sectional studies performed in the U.S. and Europe. The odds ratio for periodontitis in current smokers has been estimated to range from as low as 1.5 to as high as *7.3,* depending on the observed severity of periodontitis.[50] A metaanalysis of data from six such studies involving *2361* subjects indicated that current smokers were nearly *3* times more likely to have severe periodontitis than nonsmokers .[49] The detrimental impact of long-term smoking on the periodontal and dentate status of older adults has been clearly demonstrated. Older-adult smokers are approximately *3* times more likely to have severe periodontal disease [4,44] and the number of years of tobacco use is a significant factor in tooth loss, coronal root caries, and periodontal disease .[32,33] Smoking also has been shown to affect periodontal disease severity in younger individuals. Cigarette smoking is associated with increased severity of generalized aggressive periodontitis (formerly termed "early onset periodontitis") in young adults,[64] and young adults between the ages of *19* to *30* years who smoke are *3.8* times more likely to have periodontitis than nonsmokers .[26] Longitudinal studies have demonstrated that young individuals smoking more than 15 cigarettes per day showed the highest risk for tooth loss[30] and smokers are greater than *6* times more likely than nonsmokers to demonstrate continued attachment loss.[31] Over a 10-year period, bone loss has been reported to be twice as rapid in smokers when compared with nonsmokers" and proceeds more rapidly even in the presence of excellent plaque control.[10]

Less information is available on the effects of cigar and pipe smoking, but it appears that effects similar to cigarette smoking may be observed with this form of tobacco use .[2,20,21,42] The prevalence of moderate and severe periodontitis and the percentage of teeth with >_5 mm of attachment loss was most severe in current cigarette smokers, but cigar and pipe smokers showed a severity of disease intermediate between the current cigarette smokers and nonsmokers .[2] Tooth loss is also increased in cigar and pipe smokers when compared with nonsmokers .[42]

Smokeless tobacco use has been associated with oral leukoplakia and carcinoma.[15,75] However, there do not appear to be any generalized effects on periodontal disease progression, other than localized attachment loss and recession at the site of tobacco product placement .[6°]

Of great interest is the observation that former smokers have less risk for periodontitis than current smokers but more risk than nonsmokers and that the risk for periodontitis decreases with the increasing number of years since quitting smoking.[69] This suggests that the effects of smoking on periodontal disease progression are reversible with smoking cessation and that smoking cessation programs should be an integral component of periodontal education and therapy.

EFFECTS OF SMOKING ON THE ETIOLOGY AND PATHOGENESIS OF PERIODONTAL DISEASE

The increased prevalence and severity of periodontal destruction associated with smoking suggests that the host-bacterial interactions normally seen in chronic periodon-

titis are altered, resulting in more aggressive periodontal breakdown (see Chapters 6-8) (Table 14-2). This imbalance between bacterial challenge and host response may be due to changes in the composition of the subgingival plaque, with increases in the numbers and/or virulence of pathogenic organisms; changes in the host response to the bacterial challenge; or a combination of both. Recent evidence on the effects of smoking on the microbiology, immunology, and physiology of periodontitis are discussed below.

Microbiology

Studies have failed to demonstrate a difference in the rate of plaque accumulation of smokers compared with nonsmokers, suggesting that if an alteration in the microbial challenge in smokers exists, it is due to a qualitative rather than quantitative alteration in the plaque.$ Several studies have explored the changes that may occur in subgingival plaque as a result of smoking with conflicting and inconclusive results. In a study of 142 patients with chronic periodontitis, plaque samples from deep pockets (>>_6 mm) showed no differences in the counts of Actinobacillus actinomycetemcomitans, Porphymmonas gingivalis, and Prevotella intermedia.57 In a similar study of 615 patients, the prevalence of A. actinomycetemcomitans, P. gingivalis, P. intermedia, and Eikenella corrodens was not found to be significantly different between smokers and nonsmokers using immunoassay.67 In contrast, other studies have shown differences in the microbial composition of subgingival plaque between smokers and nonsmokers. In a study of 798 subjects with different smoking histories, it was found that smokers had significantly higher levels of Bacteroides forsythus and that smokers were 2.3 times more likely to harbor B. forsythus than nonsmokers and former smokers.[76] Of particular interest was the observation that smokers do not respond to mechanical therapy as well as nonsmokers and that this is associated with increased levels of B. forsythus, A. actinomycetemcomitans, and P. gingivalis remaining in the pockets after therapy in the smoking group when compared with nonsmokers.[23,24,27,59] Many discrepancies between the findings of microbiologic studies are a function of the methodology involved, including bacterial counts versus proportions or prevalence of bacteria, number of sites sampled and the pocket depths selected, the sampling technique, the disease status of the subject, and the methods of bacterial enumeration and data analysis.[28] In an attempt to overcome some of these problems, a recent study sampled subgingival plaque from all teeth with the exception of third molars in 272 adult subjects, including 50 current smokers, 98 past smokers, and 124 nonsmokers.[28] Using checkerboard DNA-DNA hybridization technology to screen for 29 different subgingival species, it was found that members of the orange and red complexes (see Chapter 6) including Eikenella nodatum, Fusobacterium nucleatum ss. vincentii, P. intermedia, Peptostreptococcus micros, Prevotella nigrescens, B. forsythus, P. gingivalis, and Treponema denticola were significantly more prevalent in current smokers than in nonsmokers and former smokers. Of interest was that the increased prevalence of these periodontal pathogens was due to an increased colonization of shallow sites (pocket depth <4 mm) with no differences between smokers, former smokers, and nonsmokers in pockets >>_4 mm. In addition, these pathogenic bacteria were more prevalent in the maxilla than the mandible. These data suggest that smokers have a greater extent of colonization by periodontal pathogens than nonsmokers or former smokers and that this colonization may lead to an increased prevalence of periodontal breakdown.

TABLE 14-2

Effects of Smoking on the Etiology and Pathogenesis of Periodontal Disease

Etiologic Factor	Impact of Smoking
Microbiology	No effect on the rate of plaque accumulation
	↑ Colonization of shallow periodontal pockets by periodontal pathogens
	↑ Levels of periodontal pathogens in deep periodontal pockets
Immunology	Altered neutrophil chemotaxis, phagocytosis, and oxidative burst
	↑ TNF-α, and PGE_2 in GCF
	↑ Neutrophil collagenase and elastase in GCF
	↑ Production of PGE_2 by monocytes in response to LPS
Physiology	↓ Gingival blood vessels with ↑ inflammation
	↓ GCF flow and bleeding on probing with ↑ inflammation
	↓ Subgingival temperature
	↑ Time needed to recover from local anaesthesia

↓, Decreased; ↑, increased. See text for description of other abbreviations.

Immunology

The immune response of the host to plaque accumulation is essentially protective. In periodontal health and gingivitis, a balance exists between the bacterial challenge of plaque and the immune response from within the gingival tissues, with no resulting loss of periodontal support. In contrast, periodontitis appears to be associated with an alteration in the host-bacterial balance that may be initiated by changes in the bacterial composition of subgingival plaque, changes in the immune response, or a combination of both elements (see Chapters 6-8). Smoking exerts a major effect on the protective elements of the immune response, resulting in an increase in the extent and severity of periodontal destruction. The deleterious effects of smoking appear to be due in part to a down regulation of the immune response to bacterial challenge. The neutrophil is an important component of the host response to bacterial infection, and alterations in neutrophil number or function may result in localized and/or systemic infections. Critical functions of neutrophils include chemotaxis (directed locomotion from

the blood stream to the site of infection), phagocytosis (internalization of foreign particles such as bacteria), and killing using oxidative and nonoxidative mechanisms. Neutrophils, obtained from the peripheral blood or saliva of smokers or exposed in vitro to whole tobacco smoke or nicotine, have been shown to demonstrate functional alterations in chemotaxis, phagocytosis, and the oxidative burst. Smoking has been shown to impair the chemotaxis and phagocytosis of neutrophils obtained from the oral cavity,[19,38] and in vitro studies of the effects of tobacco products on neutrophils have shown detrimental effects on cell movement and the oxidative burst.[14,37,43,62,65] In addition, the production of antibody essential for phagocytosis and killing of bacteria, specifically IgG2 levels to periodontal pathogens, has been reported to be reduced in smokers versus nonsmokers with periodontitis,[13,25,58,68] suggesting that smokers may have reduced protection against periodontal infection. In contrast, elevated levels of TNF-a have been demonstrated in the gingival crevicular fluid of smokers[12] as well as elevated levels of PGE2, neutrophil elastase, and matrix metalloproteinase-8.[66] In vitro studies also have demonstrated that exposure to nicotine increases the secretion of PGE2 by monocytes in response to LPS.[51]

These data suggest that smoking may impair the response of neutrophils to periodontal infection but may also increase the release of tissue-destructive enzymes. The exact changes in the immunologic mechanisms involved in the rapid tissue destruction seen in smokers are currently unclear. Further studies are needed to define the effects of tobacco use on the immune response and tissue destruction in periodontitis.

Physiology

Previous studies have shown that the clinical signs of inflammation are less pronounced in smokers when compared with nonsmokers.[6,16] These observations may be due to alterations in the inflammatory response in smokers, as outlined previously, or due to alterations in the vascular response of the gingival tissues. Although no significant differences in the vascular density of healthy gingiva have been observed between smokers and nonsmokers,[52] the response of the microcirculation to plaque accumulation appears to be altered in smokers when compared with nonsmokers. With developing inflammation, increases in gingival crevicular fluid flow,' bleeding on probing,' and gingival blood vessels' were less in smokers when compared with nonsmokers. In addition, the oxygen concentration in healthy gingival tissues appears to be less in smokers than nonsmokers, although this condition is reversed in the presence of moderate inflammation.[29] Subgingival temperatures are lower in smokers than nonsmokers,[18] and recovery from the vasoconstriction caused by local anaesthetic administration takes longer in smokers.[39,72] These cumulative data suggest the presence of significant alterations in the gingival microvasculature of smokers when compared with nonsmokers and that these changes lead to decreased blood flow and decreased clinical signs of inflammation.

EFFECTS OF SMOKING ON THE RESPONSE TO PERIODONTAL THERAPY

Nonsurgical Therapy

Numerous studies have indicated that current smokers do not respond as well to periodontal therapy as nonsmokers or former smokers (Table 14-3). The majority of clinical research supports the observation that pocket depth reduction is more effective in nonsmokers than in smokers using nonsurgical periodontal therapy (Phase I therapy) including oral hygiene instruction, scaling, and root planing.[1,23,24,27,36,56,59] In addition, gains in clinical attachment as a result of scaling and root planing are less pronounced in smokers than in nonsmokers. In a study of patients with previously untreated advanced periodontal disease, scaling and root planing plus oral hygiene resulted in significantly greater average reductions in pocket depth and bleeding on probing in nonsmokers than in smokers when evaluated 6 months after completion of therapy." Average pocket reductions of 2.5 mm for nonsmokers and 1.9 mm for smokers were observed in pockets that averaged 7 mm before treatment, even though plaque scores were less than favorable. In another study, the nonsurgical management of pockets >_5 mm showed that smokers had less pocket depth reduction than nonsmokers after 3 months (1.29 versus 1.76 mm) as well as fewer gains in clinical attachment levels.[23] When a higher level of plaque control can be achieved as part of nonsurgical care, the differences in the resolution of 4- to 6-mm pockets between nonsmokers and smokers become clinically less significant.[56] When pockets persist in smokers and nonsmokers after therapy, adjunctive topical antimicrobial therapy can be used to try to resolve the remaining pocket depths (see Chapter 50). When scaling and root planing is used in combination with either topical subgingivally placed tetracycline fibers, subgingival minocycline gel, or subgingival metronidazole gel, smokers continue to show less pocket reduction than nonsmokers.[4°] It can be concluded that smokers respond less well to nonsurgical therapy than nonsmokers. However, in the presence of excellent plaque control, these differences may be minimized. When comparing current smokers with former smokers and nonsmokers, the former and nonsmoking subjects appear to respond equally well to nonsurgical care,[23] reinforcing the need for patients to be informed of the benefits of smoking cessation.

Surgical Therapy and Implants

The less favorable response of the periodontal tissues to nonsurgical therapy that is observed in current smokers also appears to apply to surgical therapy. In a longitudinal comparative study of the effects of four different treatment modalities including coronal scaling, root planing, modified Widman flap surgery, and osseous resection surgery, smokers *(heavy* defined as >_20 cigarettes/day; light defined as <_19 cigarettes/day) consistently showed less pocket reduction and less gain in clinical attachment levels than nonsmokers or former smokers." These differences began immediately after the completion of therapy and continued throughout 7 years of supportive peri-

TABLE 14-3

Effects of Smoking on the Response to Periodontal Therapy

Therapy	Effects of Smoking
Nonsurgical	↓ Clinical response to scaling and root planing ↓ Reduction in pocket depth ↓ Gain in clinical attachment levels ↓ Negative impact of smoking with ↑ level of plaque control
Surgery and implants	↓ Pocket depth reduction postsurgery ↑ Deterioration of furcations postsurgery ↓ Gain in clinical attachment levels, ↓ bone fill, ↑ recession, and ↑ membrane exposure following GTR ↓ Pocket depth reduction after DFDBA allografts ↓ Pocket depth reduction and gain in clinical attachment levels after open flap debridement Conflicting data on the impact of smoking on implant success Smoking cessation should be recommended prior to implants
Maintenance	↑ Pocket depth during maintenance ↓ Gain in clinical attachment levels
Recurrent (refractory) disease	↑ Recurrent/refractory disease in smokers ↑ Need for retreatment in smokers ↑ Need for antibiotics in smokers to control the negative effects of periodontal infection on surgical outcomes ↑ Tooth loss in smokers after surgical therapy

↓, Decreased; ↑, increased. See text for description of other abbreviations.

odontal therapy. During the 7 years, deterioration of furcation areas was greater in heavy and light smokers when compared with former and nonsmokers.

Smoking also has been shown to have a negative impact on the outcomes of guided tissue regeneration (GTR)[70,73] and the treatment of intrabony defects by bone allografts.[61] By 12 months after GTR therapy for deep intrabony defects, smokers gained less than half as much clinical attachment as nonsmokers (2.1 versus 5.2 mm).[70] In a second study, 73 smokers also showed less gain in clinical attachment (1.2 versus 3.2 mm), more gingival recession, and less gain in bone fill of the defect. In addition, the GTR membranes were exposed in all the smokers and approximately half of the nonsmokers (Table 14-4).

Similarly, after the use of decalcified freeze dried bone allograft (DFDBA) for the treatment of intrabony defects, smokers showed less percentage reduction in presurgical pocket depth than nonsmokers (41.9% reduction for smokers versus 48.3% for nonsmokers).[61]

Open flap debridement surgery without regenerative or grafting procedures is the most common surgical procedure used for accessing the root and osseous surfaces. By 6 months after this procedure, smokers showed significantly less reduction of deep pockets (≥7 mm) than nonsmokers (3 mm for smokers versus 4 mm for nonsmokers) and significantly less gain in clinical attachment (1.8 versus 2.8 mm), even though the patients received supportive periodontal therapy every month for 6 months.[63] Of increased significance was the observation that only 16% of deep pockets in smokers returned to ≤3 mm 6 months after surgery, whereas 47% of the deep pockets in nonsmokers were ≤3 mm after completion of therapy.

TABLE 14-4

Postsurgery Changes in Clinical Parameters of the Healing Response in Smoker and Nonsmoker Patients

	Smokers	Nonsmokers	P-Value
CAL gain	1.2 ± 1.3 mm	3.2 ± 2.0 mm	<0.007
GR increase	2.8 ± 1.2 mm	1.3 ± 1.3 mm	<0.008
PBL gain	0.5 ± 1.5 mm	3.7 ± 2.2 mm	<0.000
ME	10/10	15/28	<0.008

CAL, Clinical attachment level; GR, gingival recession; *ME,* prevalence of membrane exposure at removal; *PBL,* probing bone level. J Clin Periodontol 1997; 24:366.

The impact of smoking on implant success is unclear at present. Several studies have shown that implant success rates are reduced in smokers[3,17,22,35] while other studies have shown no effect.[48,74] Since numerous factors can influence implant success (see Chapters 68-73), further controlled clinical trials are needed to address the role of smoking as an independent variable in implant failure. However, with existing evidence supporting a negative

effect of smoking on long-term implant success, patients should be informed and advised of the benefits of smoking cessation and the potential risks of smoking for implant failure.

Maintenance Therapy

The detrimental effects of smoking on treatment outcomes appears to be long lasting, and independent of the frequency of maintenance therapy. After four different modalities of therapy including scaling, scaling and root planing, modified Widman flap surgery, and osseous surgery, maintenance therapy was performed by an hygienist every 3 months for 7 years .36 Smokers consistently had deeper pockets than nonsmokers and less gain in attachment when evaluated each year for the 7-year period. Heavy smokers (>_20 cigarettes/day) had more plaque than light smokers, former smokers, and nonsmokers. Even with more intensive maintenance therapy given every month for 6 months after flap surgery, 63 smokers had deeper and more residual pockets than nonsmokers, even though no significant differences in plaque or bleeding on probing scores were found. These data suggest that the effects of smoking on the quality of subgingival plaque, the host response, and the healing characteristics of the periodontal tissues may have a long-term effect on pocket resolution in smokers that may not be managed by conventional periodontal therapy. More studies are needed to examine the effects of antimicrobial agents combined with host-modulating agents in an attempt to control periodontal disease in smokers.

Recurrent (Refractory) Disease

Because of the difficulty in controlling periodontal disease in smokers, many smokers become refractory to traditional periodontal treatment and tend to show more periodontal breakdown than nonsmokers after therapy.45,47 The question has been raised as to whether patients are truly refractive to therapy or whether the therapy administered was insufficient to control the disease process. 41,47 It is now thought that patients formerly considered refractive to therapy actually undergo continuous or recurrent disease; for this reason, the diagnosis of refractory periodontitis has been removed as a distinct classification (see Chapter 4). The complex effects of smoking on the subgingival microflora and host response provide a model for studying new modalities of therapy for controlling periodontitis. In studies of patients who failed to respond to conventional therapy including different combinations of oral hygiene instruction, scaling and root planing, surgery, and antibiotics, approximately 90% of these so-called "refractory" patients were smokers .45,46 In one study, **the mean age of the refractory patients** was 42 years and 28 of **the** 31 refractory patients were smokers. 45 Of the 31 patients, 19% had been retreated once surgically for pocket elimination, 10% had been retreated twice surgically, and the patients had received an average of four episodes of adjunctive antibiotics. During the course of treatment, 36% of patients had lost an average of 3 teeth (range 1-10).

It is clear from these studies that smokers may present with periodontal disease at an early age, may be difficult to treat with conventional therapy, and may continue to have progressive or recurrent periodontitis leading to tooth loss. Further studies are needed to determine the level and type of therapy required to provide long-term maintenance of periodontal health in individuals who wish to continue smoking.

Periodontal Pathology

Michael G. Newman and Fermin A. Carranza

The thorough knowledge of the microscopic tissue changes in disease provides a sound basis for the understanding and interpretation of the clinical and radiographic findings encountered in our patients. This information is essential to comprehend the biologic nature of the periodontal responses to injury and healing.

This part provides information of the gingival diseases (Section One) and periodontal diseases (Section Two). The latter section also presents chapters with detailed descriptions of the different diseases that can affect the periodontium.

Defense Mechanisms of the Gingiva

- **Role in Periodontal Pathology**

The gingival tissue is constantly subjected to mechanical and bacterial aggressions. The saliva, the epithelial surface, and the initial stages of the inflammatory response provide resistance to these actions. The role of the epithelium, through its degree of keratinization and turnover rate, were reviewed in Chapter 1. The permeability of the junctional and sulcular epithelia and the role of sulcular fluid, leukocytes, and saliva is described here.

SULCULAR FLUID

The presence of sulcular fluid or gingival crevicular fluid (GCF) has been known since the nineteenth century, but its composition and possible role in oral defense mechanisms were elucidated by the pioneering work of Waerhaug[4] and Brill and Krasse[14] in the 1950s. The latter investigators introduced filter paper into the gingival sulci of dogs that had previously been injected intramuscularly with fluorescein; within 3 minutes the fluorescent material was recovered on the paper strips. This indicated a passage of fluid from the bloodstream through the tissues and exiting via the gingival sulcus.

In subsequent studies, Brill[11,12] confirmed the presence of GCF in humans and considered it a transudate. However, others[74,129] demonstrated that GCF is an inflammatory exudate, not a continuous transudate. In a strictly normal gingiva, little or no fluid can be collected.

More recently, interest in the development of tests for the detection or prediction of periodontal disease has resulted in numerous research papers dealing with the components, origin, and function of GCF.

Methods of Collection

The most difficult hurdle to overcome when collecting GCF is the scarcity of material that can be obtained from the sulcus. Many collection methods have been tried.[10,13,59,63,64,74,76,104,124,125] These methods include the use of absorbing paper strips, twisted threads placed around and into the sulcus, micropipettes, and intracrevicular washings.

The absorbing paper strips are placed within the sulcus (intrasulcular method) or at its entrance (extrasulcular method) (Fig. 15-1). The placement of the filter paper strip in relation to the sulcus or pocket is important. The Brill technique places it into the pocket until resistance is encountered (see Fig. 15-1, A). This method introduces a degree of irritation of the sulcular epithelium that can, by itself, trigger the flow of fluid.

To minimize this irritation, We and Holm-Pedersen[74] placed the filter paper strip just at the entrance of the pocket or over the pocket entrance (see Fig. 15-1, B, C. In this way, fluid seeping out is picked up by the strip, but the sulcular epithelium is not in contact with the paper.

Preweighed twisted threads were used by Weinstein et a1.[129] The threads were placed in the gingival crevice around the tooth, and the amount of fluid collected was estimated by weighing the sample thread.

The use of micropipettes permits the collection of fluid by capillarity. Capillary tubes of standardized length and diameter are placed in the pocket, and their content is later centrifuged and analyzed.[10,12,13]

Crevicular washings can be used to study GCF from clinically normal gingiva. One method uses an appliance consisting of a hard acrylic plate covering the maxilla with soft borders and a groove following the gingival margins; it is connected to four collection tubes. The washings are obtained by rinsing the crevicular areas from one side to the other, using a peristaltic pump.[21]

A modification of the method uses two injection needles fitted one within the other such that during sampling the inside, or ejection, needle is at the bottom of the pocket and the outside, or collecting, one is at the gingival margin. The collection needle is drained into a sample tube by continuous suction.[104]

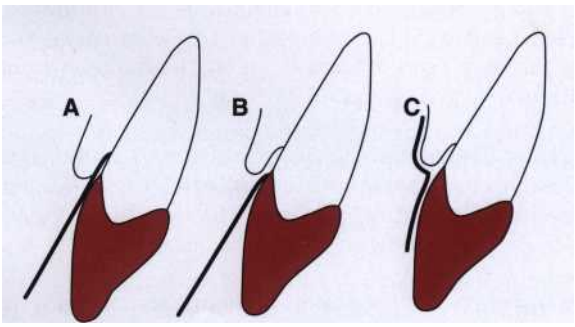

Fig. 15-1 Placement of filter strip in gingival sulcus for collection of fluid. A, Intrasulcular method. B and C, Extrasulcular methods.

Permeability of junctional and Sulcular Epithelia

The initial studies by Brill and Krasse[14] with fluorescein were later confirmed with substances such as India ink[97] and saccharated iron oxide." Substances that have been shown to penetrate the sulcular epithelium include albumin,[96,125] endotoxin,[95,100,101,109] thymidine,[49] histamine,[28] phenytoin,[120] and horseradish peroxidase.[80,81] These findings indicate permeability to substances with a molecular weight of up to 1 million.'[10]

Squier and Johnson[119] reviewed the mechanisms of penetration through an intact epithelium. Intercellular movement of molecules and ions along intercellular spaces appears to be a possible mechanism. Substances taking this route do not traverse the cell membranes.

Amount

The amount of GCF collected on a paper strip can be evaluated in a variety of ways. The wetted area can be made more visible by staining with ninhydrin; it is then measured planimetrically on an enlarged photograph or with the help of a magnifying glass or a microscope.

An electronic method has been devised for measuring the fluid collected on a "blotter" (Periopaper), employing an electronic transducer (Periotron, Harco Electronics, Winnipeg, Manitoba, Canada) (Fig. 15-2). The wetness of the paper strip affects the flow of an electronic current and gives a digital readout. A comparison of the ninhydrin-staining method and the electronic method performed in vitro revealed no significant differences between the two techniques.[122]

The amount of GCF collected is extremely small. Measurements performed by Cimasoni[21] showed that a strip of paper 1.5-mm wide inserted 1 mm within the gingival sulcus of a slightly inflamed gingiva absorbs about 0.1 mg of GCF in 3 minutes. Challacombel[9] used an isotope dilution method to measure the amount of

Fig. 15-2 Electronic machine for measuring the amount of fluid collected on filter paper.

Composition

The components of GCF can be characterized according to individual proteins, [76,87,106] specific antibodies, antigens, [35,94] and enzymes of several specificities." The GCF also contains cellular elements [28.31.131]

Many research efforts have attempted to use GCF components to detect or diagnose active disease or to predict patients at risk for periodontal disease [2] So far, more than 40 compounds found in GCF have been analyzed, [91] but their origin is not known with certainty. These compounds can be host derived or produced by the bacteria in the gingival crevice, but their source can be hard to elucidate. Examples of this are X-ß-glucuronidase, a lysosomal enzyme and lactic acid dehydrogenase, a cytoplasmic enzyme. The source for collagenases can be fibroblasts or polymorphonuclear neutrophils (PMNs), [89] or collagenases can be secreted by bacteria. [35] Phospholipases are lysosomal and cytoplasmic enzymes but are also produced by microorganisms. [15] The majority of GCF elements detected thus far have been enzymes, but there are nonenzymatic substances as well (Table *15-1)*.

Cellular Elements. Cellular elements found in GCF include bacteria, desquamated epithelial cells, and leukocytes (PMNs, lymphocytes, and monocytes/macrophages), which migrate through the sulcular epithelium. [28,31]

Electrolytes. Potassium, sodium, and calcium have been studied in GCE Most studies have shown a positive correlation of calcium and sodium concentrations and the sodium-to-potassium ratio with inflammation. [-56-58.63] (For further information, see references *12* and 13 and Table *15-2.)*

Organic Compounds. Both carbohydrates and proteins have been investigated. Glucose hexosamine and hexuronic acid are two of the compounds found in GCF .47 Blood glucose levels do not correlate with GCF glucose levels; glucose concentration in GCF is three to four times greater than that in serum.47 This is interpreted not only as a result of metabolic activity of adjacent tissues, but also as a function of the local microbial flora.

The total protein content of GCF is much less than that of serum. 13,14 No significant correlations have been found between the concentration of proteins in GCF and the severity of gingivitis, pocket depth, or extent of bone loss.'

Metabolic and bacterial products identified in GCF include lactic acid,48 urea,42 hydroxyproline,93 endotoxins,114,115 cytotoxic substances, hydrogen sulphide,118 and antibacterial factors .27 Many enzymes have also been identified (see Tables 15-1 and 15-2).

The methodology used for the analysis of GCF components is as varied as the diversity of those components. A few examples suffice, such as fluorometry for the detection of metalloproteases28; enzyme-linked immunoabsorbent assay (ELISA) tests to detect enzyme levels and interleukin-lbeta (IL-1ß)69; radio-immunoassays to detect cyclooxygenase derivatives$$ and procollagen 111[123]; timidazole detected by high-pressure liquid chromatography (HPLC)18; acute phase proteins detected by direct and indirect immunodots113; and others.

Cellular and Humoral Activity in Gingival Crevicular Fluid

Monitoring periodontal disease is a complicated task, because there are very few noninvasive procedures that can follow the initiation and progress of the disease. Analysis of GCF constituents in health and disease may be extremely useful because of GCF's simplicity and the fact that it can be obtained with noninvasive methods.

Analysis of GCF has identified cell and humoral responses in both healthy individuals and those with periodontal disease.66 The cellular immune response includes the appearance in GCF of cytokines (see Table 15-1), but there is no clear evidence of a relationship between them and disease. However, interleukin-1 alpha (IL-la) and IL-1/3 are known to increase the binding of PMNs and monocytes/macrophages to endothelial cells, stimulate the production of prostaglandin (PGE2) and release of lysosomal enzymes, and stimulate bone resorption.69 There is also preliminary evidence of the presence of interferon-a in GCF ,66 which may have a protective role in periodontal disease because of its ability to inhibit the bone resorption activity of IL-1ß.44

Because the amount of fluid recoverable from gingival crevices is small, only the use of very sensitive immunoassays permits the analysis of the specificity of antibodies." A study comparing antibodies in different crevices with serum antibodies directed at specific microorganisms did not provide any conclusive evidence about the significance of the antibody presence in GCF in periodontal disease.66

Even though the role of antibodies in the gingival defense mechanisms is hard to ascertain, there is a consensus indicating that in a patient with periodontal disease, (1) a reduction in antibody response is detrimental and (2) an antibody response plays a protective role in periodontal disease .65

Clinical Significance

As mentioned previously, GCF is an inflammatory exudate.74 Its presence in clinically normal sulci can be explained by the fact that gingiva that appears clinically normal invariably exhibits inflammation when examined microscopically.

The amount of GCF is greater when inflammation is present[34,111] and is sometimes proportional to the severity of inflammation.'° GCF production is not increased by trauma from occlusion79 but is increased by mastication of coarse foods, toothbrushing and gingival massage, ovulation,71 hormonal contraceptives,72 and smoking.82 Other factors that influence the amount of GCF are circadian periodicity and periodontal therapy.

Circadian Periodicity. There is a gradual increase in GCF amount from 6 AM to 10 PM and a decrease afterward.'

Sex Hormones. Female sex hormones increase GCF flow, probably because they enhance vascular permeability.69 Pregnancy, ovulation,68 and hormonal contraceptives'° all increase gingival fluid production.

Mechanical Stimulation. Chewing12 and vigorous gingival brushing stimulate the flow of GCF. Even the minor stimuli represented by intrasulcular placement of paper strips increases the production of fluid.

Smoking. Smoking produces an immediate transient but marked increase in GCF flow.82

Periodontal Therapy. There is an increase in GCF production during the healing period after periodontal surgery.3

Drugs in Gingival Crevicular Fluid

Drugs that are excreted through the GCF may be used advantageously in periodontal therapy. Bader and Goldhaber6 demonstrated in dogs that tetracyclines are excreted through the GCF; this finding triggered extensive research that demonstrated a concentration of tetracycline's in GCF when compared with serum .43 Metronidazole is another antibiotic that has been detected in human GCF32 (see Chapter 50).

LEUKOCYTES IN THE DENTOGINGIVAL AREA

Leukocytes have been found in clinically healthy gingival sulci in humans and experimental animals. The leukocytes found are predominantly PMNs. They appear in small numbers extravascularly in the connective tissue adjacent to the bottom of the sulcus; from there, they travel across the epithelium'[8,45] to the gingival sulcus, where they are expelled (Figs. 15-3 and 15-4).

Leukocytes are present in sulci even when histologic sections of adjacent tissue are free of inflammatory infiltrate. Differential counts of leukocytes from clinically healthy human gingival sulci have shown 91.2% to 91.5% PMNs and 8.5% to 8.8% mononuclear cells.[,,,]

Mononuclear cells were identified as 58% B lymphocytes, 24% T lymphocytes, and 18% mononuclear phagocytes. The ratio of T lymphocytes to B lymphocytes was found to be reversed from the normal ratio of about 3:1 found in peripheral blood to about 1:3 in GCE.[131]

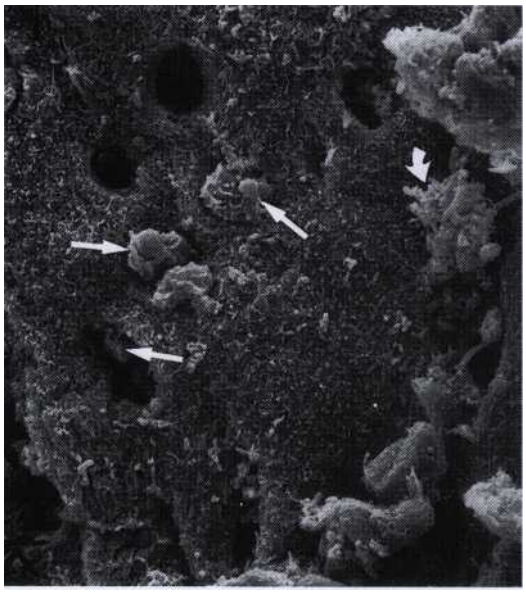

Fig. 15-3 Scanning electron microscope view of periodontal pocket wall. Several leukocytes are emerging (straight arrows), **some partially covered by bacteria** *(curved* arrow). **Empty holes correspond to tunnels through which leukocytes have emerged.**

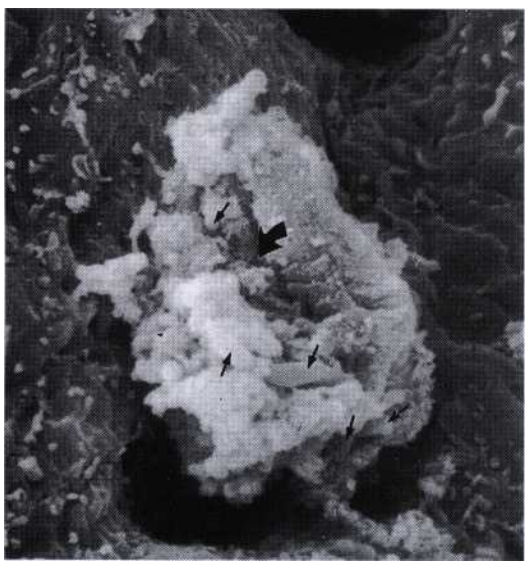

Fig. 15-4 Scanning electron microscope view at higher magnification than Fig. 15-3. A leukocyte emerging from the pocket wall is covered with bacteria (small arrows). **The large curved arrow points to a phagosomal vacuole through which bacteria are being engulfed.**

Leukocytes are attracted by different plaque bacteria[54,130] but can also be found in the dentogingival region of germ-free adult animals.[1-5,103] Leukocytes were reported in the gingival sulcus in nonmechanically irritated (resting) healthy gingiva, indicating that their migration may be independent of an increase in vascular permeability.[,,,] The majority of these cells are viable and have been found to have phagocytic and killing capacity.[62,92,98] Therefore they constitute a major protective mechanism against the extension of plaque into the gingival sulcus.

Leukocytes are also found in saliva (see following discussion). The main port of entry of leukocytes into the oral cavity is the gingival sulcus.[107]

SALIVA

Salivary secretions are protective in nature because they maintain the oral tissues in a physiologic state (Table 15-3). Saliva exerts a major influence on plaque by mechanically cleansing the exposed oral surfaces, by buffering acids produced by bacteria, and by controlling bacterial activity.

Antibacterial Factors

Saliva contains numerous inorganic and organic factors that influence bacteria and their products in the oral environment. Inorganic factors include ions and gases, bicarbonate, sodium, potassium, phosphates, calcium, fluorides, ammonium, and carbon dioxide. Organic factors include lysozyme, lactoferrin, myeloperoxidase, lactoperoxidase, and agglutinins such as glycoproteins, mucins, ß2-macroglobulins, fibronectins,[123] and antibodies.

TABLE 15-3

Role of Saliva in Oral Health

Function	Salivary Components	Probable Mechanism
Lubrication	Glycoproteins, mucoids	Coating similar to gastric mucin
Physical protection	Glycoproteins, mucoids	Coating similar to gastric mucin
Cleansing	Physical flow	Clearance of debris and bacteria
Buffering	Bicarbonate and phosphate	Antacids
Tooth integrity maintenance	Minerals	Maturation, remineralization
	Glycoprotein pellicle	Mechanical protection
Antibacterial action	IgA	Control of bacterial colonization
	Lysozyme	Breaks bacterial cell walls
	Lactoperoxidase	Oxidation of susceptible bacteria

Lysozyme is a hydrolytic enzyme that cleaves the linkage between structural components of the glycopeptide muramic acid-containing region of the cell wall of certain bacteria in vitro. Lysozyme works on both gram-negative and gram-positive organisms"; Veillonella species and **Actinobacillus actinomycetemcomitans are some of their targets.** It probably repels certain transient bacterial invaders of the mouth.53

The lactoperoxidase-thiocyanate system in saliva has been shown to be bactericidal to some strains of Lactobacillus and Streptococcus84,102 by preventing the accumulation of lysine and glutamic acid, both of which are essential for bacterial growth. Another antibacterial finding includes lactoferrin, which is effective against Actinobacillus species."

Myeloperoxidase, an enzyme similar to salivary peroxidase, is released by leukocytes and is bactericidal for Actinobacillus" but has the added effect of inhibiting the attachment of Actinomyces strains to hydroxyapatite. 16

Salivary Antibodies

Saliva, like GCF, contains antibodies that are reactive with indigenous oral bacterial species. Although immunoglobulins G (IgG) and M (IgM) are present, the preponderant immunoglobulin found in saliva is immunoglobulin A (IgA). However, IgG is more prevalent in GCE.121 Major and minor salivary glands contribute all the secretory IgA (sIgA) and lesser amounts of IgG and IgM. GCF contributes most of the IgG, complement, and PMN that, in conjunction with IgG or IgM, inactivate or opsonize bacteria.

Salivary antibodies appear to be synthesized locally, for they react with strains of bacteria indigenous to the mouth but not with organisms characteristic of the intestinal tract .36,38 Many bacteria found in saliva have been shown to be coated with IgA, and the bacterial deposits on teeth contain both IgA and IgG in quantities greater than 1% of their dry weight.37 It has been shown that IgA antibodies present in parotid saliva can inhibit the attachment of oral Streptococcus species to epithelial cells .13,128 Gibbons and colleagues 36-38 suggested that antibodies in secretions may impair the ability of bacteria to attach to mucosal or dental surfaces.

The enzymes normally found in the saliva are **derived from the salivary glands, bacteria, leukocytes, oral tissues, and ingested substances; the major enzyme is parotid amylase.** Certain salivary enzymes have been reported in increased concentrations in periodontal disease; these are hyaluronidase and lipase," ß-glucuronidase and chondroitin sulfatase," amino acid decarboxylases, 41 catalase, peroxidase, and collagenase. 60

Proteolytic enzymes in the saliva are generated by both the host and oral bacteria. These enzymes have been recognized as contributors to the initiation and progression of periodontal disease. 49,78 To combat these enzymes, saliva contains antiproteases that inhibit cysteine proteases such as cathepsinssl and antileucoproteases that inhibit elastase. 89 Another antiprotease identified as a tissue inhibitor of matrix metalloproteinase (TIMP) has been shown to inhibit the activity of collagen-degrading enzymes .z6

High-molecular-weight mucinous glycoproteins in saliva bind specifically to many plaque-forming bacteria. The glycoprotein-bacteria interactions facilitate bacterial accumulation on the exposed tooth surface. 33,36--38,130 The specificity of these interactions has been demonstrated. The interbacterial matrix of human plaque appears to contain polymers similar to salivary glycoproteins that may aid in maintaining the integrity of plaque. In addition, these glycoproteins selectively adsorb to the hydroxyapatite to make up part of the acquired pellicle. Other salivary glycoproteins inhibit the sorption of some bacteria to the tooth surface and to epithelial cells of the oral mucosa. This activity appears to be associated with the glycoproteins that possess blood group reactivity. 1,33,36,38,1z8 Another effect of mucin is the deletion of bacterial cells from the oral cavity by aggregation with mucin-rich films.

Glycoproteins and a glycolipid present on mammalian cell surfaces appear to serve as receptors for the attachment of some viruses and bacteria. Thus the close similarity between glycoproteins of salivary secretions and components of the epithelial cell surface suggests that the secretions can competitively inhibit antigen sorption and therefore may limit pathologic alterations.

Salivary Buffers and Coagulation Factors

The maintenance of physiologic hydrogen ion concentration (pH) at the mucosal epithelial cell surface and the tooth surface is an important function of salivary buffers. Their primary effect has been studied in relationship to dental caries. In saliva the most important salivary buffer is the bicarbonate-carbonic acid system."

Saliva also contains coagulation factors (factors VIII, IX, and X; plasma thromboplastin antecedent [PTA]; and the Hageman factor) that hasten blood coagulation and protect wounds from bacterial invasion.67 The presence of an active fibrinolytic enzyme has also been suggested.

Leukocytes

In addition to desquamated epithelial cells, the saliva contains all forms of leukocytes, of which the principal cells are PMNs. The number of PMNs varies from person to person at different times of the day and is increased in gingivitis. PMNs reach the oral cavity by migrating through the lining of the gingival sulcus. Living PMNs in saliva are sometimes referred to as orogranulocytes, and their rate of migration into the oral cavity is termed the orogranulocytic migratory rate. Some investigators think that the rate of migration is correlated with the severity of gingival inflammation and is therefore a reliable index for assessing gingivitis.117

Role in Periodontal Pathology

Saliva exerts a major influence on plaque initiation, maturation, and metabolism. Salivary flow and composition also influence calculus formation, periodontal disease, and caries. The removal of the salivary glands in experimental animals significantly increases the incidence of dental caries39 and periodontal disease46 and delays wound healing.'112

In humans, an increase in inflammatory gingival diseases, dental caries, and rapid tooth destruction associated with cervical or cemental caries is partially a consequence of **decreased salivary** gland secretion (xerostomia). Xerostomia may result from a variety of factors, among them sialolithiasis, sarcoidosis, Sjogren's syndrome, Mikulicz's disease, irradiation, and surgical removal of the salivary glands (see Chapters 38 and 39).

Gingival Inflammation

Fermin A. Carranza, John W. Rapley, and Susan Kinder Haake

CHAPTER

CHAPTER OUTLINE

STAGE I GINGIVITIS: THE INITIAL LESION
STAGE II GINGIVITIS: THE EARLY LESION
STAGE III GINGIVITIS: THE ESTABLISHED LESION
STAGE IV GINGIVITIS: THE ADVANCED LESION

athologic changes in gingivitis are associated with the presence of oral microorganisms in the gingival sulcus (see Chapter 8). These organisms are capable of synthesizing products (e.g., collagenase, hyaluronidase, protease, chondroitin sulfatase, or endotoxin) that cause damage to epithelial and connective tissue cells, as well as to intercellular constituents, such as collagen, ground substance, and glycocalyx (cell coat). The resultant widening of the spaces between the junctional epithelial cells during early gingivitis may permit injurious agents derived from bacteria, or bacteria themselves, to gain access to the connective tissue.[10-38,42]

Microbial products activate monocytes and macrophages to produce vasoactive substances such as prostaglandin E_2, interferon, tumor necrosis factor, or interleukin-1.[23,32]

The sequence of events in the development of gingivitis occurs in three different stages (Table 16-1).[34] Obviously, one stage evolves into the next, with no clear-cut dividing lines.

STAGE I GINGIVITIS: THE INITIAL LESION

The first manifestations of gingival inflammation are vascular changes consisting essentially of dilation of capillaries and increased blood flow. These initial inflammatory changes occur in response to microbial activation of resident leukocytes and the subsequent stimulation of endothelial cells. Clinically, this initial response of the gingiva to bacterial plaque (subclinical gingivitis[25]) is not apparent.

Microscopically, some classic features of acute inflammation can be seen in the connective tissue beneath the junctional epithelium. Changes in blood vessel morphologic features (e.g., widening of small capillaries or venules) and adherence of neutrophils to vessel walls (margination) occur within 1 week and sometimes as early as 2 days after plaque has been allowed to accumulate[18,38] (Fig. 16-1). Leukocytes, mainly polymorphonuclear neutrophils (PMNs), leave the capillaries by migrating through the walls (diapedesis, emigration)[27-37,46] (Fig. 16-2). They can be seen in increased quantities in the connective tissue, the junctional epithelium, and the gingival sulcus (Figs. 16-3 and 16-4).[2,3,24,31,35,39,40] Exudation of fluid from the gingival sulcus[18] and extravascular proteins are present.[20,21]

Subtle changes can also be detected in the junctional epithelium and perivascular connective tissue at this early stage. Lymphocytes soon begin to accumulate (see Fig. 16-2, D). The increase in the migration of leukocytes and their accumulation within the gingival sulcus may be correlated with an increase in the flow of gingival fluid into the sulcus.¢

The character and intensity of the host response determine whether this initial lesion resolves rapidly, with the restoration of the tissue to a normal state, or evolves into a chronic inflammatory lesion. If the latter occurs, an infiltrate of macrophages and lymphoid cells appears within a few days.

TABLE 16-1

Stages of Gingivitis

Stage	Time (Days)	Blood Vessels	junctional and Sulcular Epithelium	Predominant Immune Cells	Collagen	Clinical Findings
I. Initial Lesion	2-4	Vascular dilation Vasculitis	Infiltrated by PMNs	PMNs	Perivascular loss	Gingival fluid flow
II. Early Lesion	4-7	Vascular proliferation	Same as Stage I Rete peg formation Atrophic areas	Lymphocytes	Increased loss around infiltrate	Erythema Bleeding on probing
III. Established Lesion	14-21	Same as Stage II, plus blood stasis	Same as Stage II but more advanced	Plasma cells	Continued loss	Changes in color, size, texture, etc.

PMNs, **Polymorphonuclear neutrophils.**

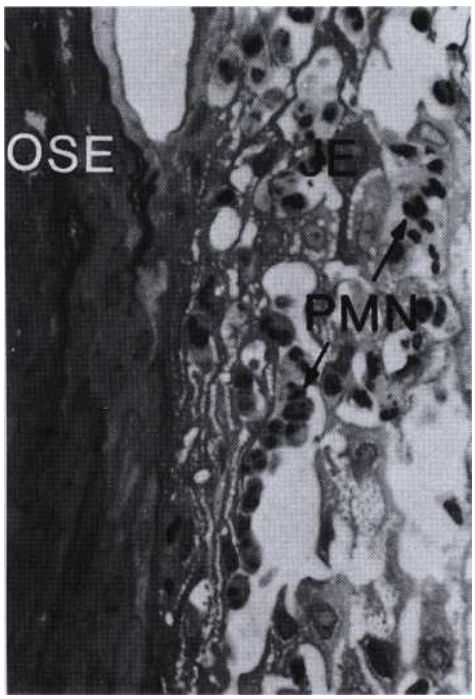

Fig. 16-1 **Human biopsy sample, experimental gingivitis. After 4 days of plaque accumulation, the blood vessels immediately adjacent to the junctional epithelium are distended and contain polymorphonuclear neutrophils (PMNs). Neutrophils have also migrated between the cells of the junctional epithelium. OSE, oral sulcular epithelium. (Magnification x500.) (from Payne WA, Page RC, Ogilvie AL, et al: Histopathologic features of the early and initial stages of experimental gingivitis in man. j Periodont Res 1975; 10:51.)**

STAGE II GINGIVITIS: THE EARLY LESION

As time goes on, clinical signs of erythema may appear, mainly owing to the proliferation of capillaries and increased formation of capillary loops between rete pegs or ridges. Bleeding on probing may also be evident.'

Microscopic examination of the gingiva reveals a leukocyte infiltration in the connective tissue beneath the junctional epithelium, consisting of mainly lymphocytes (75'%, with the majority of them T cells)",'' but also composed of some migrating neutrophils, as well as macrophages, plasma cells, and mast cells. All the changes seen in the initial lesion continue to intensify. [15,26,29,32,41] The junctional epithelium becomes densely infiltrated with neutrophils, as does the gingival sulcus, and the junctional epithelium may begin to show development of rete pegs or ridges.

There is an increase in the amount of collagen destruction' [1,26,41]; 70% of the collagen is destroyed around the cellular infiltrate. The main fiber groups affected appear to be the circular and dentogingival fiber assemblies. Alterations in blood vessel morphologic features and vascular bed patterns have also been described.[18-19]

PMNs that have left the blood vessels in response to chemotactic stimuli from plaque components travel to the epithelium, cross the basement lamina, and are found in the epithelium and are emerging in the pocket area (see Fig. 16-3). PMNs are attracted to bacteria and engulf them in the process of phagocytosis (Fig. 16-5). PMNs release their lysosomes in association with the ingestion of bacteria.[22] Fibroblasts show cytotoxic alterations [34] with a decreased capacity for collagen production.

STAGE III GINGIVITIS: THE ESTABLISHED LESION

In chronic gingivitis (stage III), the blood vessels become engorged and congested, venous return is impaired, and the blood flow becomes sluggish. The result is localized gingival anoxemia, which superimposes a somewhat bluish hue on the reddened gingiva. [17] Extravasation of

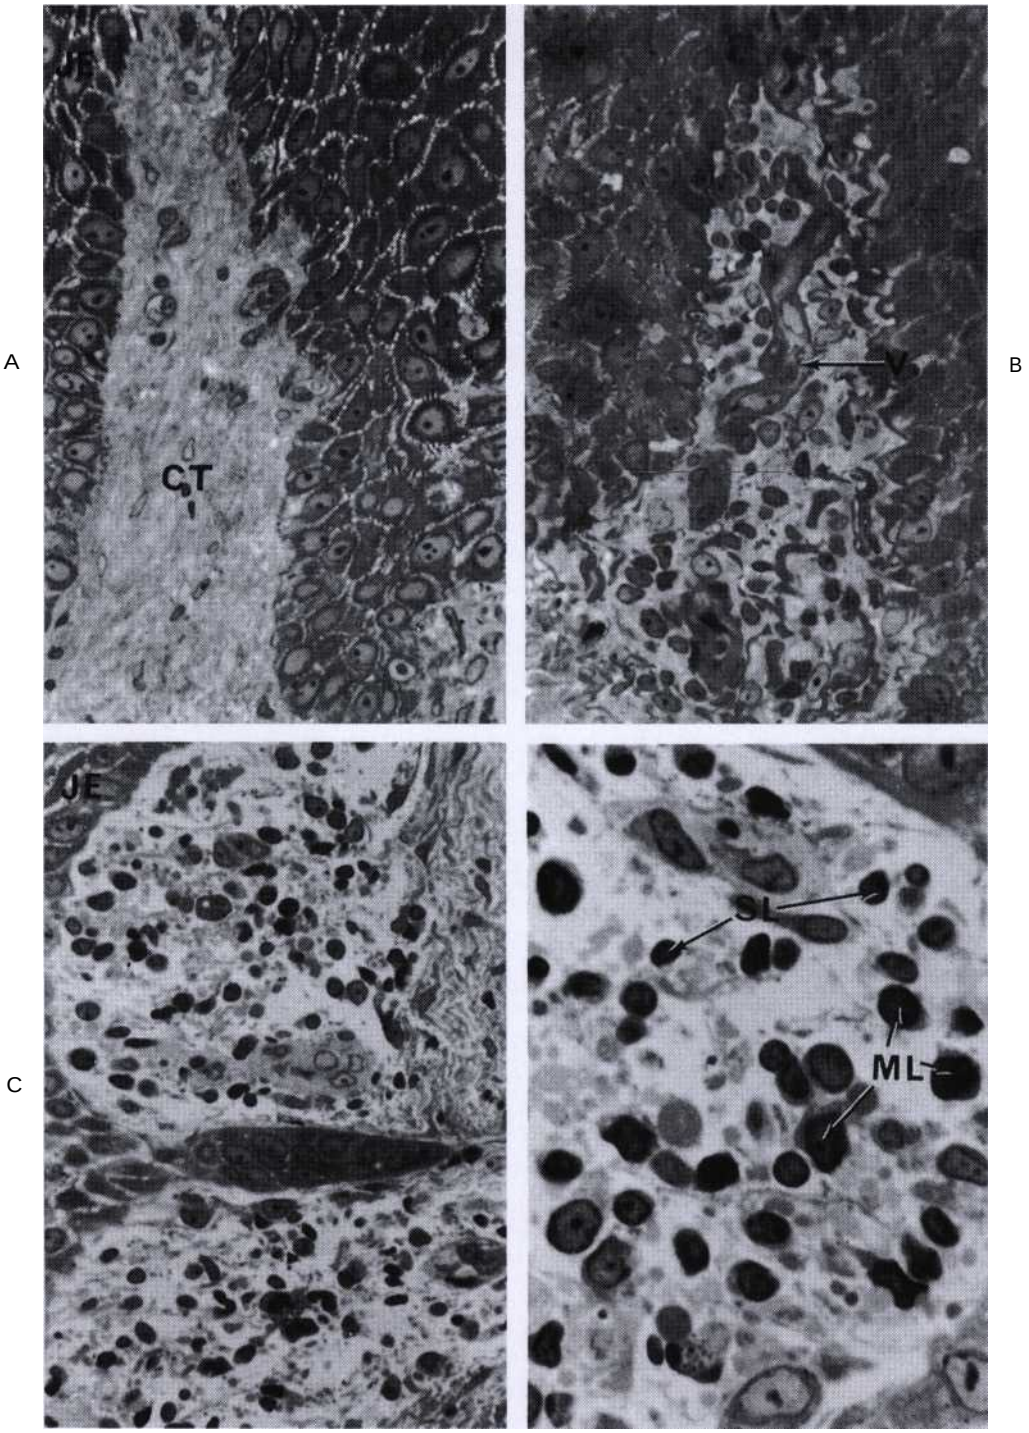

Fig. 16-2 Human biopsy, experimental gingivitis. A, Control biopsy specimen from a patient with good oral hygiene and no detectable plaque accumulation. The junctional epithelium is at the left. The connective tissue (CT) shows few cells other than fibroblasts, blood vessels, and a dense background of collagen fibers. (Magnification x 500.) B, Biopsy specimen taken after 8 days of plaque accumulation. The connective tissue is infiltrated with inflammatory cells, which displace the collagen fibers. A distended blood vessel (V) is seen in the center. (Magnification x 500.) C, After 8 days of plaque accumulation, the connective tissue next to the junctional epithelium at the base of the sulcus shows a mononuclear cell infiltrate and evidence of collagen degeneration (clear spaces around cellular infiltrate). (Magnification x 500.) D, The inflammatory cell infiltrate at higher magnification. After 8 days of plaque accumulation, numerous small- *(SL)* and medium-size *(ML)* lymphocytes are seen within the connective tissue. Most of the collagen fibers around these cells have disappeared, presumably as a result of enzymatic digestion. (Magnification x 1250.) (From Payne WA, Page RC, Ogilvie AL, et al: Histopathologic features of the initial and early stages of experimental gingivitis in man. J Periodont Res 1975; 10:51.)

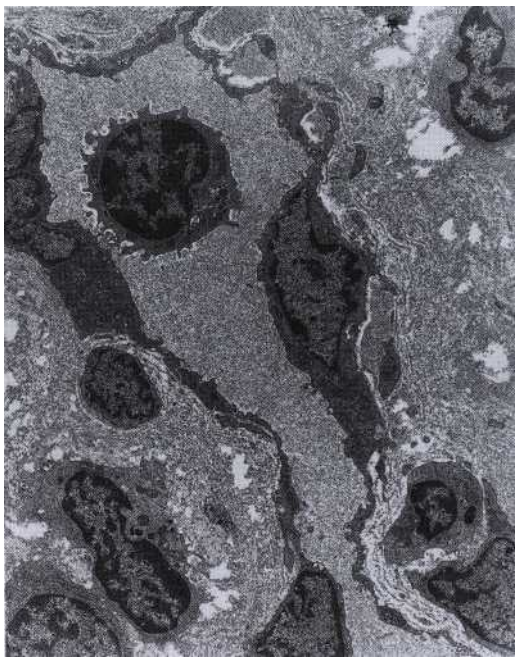

Fig. 16-4 Early human gingivitis lesion. Area of lamina propria subjacent to the crevicular epithelium showing a capillary with several extravascular lymphocytes and one lymphocyte within the lumen. The specimen also exhibits considerable loss of perivascular collagen density. (Magnification x2500.) (Courtesy Dr. Charles Cobb, Kansas City, Mo.)

red blood cells (RBCs) into the connective tissue and breakdown of hemoglobin into its component pigments can also deepen the color of the chronically inflamed gingiva. The established lesion can be described as moderately to severely inflamed gingiva.

In histologic sections, an intense, chronic inflammatory reaction is observed. Several detailed cytologic studies have been carried out on chronically inflamed gingiva.[12,14,15,33,40,43,45] A key feature that differentiates the established lesion is the increase in the number of plasma cells, which become the preponderant inflammatory cell type. Plasma cells invade the connective tissue not only immediately below the junctional epithelium, but also deep into the connective tissue, around blood vessels, and between bundles of collagen fibers.[15] The junctional epithelium reveals widened intercellular spaces filled with granular cellular debris, including lysosomes derived from disrupted neutrophils, lymphocytes, and monocytes (Fig. 16-6). The lysosomes contain acid hydrolases that can destroy tissue components. The junctional epithelium develops rete pegs or ridges that protrude into the connective tissue, and the basal lamina is destroyed in some areas. In the connective tissue, collagen fibers are destroyed around the infiltrate of intact and disrupted plasma cells, neutrophils, lymphocytes, monocytes, and mast cells (Fig. 16-7).

The predominance of plasma cells is a primary characteristic of the established lesion. However, several studies of human experimental gingivitis have failed to demonstrate plasma cell predominance in the affected connective tissues,[8,43] including one study of 6-month duration.[15] Increases in the proportions of plasma cells were evident with long-standing gingivitis,[15] but the time for the development of the classic "established lesion" may exceed 6 months.

An inverse relationship appears to exist between the number of intact collagen bundles and the number of inflammatory cells.[11] Collagenolytic activity is increased

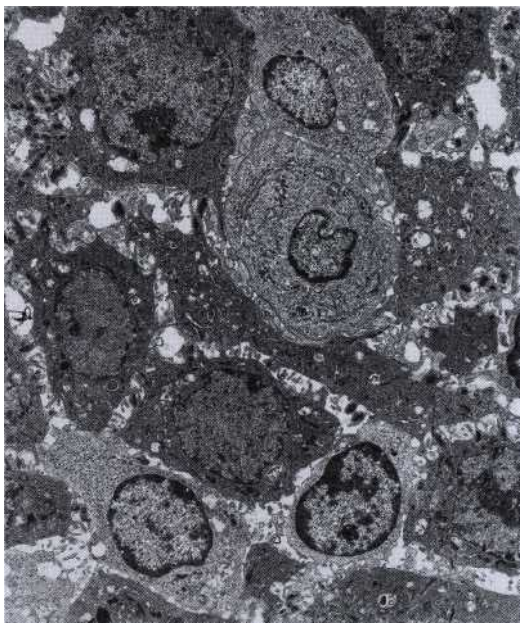

Fig. 16-6 Established gingivitis in a human subject. An area of crevicular epithelium exhibiting enlarged intercellular spaces with numerous microvilli and desmosomal junctions. Several lymphocytes, both small and large, are seen migrating through the epithelial layer. (Magnification x3000.)

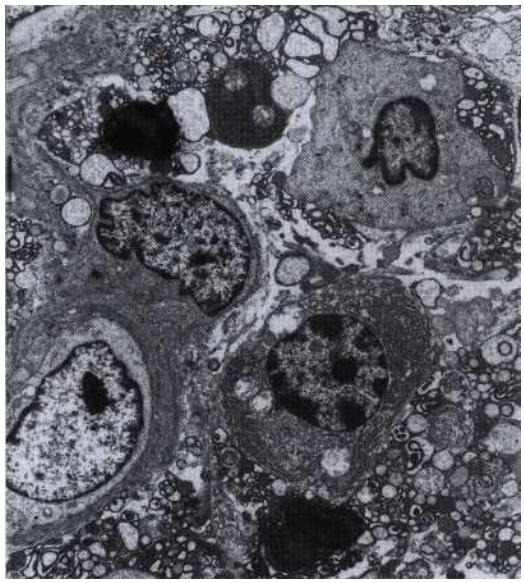

Fig. 16-7 Advanced gingivitis in a human subject. Specimen from the lamina propria exhibiting plasma cell degeneration with abundant cellular debris visible. (Magnification x3000.) (Courtesy Dr. Charles Cobb, Kansas City, Mo.)

in inflamed gingival tissue[16] by the enzyme collagenase. Collagenase is normally present in gingival tissuess and is produced by some oral bacteria and by PMNs.

Enzyme histochemistry studies have shown that chronically inflamed gingiva have elevated levels of acid and alkaline phosphatase[47] (3-glucuronidase, a-glucosidase, f3-galactosidase, esterases," aminopeptidase,[30,36] and cytochrome oxidase.[9] Neutral mucopolysaccharide levels are decreased," presumably as a result of degradation of the ground substance.

STAGE IV GINGIVITIS: THE ADVANCED LESION

Extension of the lesion into alveolar bone characterizes a fourth stage known as the *advanced lesion"* or *phase of periodontal breakdown."* This is described in detail in Chapters 22 and 23.

Clinical Features of Gingivitis

Fermin A. Carranza and John W. Rapley

CHAPTER OUTLINE

COURSE AND DURATION
DISTRIBUTION
CLINICAL FINDINGS
- **Gingival Bleeding on Probing**
- **Gingival Bleeding Caused by Local Factors**
- **Color Changes in the Gingiva**
- **Color Changes Associated with Systemic Factors**
- **Changes in the Consistency of the Gingiva**
- **Changes in the Surface Texture of the Gingiva**
- **Changes in the Position of the Gingiva**
- **Changes in Gingival Contour**

COURSE AND DURATION

Acute gingivitis is of sudden onset and short duration and can be painful. A less severe phase of the acute condition has been termed subacute. Recurrent gingivitis reappears after having been eliminated by treatment or disappearing spontaneously. Chronic gingivitis is slow in onset and of long duration, and is painless, unless complicated by acute or subacute exacerbations. Chronic gingivitis is the type most commonly encountered (Fig. 17-1 and Color Fig. 17-1). Chronic gingivitis is a fluctuating disease in which inflammation persists or resolves and normal areas become inflamed. [14,15]

DISTRIBUTION

Localized gingivitis is confined to the gingiva of a single tooth or group of teeth while generalized gingivitis involves the entire mouth. Marginal gingivitis involves the gingival margin and may include a portion of the contiguous attached gingiva. Papillary gingivitis involves the interdental papillae and often extends into the adjacent portion of the gingival margin. Papillae are involved more frequently than the gingival margin, and the earliest signs of gingivitis often occur in the papillae. Diffuse gingivitis affects the gingival margin, the attached gingiva, and the interdental papillae.

The distribution of gingival disease in individual cases is described by combining the preceding terms as follows:

Localized marginal gingivitis is confined to one or more areas of the marginal gingiva (Fig. 17-2).

Localized diffuse gingivitis extends from the margin to the mucobuccal fold but is limited in area (Fig. 17-3; see Color Fig. 17-1, A).

Localized papillary gingivitis is confined to one or more interdental spaces in a limited area (Fig. 17-4; see Color Fig. 17-1, B).

Generalized marginal gingivitis involves the gingival margins in relation to all the teeth. The interdental papillae are usually affected in generalized marginal gingivitis (Fig. 17-5; see Color Fig. 17-1, *C.*

Generalized diffuse gingivitis involves the entire gingiva. The alveolar mucosa and attached gingiva are affected, so the mucogingival junction is sometimes obliterated (Fig. 17-6; Color Fig. 17-1, D). Systemic conditions can be involved in the cause of generalized diffuse gingivitis and should be evaluated if suspected as an etiologic co-factor.

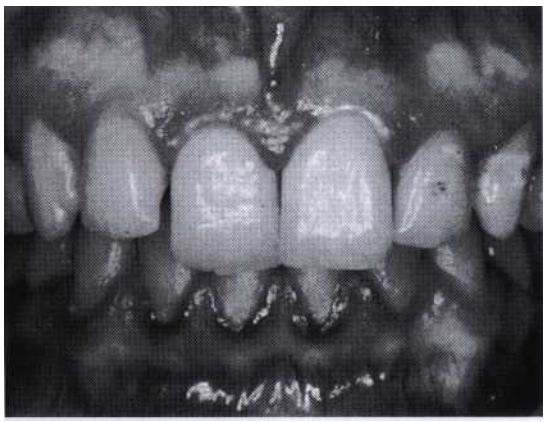

Fig. 17-1 Chronic gingivitis. The marginal and interdental gingivae are smooth, edematous, and discolored.

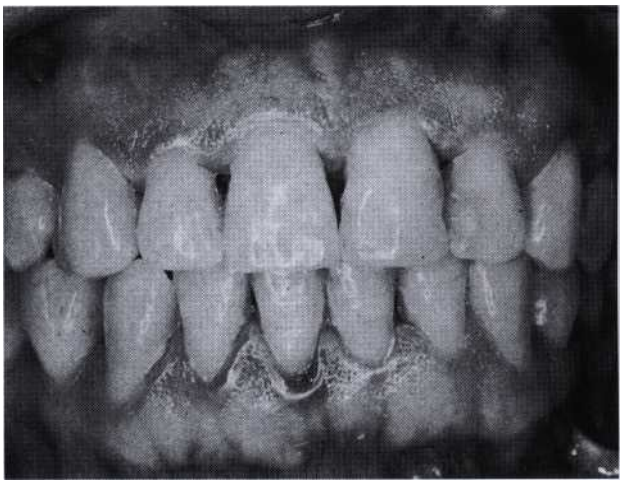

Fig. 17-2 Localized marginal gingivitis in the mandibular anterior region.

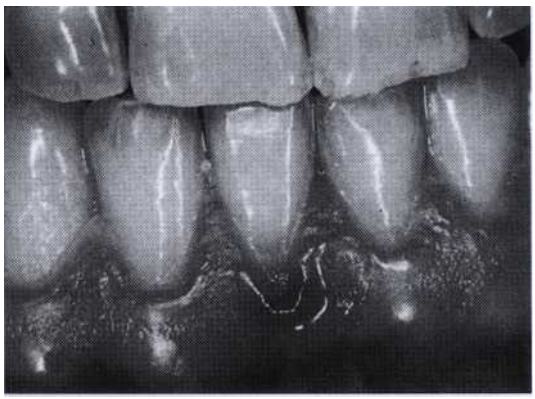

Fig. 17-3 Localized diffuse gingivitis involving both the marginal and the attached gingiva.

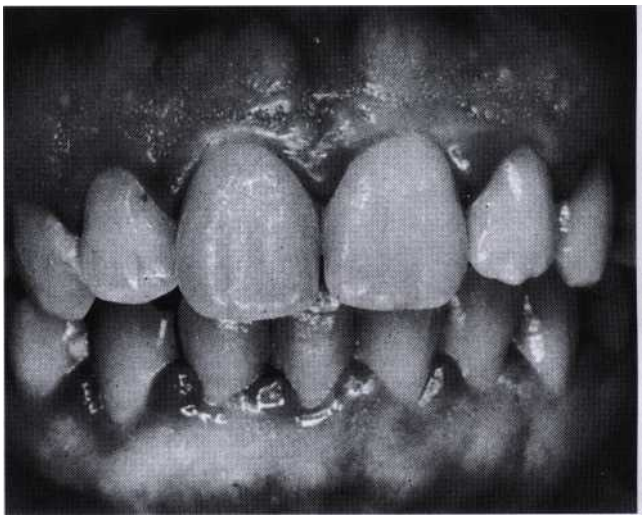

Fig. 17-4 Papillary gingivitis.

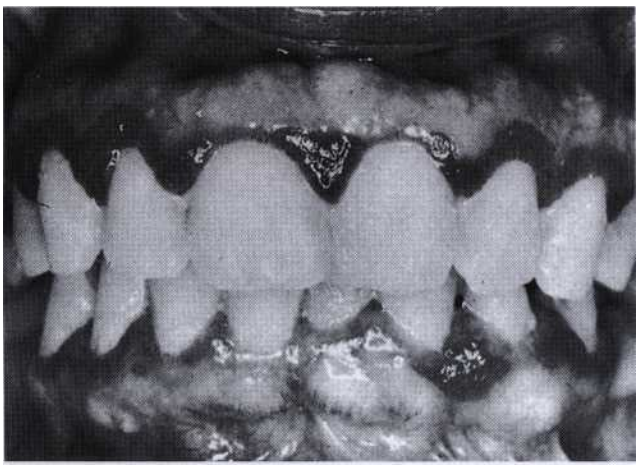

Fig. 17-5 Generalized marginal gingivitis. The interdental papillae are also involved.

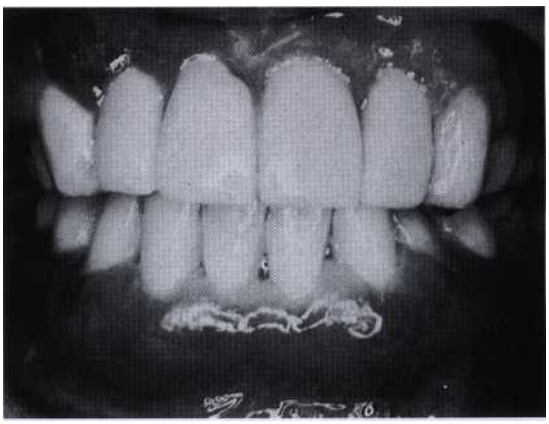

Fig. 17-6 Generalized diffuse gingivitis. The marginal, interdental, and attached gingivae are involved in chronic desquamative gingivitis.

CLINICAL FINDINGS

In evaluating the clinical features of gingivitis, it is necessary to be systematic. Attention should be focused on subtle tissue alterations, because these may be of diagnostic significance. A systematic clinical approach requires an orderly examination of the gingiva for color, contour, consistency, position, ease and severity of bleeding, and pain. These clinical characteristics and the microscopic changes responsible for each are discussed in this chapter.

Gingival Bleeding on Probing

The two earliest symptoms of gingival inflammation preceding established gingivitis, are (1) increased gingival crevicular fluid production rate and (2) bleeding from the gingival sulcus on gentle probing (Fig. 17-7; see Color Fig. 17-1, G,H). Gingival crevicular fluid is discussed in detail in Chapter 15.

Gingival bleeding varies in severity, duration, and the ease with which it is provoked. *Bleeding on probing is easily detectable clinically and therefore is of value for the early diagnosis and prevention of more advanced gingivitis.* It has been shown that bleeding on probing appears earlier than a change in color or other visual signs of inflammation[15,16,20]; in addition, the use of bleeding rather than color changes to diagnose early gingival inflammation is advantageous in that bleeding is a more objective sign that requires less subjective estimation by the examiner. Several gingival indices based on bleeding have been developed[1,6,26] and are described in Chapter 5. (For further considerations on probing, see Chapter 30.)

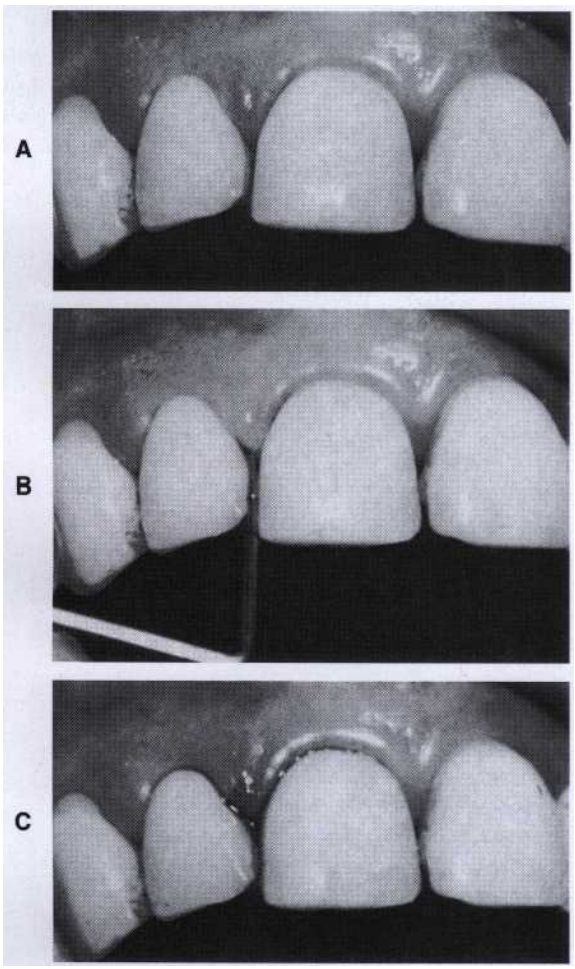

Fig. 17-7 Bleeding on probing. A, Mild gingivitis with slight edema. B, Introduction of the periodontal probe to the bottom of the gingival sulcus. C, Bleeding appears after a few seconds. (Courtesy Dr. Joseph Hsiou, Los Angeles, Calif.)

Gingival Bleeding Caused by Local Factors

Chronic and Recurrent Bleeding. The most common cause of abnormal gingival bleeding on probing is chronic inflammation." The bleeding is chronic or recurrent and is provoked by mechanical trauma (e.g., from toothbrushing, toothpicks, or food impaction) or by biting into solid foods such as apples.

In gingival inflammation, the following histopathologic alterations result in abnormal gingival bleeding: dilation and engorgement of the capillaries and thinning or ulceration of the sulcular epithelium (Fig. 17-9). Because the capillaries are engorged and closer to the surface and the thinned, degenerated epithelium is less protective, stimuli that are ordinarily innocuous cause rupture of the capillaries and gingival bleeding.

Sites that bleed on probing have a greater area of inflamed connective tissue (i.e., cell-rich, collagen-poor tissue) than do sites that do not bleed. In most cases, the cellular infiltrate of sites that bleed on probing is predominantly lymphocytic (a characteristic of stage II, or early gingivitis).[2,7,10]

The severity of the bleeding and the ease with which it is provoked depend on the intensity of the inflammation. After the vessels are damaged and rupture, a complex of mechanisms induce hemostasis.35 The vessel walls contract, and blood flow is diminished; blood platelets adhere to the edges of the tissue; and a fibrous clot is formed, which contracts and results in approximation of the edges of the injured area. Bleeding recurs, however, when the area is irritated.

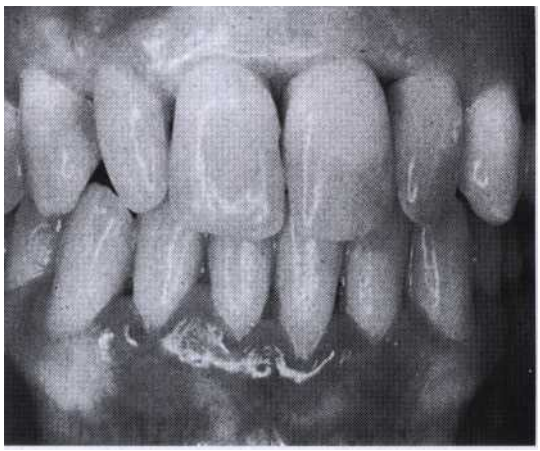

Fig. 17-8 Vertical discoloration of marginal and attached gingivae associated with periodontal pockets.

In cases of moderate or advanced periodontitis, the presence of bleeding on probing is considered a sign of active tissue destruction (see Chapter 22).

Acute Bleeding. Acute episodes of gingival bleeding are caused by injury or occur spontaneously in acute gingival disease. Laceration of the gingiva by toothbrush bristles during aggressive toothbrushing or by sharp pieces of hard food can cause gingival bleeding even in the absence of gingival disease. Gingival burns from hot foods or chemicals increase the ease of gingival bleeding.

Spontaneous bleeding or bleeding on slight provocation can occur in acute necrotizing ulcerative gingivitis. In this condition, engorged blood vessels in the inflamed connective tissue are exposed by ulceration of the necrotic surface epithelium.

Gingival Bleeding Associated with Systemic Changes. In some systemic disorders, gingival hemorrhage occurs spontaneously or after irritation and is excessive and difficult to control. These hemorrhagic diseases represent a wide variety of conditions that vary in etiologic factors and clinical manifestations. Such conditions have the common feature of a hemostatic mechanism failure and result in abnormal bleeding in the skin, internal organs, and other tissues, including the oral mucosa.

The hemorrhagic tendency may be due to failure of one or more of the hemostatic mechanisms.[33] Hemorrhagic disorders in which abnormal gingival bleeding is encountered include vascular abnormalities (vitamin C deficiency or allergy such as Schonlein-Henoch purpura), platelet disorders (thrombocytopenic purpura), hypoprothrombinemia (vitamin K deficiency), other coagulation defects (hemophilia, leukemia, Christmas disease), deficient platelet thromboplastic factor (PF3) resulting from uremia,[21] multiple myeloma,[3] and postrubella purpura.[14] Bleeding may follow the administration of excessive amounts of drugs such as salicylates and the administration of anticoagulants such as dicumarol and heparin. (Periodontal involvement in hematologic disorders is considered in Chapter 12.)

Color Changes in the Gingiva

Color Changes in Chronic Gingivitis. Change in color is an important clinical sign o f gingival disease. The normal gingival color is "coral pink" and is produced by the tissue's vascularity and modified by the overlying epithelial layers. For this reason, the gingiva becomes more red when there is an increase in vascularization or the degree of epithelial keratinization becomes reduced or disappears. The color becomes more pale when vascularization is reduced (in association with fibrosis of the corium) or epithelial keratinization increases.

Thus chronic inflammation intensifies the red or bluish red color, because of vascular proliferation and reduction of keratinization due to epithelial compression by the inflamed tissue. Additionally, venous stasis will contribute a bluish hue. The gingival color changes with increasing chronicity of the inflammatory process. The changes start in the interdental papillae and gingival margin and spread to the attached gingiva (see Fig. 17-1). Proper diagnosis and treatment require an understanding of the tissue changes that alter the color of the gingiva at the clinical level.

Color Changes in Acute Gingivitis. Color changes in acute gingival inflammation differ in both nature and distribution from those in chronic gingivitis. The color changes may be marginal, diffuse, or patchlike, depending on the underlying acute condition. In acute

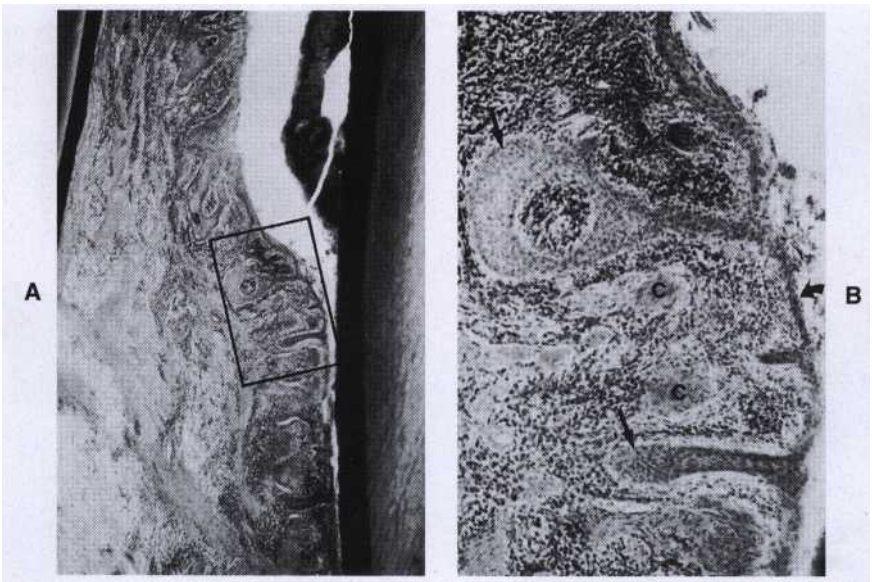

Fig. 17-9 A, Microscopic view of interdental space in a human autopsy specimen. B, Higher magnification of the area within the rectangle in A. Note the dense inflammatory infiltrate, the thinned epithelium (curved arrow), the extension of rete pegs (straight arrows), and the remnants of collagen fibers (C).

necrotizing ulcerative gingivitis the involvement is marginal; in herpetic gingivostomatitis, it is diffuse; and in acute reactions to chemical irritation, it is patchlike or diffuse.

Color changes vary with the intensity of the inflammation. Initially, there is an increasingly red erythema. If the condition does not worsen, this is the only color change until the gingiva reverts to normal. In severe acute inflammation, the red color gradually becomes a dull, whitish gray. The gray discoloration produced by tissue necrosis is demarcated from the adjacent gingiva by a thin, sharply defined erythematous zone. Detailed descriptions of the clinical and pathologic features of the various forms of acute gingivitis are found in Chapter 19.

Metallic Pigmentation. Heavy metals (bismuth, arsenic, mercury, lead, silver) absorbed systemically from therapeutic use or occupational or household environments may discolor the gingiva and other areas of the oral mucosa.[19] These changes are rare but still should be ruled out in suspected cases.

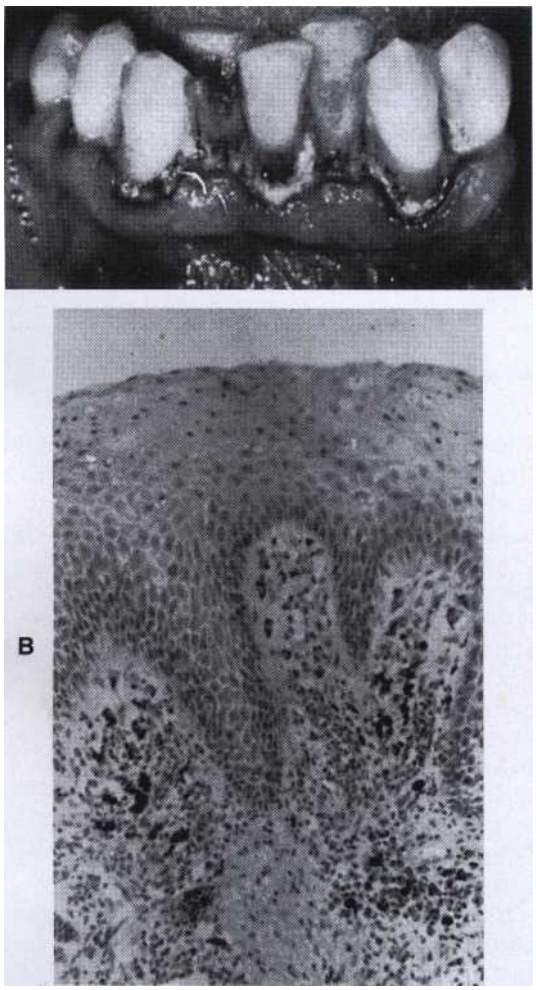

Fig. 17-10 Bismuth line. A, Linear discoloration of the gingiva in relation to local irritation in a patient receiving bismuth therapy. B, Biopsy specimen showing bismuth particles engulfed by monocytes/macrophages.

Typically, they produce a black or bluish line in the gingiva that follows the contour of the margin (Fig. 17-10). The pigmentation may also appear as isolated black blotches involving the interdental marginal and attached gingiva. This is different from tattooing produced by the accidental embedding of amalgam or other metal fragments[5] (Fig. 17-11).

Gingival pigmentation from systemically absorbed metals results from perivascular precipitation of metallic sulfides in the subepithelial connective tissue. Gingival pigmentation is not a result of systemic toxicity. It occurs only in areas of inflammation, where the increased permeability of irritated blood vessels permits seepage of the metal into the surrounding tissue. In addition to inflamed gingiva, mucosal areas irritated by biting or abnormal chewing habits (e.g., the inner surface of the lips, the cheek at the level of the occlusal line, and the lateral border of the tongue) are common pigmentation sites. Pigmentation can be eliminated by treating the inflammatory changes without necessarily discontinuing the metal-containing medication.

Color Changes Associated with Systemic Factors

Many systemic diseases may cause color changes in the oral mucosa, including the gingiva.[8] In general, these abnormal pigmentations are nonspecific in nature and should stimulate further diagnostic efforts or referral to the appropriate specialist.[52]

Endogenous oral pigmentations can be due to melanin, bilirubin, or iron.[11] Melanin oral pigmentations can be normal physiologic pigmentations and are commonly found in highly pigmented ethnic groups (see Chapter 1). Diseases that increase melanin pigmentation include the following:

Addison's disease: caused by adrenal dysfunction and produces isolated patches of discoloration varying from bluish black to brown

Peutz-feghers syndrome: produces intestinal polyposis and melanin pigmentation in the oral mucosa and lips

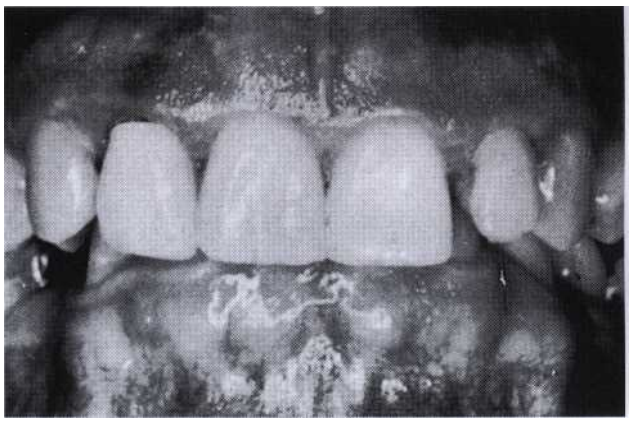

Fig. 17-11 Discoloration of the gingiva over the lateral incisor caused by embedded metal particles.

Albright's syndrome (polyostotic fibrous dysplasia) and von Recklinghausen's disease (neurofibromatosis: produce areas of oral melanin pigmentation

Skin and mucous membranes can also be stained by bile pigments. jaundice is best detected by examination of the sclera, but the oral mucosa may also acquire a yellowish color. The deposition of iron in hemochromatosis may produce a blue-gray pigmentation of the oral mucosa. Several endocrine and metabolic disturbances, including diabetes and pregnancy, may result in color changes. Blood dyscrasias such as anemia, polycythemia, and leukemia may also induce color changes.

Exogenous factors capable of producing color changes in the gingiva include atmospheric irritants such as coal and metal dust and coloring agents in food or lozenges. Tobacco causes hyperkeratosis of the gingiva and also may induce a significant increase in melanin pigmentation of the oral mucosa.[27] Localized bluish black areas of pigment are commonly due to amalgam implanted in the mucosa (see Fig. 17-11).

Changes in the Consistency of the Gingiva

Both chronic and acute inflammation produce changes in the normal firm, resilient consistency of the gingiva. As noted in the preceding discussion, in chronic gingivitis, both destructive (edematous) and reparative (fibrotic) changes coexist, and the consistency of the gingiva is determined by their relative predominance (Figs. 17-12 and 17-13). Table 17-1 summarizes the clinical alterations in the consistency of the gingiva and the microscopic changes that produce them.

Calcified Masses in the Gingiva. Calcified microscopic masses may be found in the gingiva.[4,25] They can occur alone or in groups and vary in size, location, shape, and structure. Such masses may be calcified material removed from the tooth and traumatically displaced into the gingiva during scaling,[25] root remnants, cementum fragments, or cementicles (Fig. 17-14). Chronic inflammation and fibrosis and occasionally foreign body giant cell activity occur in relation to these masses. They are sometimes enclosed in an osteoid-like matrix. Crystalline foreign bodies have also been described in the gingiva, but their origin has not been determined.[30]

Changes in the Surface Texture of the Gingiva

Loss of surface stippling is an early sign of gingivitis. In chronic inflammation the surface is either smooth and shiny or firm and nodular, depending on whether the dominant changes are exudative or fibrotic. Smooth surface texture is also produced by epithelial atrophy in atrophic gingivitis, and peeling of the surface occurs in chronic desquamative gingivitis. Hyperkeratosis results in a leathery texture, and drug-induced gingival overgrowth produces a nodular surface.

TABLE 17-1

Clinical and Histopathologic Changes in Gingival Consistency

Clinical Changes	Underlying Microscopic Features
Chronic Gingivitis	
1. Soggy puffiness that pits on pressure.	1. Infiltration by fluid and cells of inflammatory exudate.
2. Marked softness and friability, with ready fragmentation on exploration with probe and pinpoint surface areas of redness and desquamation.	2. Degeneration of connective tissue and epithelium associated with injurious substances that provoke the inflammation and inflammatory exudate; change in connective tissue-epithelium relationship, with the inflamed, engorged connective tissue expanding to within a few epithelial cells of surface; thinning of epithelium and degeneration associated with edema and leukocytic invasion, separated by areas in which rete pegs are elongated to connective tissue.
3. Firm, leathery consistency.	3. Fibrosis and epithelial proliferation associated with long-standing chronic inflammation.
Acute Gingivitis	
1. Diffuse puffiness and softening.	1. Diffuse edema of acute inflammatory origin; fatty infiltration in xanthomatosis.
2. Sloughing with grayish, flake-like particles of debris adhering to eroded surface.	2. Necrosis with formation of a pseudomembrane composed of bacteria, PMNs, and degenerated epithelial cells in a fibrinous meshwork.
3. Vesicle formation.	3. Inter- and intracellular edema with degeneration of nucleus and cytoplasm and rupture of cell wall.

PMN, Polymorphonuclear neutrophils.

Changes in the Position of the Gingiva

Actual and Apparent Positions of the Gingiva. Recession is exposure of the root surface by an apical shift in the position of the gingiva. To understand what is meant by recession, one must distinguish between the actual and apparent positions of the gingiva. The actual position is the level of the epithelial attachment on the tooth (Fig. 17-15), whereas the apparent position is the level of the crest of the gingival margin. *The severity of recession is determined by the actual position of the gingiva, not its apparent position.*

The two types of recession are visible, which is clinically observable, and hidden, which is covered by gingiva and can be measured only by inserting a probe to the level of epithelial attachment (see Fig. 17-15). For example, in periodontal disease, the inflamed pocket wall covers part of the denuded root; thus some of the recession is hidden, and some may be visible. The total amount of recession is the sum of the two.

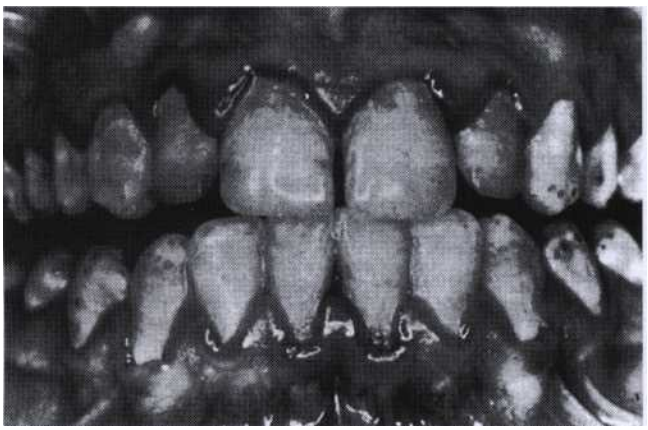

Fig. 17-12 Chronic gingivitis, showing swelling and discoloration produced when inflammatory exudate and tissue degeneration are the predominant microscopic changes. The gingiva is soft and friable and bleeds easily. Note the mottled teeth.

Fig. 17-13 Chronic gingivitis, showing a firm gingiva with a minutely nodular surface produced when fibrosis predominates in the inflammatory process.

Recession refers to the location of the gingiva, not its condition. Receded gingiva can be inflamed (Figs. 17-16 and 17-17) but may be normal except for their position (Fig. 17-18). Recession may be localized to one tooth (Fig. 17-19) or a group of teeth, or it may be generalized throughout the mouth (Fig. 17-20; see also Color Fig. 17-1, F).

ETIOLOGIC FACTORS OF RECESSION. Gingival recession increases with age; the incidence varies from 8% in children to 100% after the age of 50 years.[39] This has led some investigators to assume that recession may be a physiologic process related to aging. However, convincing evidence for a physiologic shift of the gingival

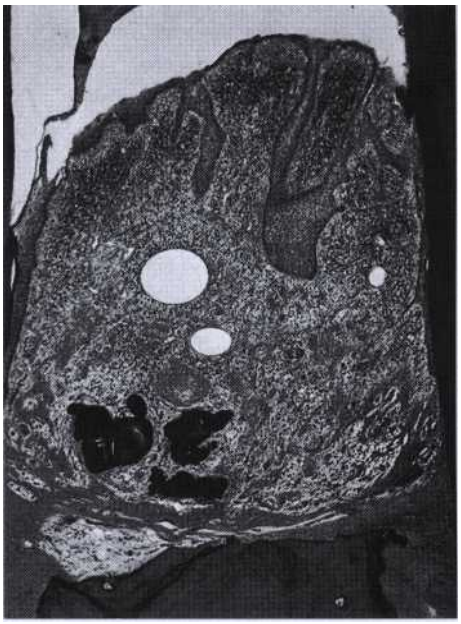

Fig. 17-14 Cementicles in the gingiva.

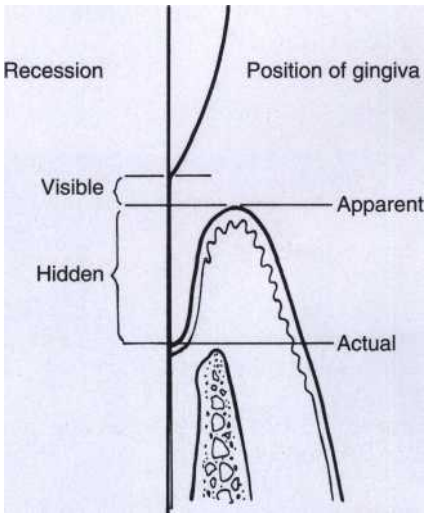

Fig. 17-15 Diagram illustrating the apparent and actual positions of the gingiva and visible and hidden recession.

attachment has never been presented.17 The gradual apical shift is most probably the result of the cumulative effect of minor pathologic involvement and/or repeated minor direct trauma to the gingiva, but in some populations without access to dental care, recession may be the result of increasing periodontal disease. [13,18]

The following etiologic factors have been implicated in gingival recession: faulty toothbrushing technique (gingival abrasion), tooth malposition, friction from soft tissues (gingival ablation) [,34] gingival inflammation, and abnormal frenum attachment. Trauma from occlusion has been suggested in the past, but its mechanism of action has never been demonstrated. Orthodontic movement in a labial direction in monkeys has been shown to result in loss of marginal bone and connective tissue attachment, as well as in gingival recession [.36]

Although toothbrushing is important for gingival health, faulty toothbrushing technique or brushing with hard bristles may cause gingival recession. Recession tends to be more frequent and severe in patients with comparatively healthy gingiva, little bacterial plaque, and good oral hygiene. [9,28,29]

Susceptibility to recession is influenced by the position of teeth in the arch, [38] the root-bone angle, and the mesiodistal curvature of the tooth surface [.24] On rotated, tilted, or facially displaced teeth, the bony plate is thinned or reduced in height. Pressure from mastication or moderate toothbrushing damages the unsupported gingiva and produces recession. The effect of the angle of the root in the bone on recession is often observed in the maxillary molar area (Fig. 17-21). If the lingual inclination of the palatal root is prominent or the buccal roots flare outward, then the bone in the cervical area is thinned or shortened, and recession results from repeated trauma of the thin marginal gingiva.

It has been noted that there may be a relationship between smoking and recession (see Chapter 14). The

mechanisms are multifactorial and may include reduction in gingival blood flow and alterations in the immune response but are not, as yet, conclusive.[11,31]

CLINICAL SIGNIFICANCE. Several aspects of gingival recession make it clinically significant. Exposed root surfaces are susceptible to caries. Abrasion or erosion of the cementum exposed by recession leaves an underlying dentinal surface that can be sensitive. Hyperemia of the pulp and associated symptoms may also result from excessive exposure of the root surface.[22] Interproximal recession creates oral hygiene problems and resulting plaque accumulation.

Changes in Gingival Contour

Changes in gingival contour are for the most part associated with gingival enlargement (see Chapter 18), but such changes may also occur in other conditions.

Of historical interest are the descriptions of indentations of the gingival margin referred to as Stillman's *clefts* (Fig. 17-22),[37] and the so-called McCall festoons (life preserver-shaped enlargement of the margin). They were attributed to trauma from occlusion, but this association

Fig. 17-22 Stillman's clefts in the gingiva.

was never proven; they represent peculiar inflammatory changes of the marginal gingiva.[4]

CHAPTER OUTLINE

INFLAMMATORY ENLARGEMENT
Chronic Inflammatory Enlargement
Acute Inflammatory Enlargement
DRUG-INDUCED GINGIVAL ENLARGEMENT
General Information
Anticonvulsants
Immunosuppressants
Calcium Channel Blockers
Idiopathic Gingival Enlargement
ENLARGEMENTS ASSOCIATED WITH SYSTEMIC DISEASES
Conditioned Enlargement
Systemic Diseases Causing Gingival Enlargement
NEOPLASTIC ENLARGEMENT (GINGIVAL TUMORS)
Benign Tumors of the Gingiva
Malignant Tumors of the Gingiva
FALSE ENLARGEMENT
Underlying Osseous Lesions
Underlying Dental Tissues

Increase in size of the gingiva is a common feature of gingival disease (Color Fig. 18-1). Accepted current terminology for this condition is gingival enlargement and gingival overgrowth. These are strictly clinical descriptive terms and avoid the erroneous pathologic connotations of terms used in the past such as hypertrophic gingivitis or gingival hyperplasia.

The many types of gingival enlargement can be classified according to etiologic factors and pathologic changes as follows:

I. Inflammatory enlargement
   A. Chronic
   B. Acute
II. Drug-induced enlargement
III. Enlargements associated with systemic diseases
   A. Conditioned enlargement
      1. Pregnancy
      2. Puberty
      3. Vitamin C deficiency
      4. Plasma cell gingivitis
      5. Nonspecific conditioned enlargement (granuloma pyogenicum)
   B. Systemic diseases causing gingival enlargement
      1. Leukemia
      2. Granulomatous diseases (Wegener's granulomatosis, sarcoidosis, and so on)
IV. Neoplastic enlargement (gingival tumors)
   A. Benign tumors
   B. Malignant tumors
V. False enlargement

Using the criteria of location and distribution, gingival enlargement is designated as follows:

Localized: Limited to the gingiva adjacent to a single tooth or group of teeth
Generalized: Involving the gingiva throughout the mouth
Marginal: Confined to the marginal gingiva
Papillary: Confined to the interdental papilla
Diffuse: Involving the marginal and attached gingivae and papillae
Discrete: An isolated sessile or pedunculated tumorlike enlargement

The degree of gingival enlargement can be scored as follows":

Grade 0: No signs of gingival enlargement
Grade I: Enlargement confined to interdental papilla
Grade II: Enlargement involves papilla and marginal gingiva
Grade III: Enlargement covers three quarters or more of the crown

INFLAMMATORY ENLARGEMENT

Gingival enlargement may result from chronic or acute inflammatory changes. The former is by far the more common. In addition, inflammatory enlargements commonly are a secondary complication to any of the other types of enlargement, creating a combined gingival enlargement. In these cases it is important to understand the double etiology and treat them adequately.

Chronic Inflammatory Enlargement

Clinical Features. Chronic inflammatory gingival enlargement originates as a slight ballooning of the interdental papilla and/or the marginal gingiva. In the early stages it produces a life preserver-shaped bulge around the involved teeth. This bulge can increase in size until it covers part of the crowns. The enlargement may be localized (Fig. *18-1)* or generalized (Fig. *18-2)* and progresses slowly and painlessly, unless it is complicated by acute infection or trauma.

Occasionally, chronic inflammatory gingival enlargement occurs as a discrete sessile or pedunculated mass resembling a tumor. It may be interproximal or on the marginal or attached gingiva (see Color Fig. *18-1, A).* The lesions are slow growing and usually painless. They may undergo spontaneous reduction in size, followed by exacerbation and continued enlargement. Painful ulceration sometimes occurs in the fold between the mass and the adjacent gingiva.

Histopathology. Chronic inflammatory gingival enlargements show the exudative and proliferative features of chronic inflammation (Fig. 18-3). Lesions that are clinically deep red or bluish red are soft and friable with a smooth, shiny surface, and they bleed easily. They also have a preponderance of inflammatory cells and fluid with vascular engorgement, new capillary formation, and associated degenerative changes. Lesions that are relatively firm, resilient, and pink have a greater fibrotic component with an abundance of fibroblasts and collagen fibers.

Etiology. Chronic inflammatory gingival enlargement is caused by prolonged exposure to dental plaque. Factors that favor plaque accumulation and retention54 include poor oral hygiene (Fig. *18-4),* as well as irritation by anatomic abnormalities and improper restorative and orthodontic appliances.

Gingival Changes Associated with Mouth Breathing. Gingivitis and gingival enlargement are often seen in mouth breathers.[14] The gingiva appears red and edematous with a diffuse surface shininess of the exposed area. The maxillary anterior region is the common site of such involvement. In many cases the altered gingiva is clearly demarcated from the adjacent unexposed normal gingiva (Fig. *18-5;* see Color Fig. *18-1, B).* The exact manner in which mouth breathing affects gingival changes has not been demonstrated. Its harmful effect is generally attributed to irritation from surface dehydration. However, comparable changes could not be produced by air drying the gingiva of experimental animals.[67]

Acute Inflammatory Enlargement

Gingival Abscess. A gingival abscess is a localized, painful, rapidly expanding lesion that is usually of sudden onset. It is generally limited to the marginal gingiva or interdental papilla. In its early stages it appears as a red swelling with a smooth, shiny surface. Within *24* to *48* hours, the lesion usually becomes fluctuant and pointed with a surface orifice from which a purulent exudate may be expressed. The adjacent teeth are often sensitive to percussion. If permitted to progress, the lesion generally ruptures spontaneously.

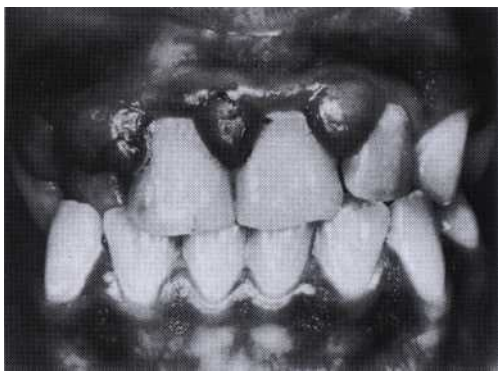

Fig. 18-1 Chronic inflammatory gingival enlargement localized to the anterior region.

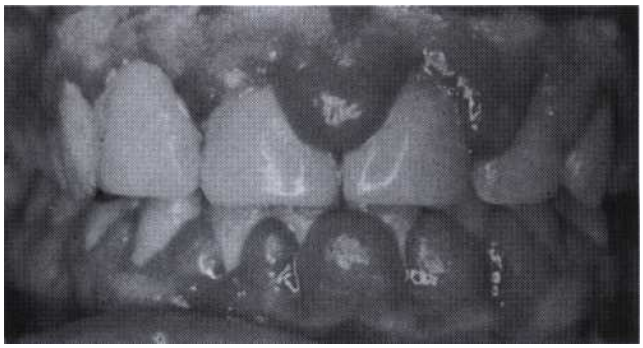

Fig. 18-2 Chronic inflammatory gingival enlargement.

HISTOPATHOLOGY. The gingival abscess consists of a purulent focus in the connective tissue, surrounded by a diffuse infiltration of polymorphonuclear leukocytes, edematous tissue, and vascular engorgement. The surface epithelium has varying degrees of intra- and extracellular edema, invasion by leukocytes, and sometimes ulceration.

ETIOLOGY. Acute inflammatory gingival enlargement results from bacteria carried deep into the tissues when a foreign substance such as a toothbrush bristle, a piece of apple core, or a lobster shell fragment is forcefully embedded into the gingiva. The lesion is confined to the gingiva and should not be confused with periodontal or lateral abscesses.

Periodontal (Lateral) Abscess. Periodontal abscesses generally produce enlargement of the gingiva, but they also involve the supporting periodontal tissues. For a detailed description of periodontal abscesses, see Chapter 22.

DRUG-INDUCED GINGIVAL ENLARGEMENT

Gingival enlargement is a well-known consequence of the administration of some anticonvulsants, immunosuppressants, and calcium channel blockers and may create speech, mastication, tooth eruption, and aesthetic problems.

Clinical and microscopic features of the enlargements caused by the different drugs are similar.23,108 These are presented first, followed by a description of the particular features of each drug.

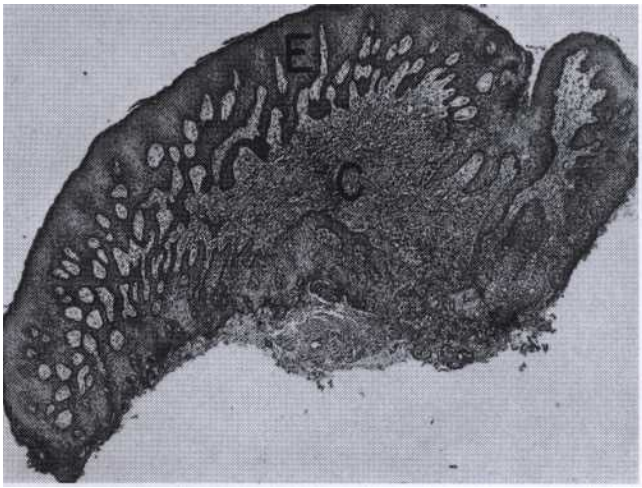

Fig. 18-3 Survey section of chronic inflammatory gingival enlargement showing the central connective tissue core (C) and thickened epithelium at the periphery (E). Note the ulceration of the epithelial surface at the lower border of the mass that was adjacent to the tooth surface.

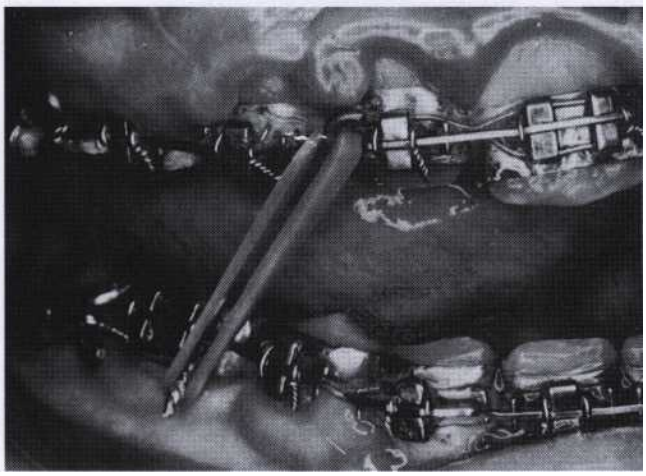

Fig. 18-4 Chronic inflammatory gingival enlargement associated with plaque accumulation around an orthodontic appliance.

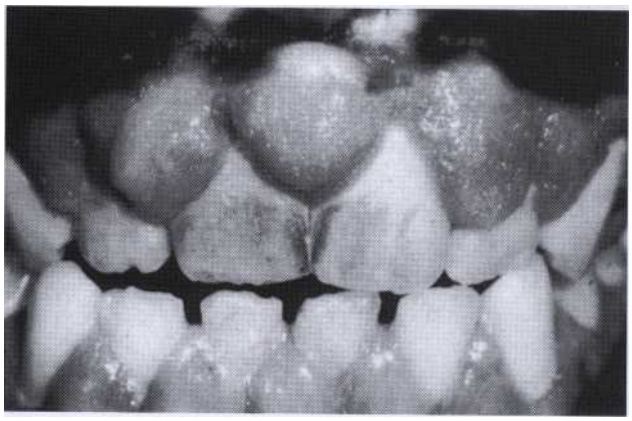

Fig. 18-6 Gingival enlargement associated with phenytoin therapy. Note the prominent papillary lesions and the firm, nodular surface. Black patches in attached gingiva are melanin-pigmented areas.

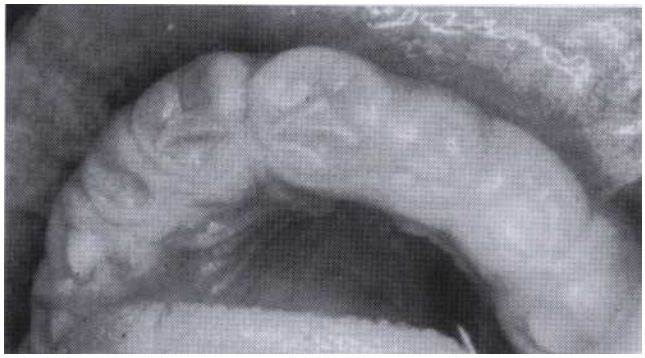

Fig. 18-7 Massive phenytoin-associated gingival enlargement in a 5-year-old patient. The teeth are almost completely covered by firm, dense tissue.

General Information

Clinical Features. The growth starts as a painless, beadlike enlargement of the interdental papilla and extends to the facial and lingual gingival margins (Fig. *18-6).* As the condition progresses, the marginal and papillary enlargements unite; they may develop into a massive tissue fold covering a considerable portion of the crowns, and they may interfere with occlusion (Figs. *18-7, 18-8;* Color Fig. *18-1, C, D, E).* When uncomplicated by inflammation, the lesion is mulberry shaped, firm, pale pink, and resilient, with a minutely lobulated surface and no tendency to bleed. The enlargement characteristically appears to project from beneath the gingival margin, from which it is separated by a linear groove.

The enlargement is usually generalized throughout the mouth but is more severe in the maxillary and mandibular anterior regions. It occurs in areas in which teeth are present, not in edentulous spaces, and the enlargement disappears in areas from which teeth are extracted. Hyperplasia of the mucosa in edentulous mouths has been reported but is rare.[32,33]

Some investigators believe that inflammation is a prerequisite for development of the enlargement, which therefore could be prevented by plaque removal and fastidious oral hygiene.[26,44,66,91,114] However, oral hygiene by means of toothbrushing[34] or the use of a chlorhexidine toothpaste[102] reduces the inflammation but does not lessen or prevent the overgrowth. Hassell and coworkers" have hypothesized that in noninflamed gingiva, fibroblasts are less active or even quiescent and do not respond to circulating phenytoin, whereas fibroblasts within inflamed tissue are in an active state as a result of the inflammatory mediators and the endogenous growth factors present.

A genetic predisposition is a suspected factor[50,96] in determining whether a person treated with phenytoin will develop gingival enlargement or not.

The enlargement is chronic and slowly increases in size. When surgically removed, it recurs. Spontaneous disappearance occurs within a few months after discontinuation of the drug (see Chapter 59).

Drug-induced enlargement may occur in mouths with little or no plaque and may be absent in mouths with abundant deposits. However, the presence of the enlargement makes plaque control difficult, often resulting in a secondary inflammatory process that complicates the gingival overgrowth caused by the drug. The resultant enlargement becomes then a combination of the increase in size caused by the drug and the complicating inflammation caused by bacteria. Secondary inflammatory changes not only add to the size of the lesion caused by the drug but also produce a red or bluish-red discoloration, obliterate the lobulated surface demarcations, and result in an increased tendency toward bleeding (see Fig. *18-12).*

Histopathology. The enlargement consists of a pronounced hyperplasia of the connective tissue and epithelium (Fig. 18-9). There is acanthosis of the epithelium, and elongated rete pegs extend deep into the connective tissue, which exhibits densely arranged collagen bundles with an increase in the number of fibroblasts and new blood vessels. An abundance of amorphous ground substance has also been reported.[78] Structural changes in the outer epithelial cell surface have been reported in cyclosporine enlargements.[4]

The enlargement begins as a hyperplasia of the connective tissue core of the marginal gingiva and increases by its proliferation and expansion beyond the crest of the gingival margin. Sometimes, particularly in cyclosporine enlargements, the connective tissue appears more highly vascularized and with foci of chronic inflammatory cells,[87] particularly plasma cells.[75]

The "mature" phenytoin enlargement has a fibroblast-to-collagen ratio equal to that of normal gingiva from normal individuals, suggesting that at some point in the development of the lesion there must have been an abnormally high fibroblastic proliferation.[51] Oxytalan fibers are numerous beneath the ep-

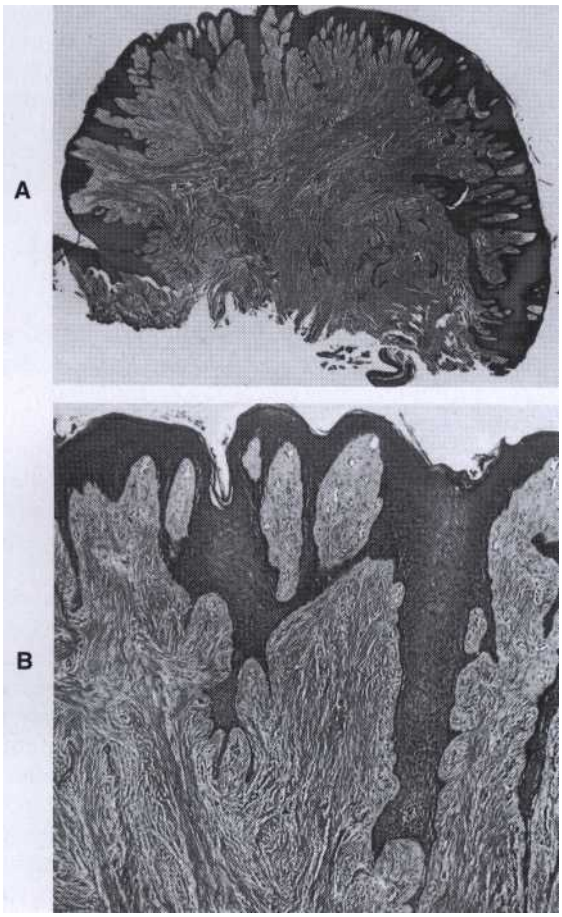

Fig. 18-8 Gingival enlargement associated with phenytoin therapy. A, Survey section showing bulbous gingival enlargement. B, Detailed view showing hyperplasia and acanthosis of the epithelium with extension of deep rete pegs into the connective tissue. The connective tissue is densely collagenous. There is little evidence of inflammation.

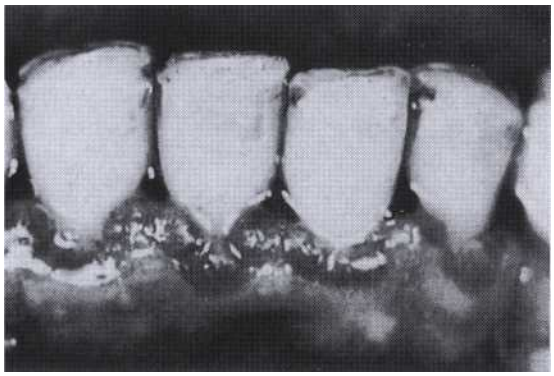

Fig. 18-9 Early recurrence after surgical removal of enlarged gingiva in a patient receiving phenytoin therapy.

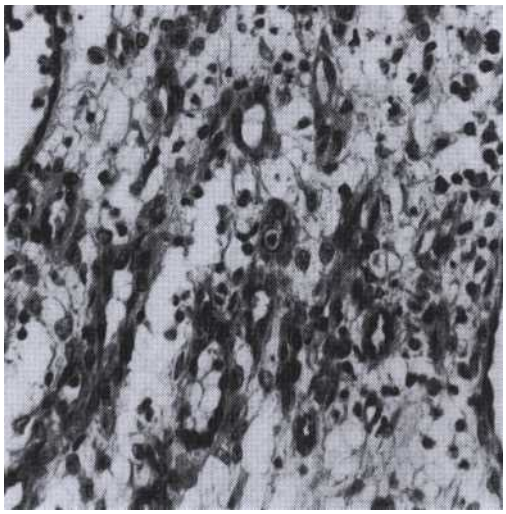

Fig. 18-10 Biopsy specimen of the recurrent gingival enlargement shown in Fig. 18-9. Note the abundance of new blood vessels.

ithelium and in areas of inflammation.[9] Inflammation is common along the sulcular surfaces of the gingiva.

Recurring enlargements appear as granulation tissue composed of numerous young capillaries and fibroblasts and irregularly arranged collagen fibrils with occasional lymphocytes (Figs. 18-10 and 18-11).

Anticonvulsants

The first drug-induced gingival enlargements reported were those produced by phenytoin (Dilantin). Dilantin is a hydantoin, introduced by Merritt and Putnam80 in 1938 for the treatment of all forms of epilepsy, except petit mal. Shortly thereafter, its relationship with gingival enlargement was reported.[41,65] Other hydantoins known to induce gingival enlargement are ethotoin (Paganone), and mephenytoin (Mesantoin).[45] Other anticonvulsants that have the same side effect are the succinimides (ethosuximide [Zerontin], methsuxinimide [Celontin]), and valproic acid (Depakene).[45]

Gingival enlargement occurs in about 50% of patients receiving the drug,[1o8] although different authors have reported incidences from 3% to 84.5%.[3,41,92] It occurs more often in younger patients.[6] Its occurrence and severity are not necessarily related to the dosage after a threshold level has been exceeded."' Phenytoin appears in the saliva. There is no consensus, however, on whether the severity of the overgrowth is related to the levels of phenytoin in plasma or saliva.[3.6,7,131] Some reports indicate a relation between the drug dosage and the degree of gingival overgrowth.[60,66]

Tissue culture experiments indicate that phenytoin stimulates proliferation of fibroblast-like cells'°[9] and epithelium.[110] Two analogues of phenytoin (1-allyl-5-phenylhydantoinate and 5-methyl-5-phenylhydantoinate) have a similar effect on fibroblast-like cells.[110] Fibroblasts from a phenytoin-induced gingival overgrowth show increased synthesis of sulfated glycosaminoglycans in vitro.[59] Phenytoin may induce a decrease in collagen degradation as a result of the production of an inactive fibroblastic collagenase[49] (Fig. 18-12).

Experimental attempts to induce gingival enlargement with phenytoin administration in laboratory animals have been successful only in the cat,[56] the ferret, and the *Macaca speciosa monkey*.[116] In experimental animals, phenytoin causes gingival enlargement that is independent of local inflammation.

In cats, one of the metabolic products of phenytoin is 5-(parahydroxyphenyl)-5-phenylhydantoin; administration of this metabolite to cats also induces gingival enlargement in some cases.[51] This led Hassell and Page[51] to hypothesize that gingival enlargement may result from the genetically determined ability or inability of the host to deal effectively with prolonged administration of phenytoin.

Systemic administration of phenytoin accelerates the healing of gingival wounds in nonepileptic humans[112] and increases the tensile strength of healing abdominal wounds in rats.[",'"] The administration of phenytoin may precipitate a megaloblastic anemia[76] and a folic-acid deficiency.[']

In conclusion, the pathogenesis of gingival enlargement induced by phenytoin is not known, but there is some evidence to link it to a direct effect on specific genetically predetermined subpopulations of fibroblasts, inactivation of collagenase, and plaque-induced inflammation.

Immunosuppressants

Cyclosporine is a potent immunosuppressive agent used to prevent organ transplant rejection and to treat several diseases of autoimmune origin.[24] Its exact mechanism of action is not well known, but it appears to selectively and reversibly inhibit helper T cells, which play a role in cellular and humoral immune responses. Cyclosporine A (Sandimmune, Neoral) is administered intravenously or by mouth, and dosages greater than 500 mg/day have been reported to induce gingival overgrowth.[29]

Cyclosporine-induced gingival enlargement is more vascularized than the phenytoin enlargement, occurs in approximately 30% of patients receiving the drug, is more frequent in children, and its magnitude appears to be related more to the plasma concentration than to the patient's periodontal status.[107] Gingival enlargement is greater in patients who are medicated with both cyclosporine and calcium channel-blocking drugs.[114,121,126]

The microscopic finding of many plasma cells plus the presence of an abundant amorphous extracellular substance has suggested that the enlargement is a hypersensitivity response to the cyclosporine.[78]

It has been reported that in experimental animals (rats) oral administration of cyclosporine also induces abundant formation of new cementum.[5]

In addition to gingival enlargement, cyclosporine induces other major side effects such as nephrotoxicity, hypertension, and hyperthricosis. Another immunosuppressive drug called *tacrolimus* has been used effectively and is also nephrotoxic, but it results in much less severe hypertension, hyperthricosis, and gingival overgrowth.[1,12,115]

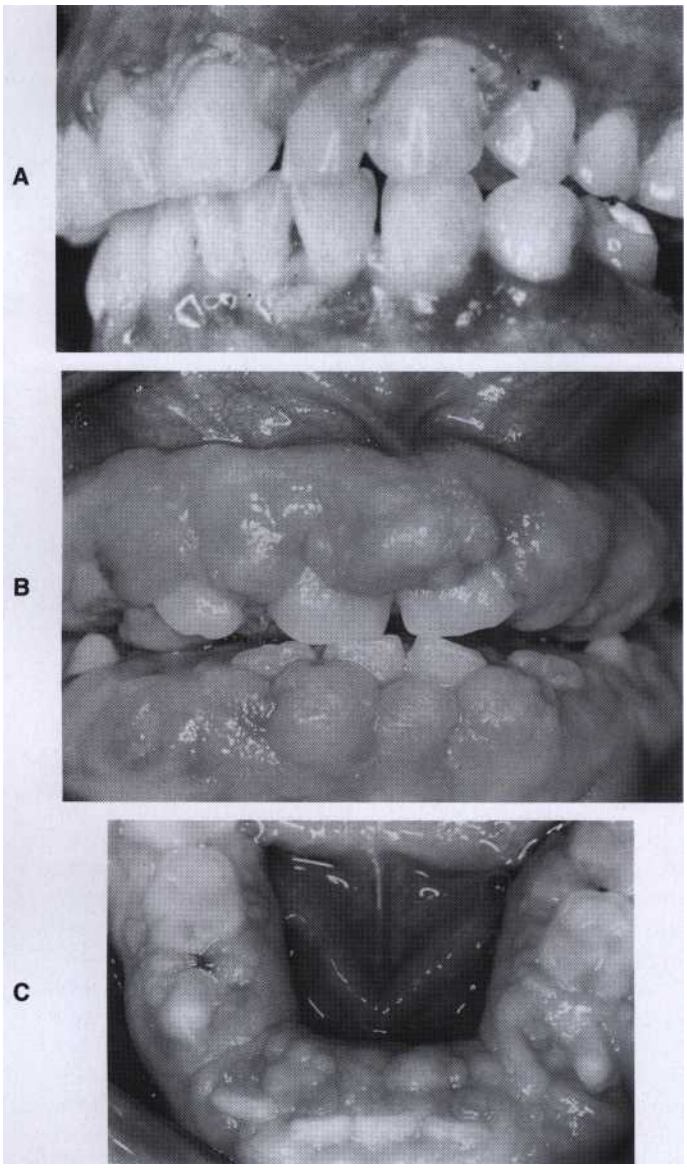

Fig. 18-11 Cyclosporine-associated gingival enlargement. A, Mild involvement located particularly on papillae between teeth No. 9 and 10, and 10 and 11. B, Advanced enlargement covering most of the crowns of the teeth. C, Occlusal view of case shown in B.

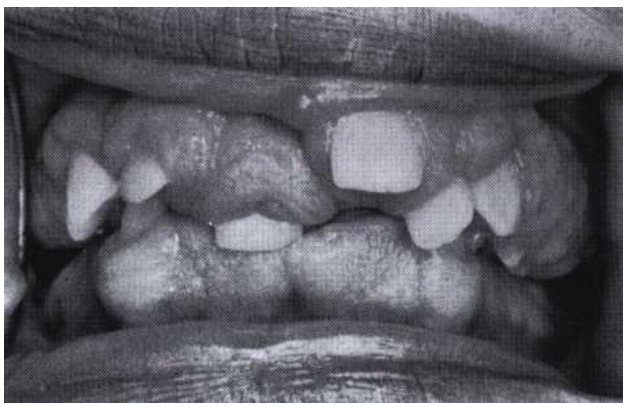

Fig. 18-12 Combined gingival enlargement in a patient receiving phenytoin therapy. The basic overgrowth is complicated by secondary inflammatory involvement. Note the edema and discoloration produced by the inflammation.

Calcium Channel Blockers

Calcium channel blockers are drugs developed for the treatment of cardiovascular conditions such as hypertension, angina pectoris, coronary artery spasms, and cardiac arrythmias.* They inhibit calcium ion influx across the cell membrane of heart and smooth muscle cells, blocking intracellular mobilization of calcium. This induces direct dilation of the coronary arteries and arterioles, improving oxygen supply to the heart muscle; it also reduces hypertension by dilating the peripheral vasculature.

Some of these drugs can induce gingival enlargement. Nifedipine, one of the most commonly used, [73,75,89] induces gingival enlargement in 20% of the cases.10 Diltiazem, felodipine, nitrendipine, and verapamil also induce gingival enlargement. [17, 30] The dihydropyridine derivative isradipidine can in some cases replace nifedipine and does not induce gingival overgrowth.130

Nifedipine is also used with cyclosporine in kidney transplant recipients, and the combined use of both drugs induces larger overgrowths. [16] Nifedipine gingival enlargement has been induced experimentally in rats, where it appears to be dose dependent[38]; in humans, however, this dose dependency is not clear.

Idiopathic Gingival Enlargement

Idiopathic gingival fibromatosis is a rare condition of undetermined cause. It has been designated by such terms as *gingivomatosis, elephantiasis, idiopathic fibromatosis, hereditary gingival hyperplasia,* and *congenital familial fibromatosis.*

* **These drugs are** [41] the *dihydroxypiridine derivatives* **(amlodipine [Lotrel, Norvasc], felodipine [Plendil], nicardipine [Cardene], Nifedipine [Adalat, Procardia]); the** *benzothiazine derivatives* **(diltiazem [Cardizem, Dilacor XR, Tlazac]); and the** *phenylalkylamine derivatives* **(verapamil [Calan, Isoptin, Verelan, Covera HS]) induced experimentally in rats where it appears to be dose dependent** [38]; **in humans, however, the dose dependency is not clear.**

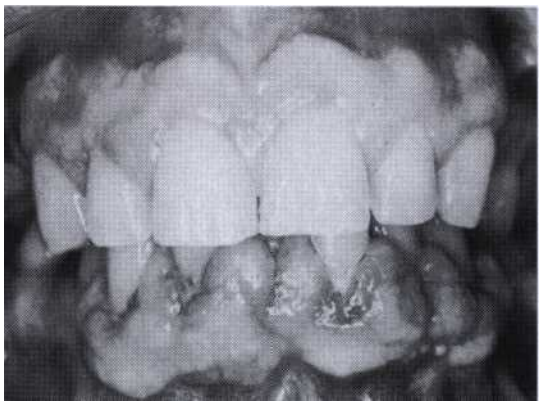

Fig. 18-13 Idiopathic hyperplastic gingival enlargement. The gingiva is firm, with a nodular, pebbled surface. The hyperplastic gingiva deflects the erupting teeth from proper alignment. (Courtesy Dr. E. I. Ball.)

Clinical Features. The enlargement affects the attached gingiva, as well as the gingival margin and interdental papillae, in contrast to phenytoin-induced overgrowth, which is often limited to the gingival margin and interdental papillae. The facial and lingual surfaces of the mandible and maxilla are generally affected, but the involvement may be limited to either jaw. The enlarged gingiva is pink, firm, and almost leathery in consistency and has a characteristic minutely pebbled surface (Fig. 18-12). In severe cases the teeth are almost completely covered, and the enlargement projects into the oral. vestibule (see Color Fig. 18-1, F). The jaws appear distorted because of the bulbous enlargement of the gingiva. Secondary inflammatory changes are common at the gingival margin.

Histopathology. There is a bulbous increase in the amount of connective tissue that is relatively avascular and consists of densely arranged collagen bundles and numerous fibroblasts. The surface epithelium is thickened and acanthotic with elongated rete pegs.

Etiology. The cause is unknown, and thus the condition is designated as idiopathic. Some cases have a hereditary basis,[35.134,136] but the genetic mechanisms involved are not well understood. A study of several families found the mode of inheritance to be autosomal recessive in some cases and autosomal dominant in others.[58,96] In some families the gingival enlargement may be linked to retardation of physical development.[64] The enlargement usually begins with the eruption of the primary or secondary dentition and may regress after extraction, suggesting the possibility that the teeth (or the plaque attached to them) may be initiating factors. The presence of bacterial plaque is a complicating factor. Gingival enlargement has been described in tuberous sclerosis, which is an inherited condition characterized by a triad of epilepsy, mental deficiency, and cutaneous angiofibromas.[119, 124]

ENLARGEMENTS ASSOCIATED WITH SYSTEMIC DISEASES

Many systemic diseases can develop oral manifestations that may include gingival enlargement. These diseases and/or conditions can affect the periodontium by two different mechanisms:

1. Magnification of an existing inflammation initiated by dental plaque. This group of diseases, discussed below under "Conditioned Enlargements," includes some hormonal conditions (e.g., pregnancy and puberty), nutritional diseases such as vitamin C deficiency, and some cases in which the systemic influence is not identified (nonspecific conditioned enlargement).
2. Manifestation of the systemic disease independently of the inflammatory status of the gingiva. This group will be described under "Systemic Diseases Causing Gingival Enlargement" and "Neoplastic Enlargement (Gingival Tumors)."

Conditioned Enlargement

Conditioned enlargement occurs when the systemic condition of the patient exaggerates or distorts the usual gingival response to dental plaque. The specific manner in which the clinical picture of conditioned gingival enlargement differs from that of chronic gingivitis depends on the nature of the modifying systemic influence. *Bacterial plaque is necessary for the initiation of this type of enlargement.* However, plaque is not the sole determinant of the nature of the clinical features.

The three types of conditioned gingival enlargement are hormonal (pregnancy, puberty), nutritional (associated with vitamin C deficiency), and allergic. Nonspecific conditioned enlargement is also seen.

Enlargement in Pregnancy. Pregnancy gingival enlargement may be marginal and generalized or may occur as single or multiple tumor-like masses (see Chapters 12 and 37).

During pregnancy there is an increase in levels of both progesterone and estrogen, which, by the end of the third trimester, reach levels 10 and 30 times the levels during the menstrual cycle, respectively.2 These hormonal changes induce changes in vascular permeability leading to gingival edema and an increased inflammatory response to dental plaque. The subgingival microbiota may also undergo changes, including an increase in *Prevotella intermedia*.[69,95]

MARGINAL ENLARGEMENT. Marginal gingival enlargement during pregnancy results from the aggravation of previous inflammation, and its incidence has been reported as 10%z[3] and 70%.[135] The gingival enlargement does not occur without the presence of bacterial plaque.

Clinical Features. The clinical picture varies considerably. The enlargement is usually generalized and tends to be more prominent interproximally than on the facial and lingual surfaces. The enlarged gingiva is bright red or magenta, soft, and friable and has a smooth, shiny surface. Bleeding occurs spontaneously or on slight provocation.

TUMORLIKE GINGIVAL ENLARGEMENT. The so-called pregnancy tumor is not a neoplasm; it is an inflammatory response to bacterial plaque and is modified by the patient's condition. It usually appears after the third month of pregnancy but may occur earlier. The reported incidence is *1.8%* to 5%."

Clinical Features. The lesion appears as a discrete, mushroomlike, flattened spherical mass that protrudes from the gingival margin or more commonly from the interproximal space and is attached by a sessile or pedunculated base (Fig. 18-14). It tends to expand laterally, and pressure from the tongue and the cheek perpetuates its flattened appearance. Generally dusky red or magenta, it has a smooth, glistening surface that often exhibits numerous deep red, pinpoint markings. It is a superficial lesion and ordinarily does not invade the underlying bone. The consistency varies; the mass is usually semifirm, but it may have various degrees of softness and friability. It is usually painless unless its size and shape foster accumulation of debris under its margin or interfere with occlusion, in which case, painful ulceration may occur.

HISTOPATHOLOGY. Gingival enlargement in pregnancy is called *angiogranuloma*. Both marginal and tumorlike enlargements consist of a central mass of connective tissue, with numerous diffusely arranged, newly formed, and engorged capillaries lined by cuboid endothelial cells (Fig. 18-15) and a moderately fibrous stroma with varying degrees of edema and chronic inflammatory infiltrate. The stratified squamous epithelium is thickened, with prominent rete pegs and some degree of intracellular and extracellular edema, prominent intercellular bridges, and leukocytic infiltration.

Although the microscopic findings are characteristic of gingival enlargement in pregnancy, they are not pathognomonic because they cannot be used to differentiate pregnant and nonpregnant patients.[77]

Most gingival disease during pregnancy can be prevented by the removal of plaque and calculus, as well as the institution of fastidious oral hygiene at the outset. In pregnancy, treatment of the gingiva that is limited to the removal of tissue without complete elimination of local irritants is followed by recurrence of gingival enlarge-

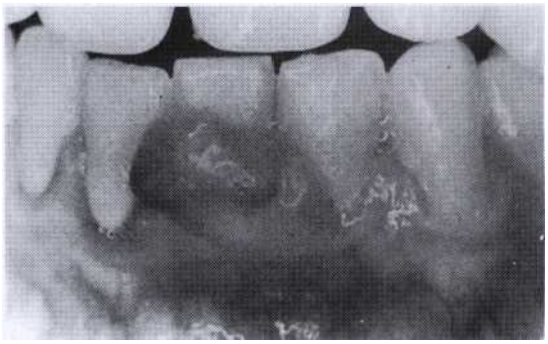

Fig. 18-14 Conditioned gingival enlargement in pregnancy.

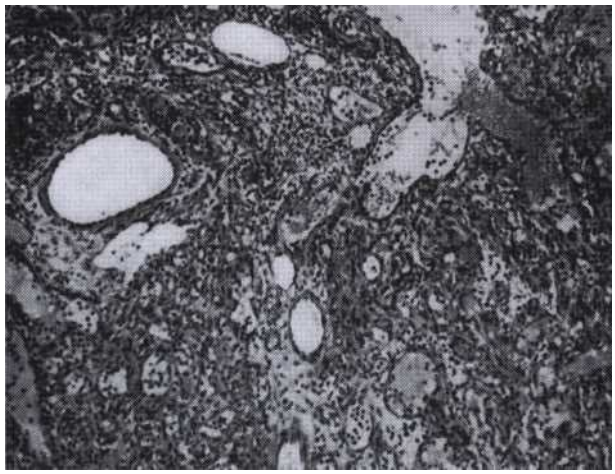

Fig. 18-15 Microscopic view of gingival enlargement in pregnancy showing an abundance of blood vessels and interspersed inflammatory cells.

ment. Although spontaneous reduction in the size of gingival enlargement commonly follows the termination of pregnancy, complete elimination of the residual inflammatory lesion requires the removal of all plaque deposits and factors that favor its accumulation.

Enlargement in Puberty. Enlargement of the gingiva is sometimes seen during puberty (see Chapters 12 and 37). It occurs in both male and female adolescents and appears in areas of plaque accumulation.

CLINICAL FEATURES. The size of the gingival enlargement far exceeds that usually seen in association with comparable local factors. It is marginal and interdental and is characterized by prominent bulbous interproximal papillae (Fig. 18-16). Often only the facial gingivae are enlarged, and the lingual surfaces are relatively unaltered. This is because the mechanical action of the tongue and the excursion of food prevent a heavy accumulation of local irritants on the lingual surface.

Gingival enlargement during puberty has all the clinical features generally associated with chronic inflammatory gingival disease. It is the degree of enlargement and the tendency to develop massive recurrence in the presence of relatively scant plaque deposits that distinguish pubertal gingival enlargement from uncomplicated chronic inflammatory gingival enlargement. After puberty, the enlargement undergoes spontaneous reduction but does not disappear until plaque and calculus are removed.

A longitudinal study of 127 children 11 to 17 years of age showed a high initial prevalence of gingival enlargement that tended to decline with age. [120] When the mean number of inflamed gingival sites per child was determined and correlated with the time at which the maximum number of inflamed sites was observed and the oral hygiene index at that time, it could be clearly seen that a pubertal peak in gingival inflammation that was unrelated to oral hygiene factors occurred. A longitudinal study of subgingival microbiota of children between the ages of 11 and 14 and their association with clinical parameters has implicated Capnocytophaga sp. in the initiation of pubertal gingivitis.83 Other studies have reported that hormonal changes coincide with an increase in the proportion of Prevotella intermedia and Prevotella nigrescens. [85,132]

HISTOPATHOLOGY. The microscopic picture is that of chronic inflammation with prominent edema and associated degenerative changes.

Enlargement in Vitamin C Deficiency. Enlargement of the gingiva is generally included in classic descriptions of scurvy. It is important to recognize that such enlargement is essentially a conditioned response to bacterial plaque. Acute vitamin C deficiency does not of itself cause gingival inflammation, but it does cause hemorrhage, collagen degeneration, and edema of the gingival connective tissue. These changes modify the response of the gingiva to plaque to the extent that the normal defensive delimiting reaction is inhibited, and the extent of the inflammation is exaggerated . [39,40] The combined effect of acute vitamin C deficiency and inflammation produces the massive gingival enlargement in scurvy (Fig. 18-17) (see Chapter 12).

CLINICAL FEATURES. Gingival enlargement in vitamin C deficiency is marginal; the gingiva is bluish red, soft, and friable and has a smooth, shiny surface. Hemorrhage, occurring either spontaneously or on slight provocation, and surface necrosis with pseudomembrane formation are common features.

HISTOPATHOLOGY. The gingiva has a chronic inflammatory cellular infiltration with a superficial acute response. There are scattered areas of hemorrhage, with engorged capillaries. Marked diffuse edema, collagen degeneration, and scarcity of collagen fibrils or fibroblasts are striking findings.

Plasma Cell Gingivitis. Plasma cell gingivitis is also referred to as atypical gingivitis and plasma cell gingivostomatitis and often consists of a mild marginal gingival enlargement that extends to the attached gingiva. A localized lesion, referred to as plasma cell granuloma, has also been described. [15]

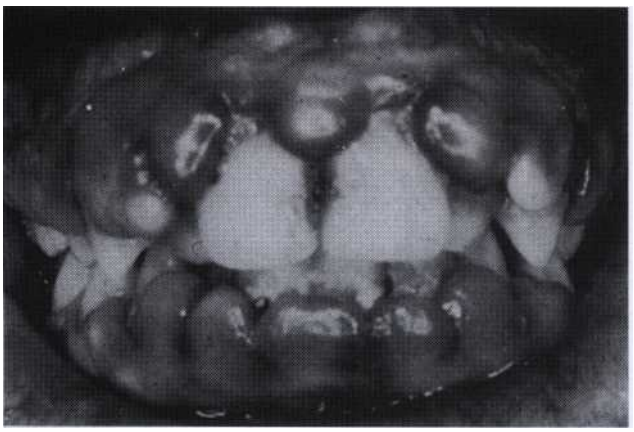

Fig. 18-16 Conditioned gingival enlargement in puberty in a 13-year-old boy.

Fig. 18-17 Gingival enlargement in vitamin C deficiency. Note the prominent hemorrhagic areas.

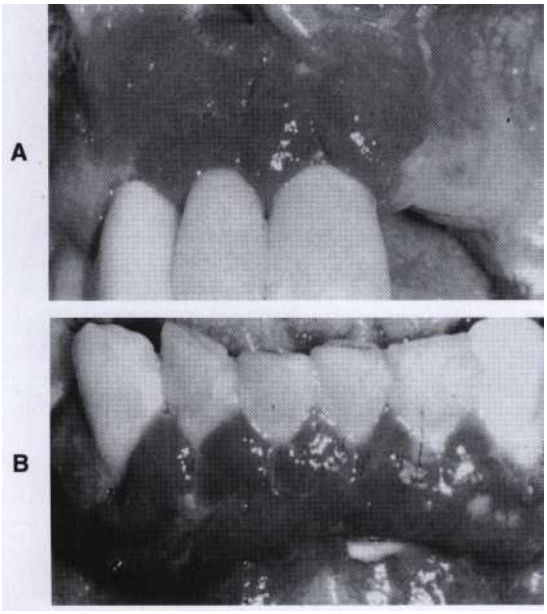

Fig. 18-18 Plasma cell granuloma of the gingiva. A, Diffuse lesions on the facial surface of the anterior maxilla. B, Mandibular lesions. (Courtesy Dr. Kim D. Zussman, Thousand Oaks, Calif.)

CLINICAL FEATURES. The gingiva appears red, friable, and sometimes granular and bleeds easily; usually it does not induce a loss of attachment (Fig. *18-18).* This lesion is located in the oral aspect of the attached gingiva and therefore differs from plaque-induced gingivitis.

HISTOPATHOLOGY. The oral epithelium shows spongiosis and infiltration with inflammatory cells; ultrastructurally there are signs of damage in the lower spinous layers and the basal layers. The underlying connective tissue contains a dense infiltrate of plasma cells that also extends to the oral epithelium, inducing a dissecting type of injury.[88]

An associated cheilitis and glossitis have been reported.63, [104] Plasma cell gingivitis is thought to be allergic in origin, possibly related to components of chewing gum, dentifrices, or various diet components. Cessation of exposure to the allergen brings resolution of the lesion.

In rare instances, marked inflammatory gingival enlargements with a predominance of plasma cells can appear associated with rapidly progressive periodontitis.90

Nonspecific Conditioned Enlargement (Pyogenic Granuloma).

Pyogenic granuloma is a tumorlike gingival enlargement that is considered an exaggerated conditioned response to minor trauma (Fig. 18-19). The exact nature of the systemic conditioning factor has not been identified.62

CLINICAL FEATURES. The lesion varies from a discrete spherical, tumorlike mass with a pedunculated attachment to a flattened, keloidlike enlargement with a broad base. It is bright red or purple and either friable or firm, depending on its duration; in the majority of cases it presents with surface ulceration and purulent exudation. The lesion tends to involute spontaneously to become a fibroepithelial papilloma or persists relatively unchanged for years.

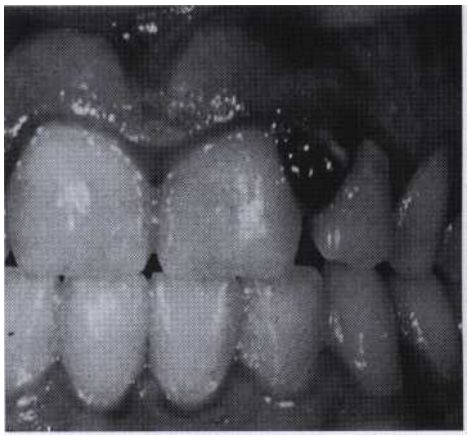

Fig. 18-19 Pyogenic granuloma in a young woman.

HISTOPATHOLOGY. Pyogenic granuloma appears as a mass of granulation tissue with chronic inflammatory cellular infiltration. Endothelial proliferation and the formation of numerous vascular spaces are the prominent features. The surface epithelium is atrophic in some areas and hyperplastic in others. Surface ulceration and exudation are common features.

Treatment consists of removal of the lesions plus the elimination of irritating local factors. The recurrence rate is about 15%.14 Pyogenic granuloma is similar in clinical and microscopic appearance to the conditioned gingival enlargement seen in pregnancy. Differential diagnosis depends on the patient's history.

Systemic Diseases Causing Gingival Enlargement

Several systemic diseases may, by different mechanisms, result in gingival enlargement. These are uncommon cases and will be only briefly discussed.

Leukemia

CLINICAL FEATURES. Leukemic enlargement may be diffuse or marginal, localized or generalized (see Chapter 12). It may appear as a diffuse enlargement of the gingival mucosa (Fig. 18-20), an oversized extension of the marginal gingiva, or a discrete tumorlike interproximal mass. In leukemic enlargement the gingiva is generally bluish red and has a shiny surface. The consistency is moderately firm, but there is a tendency toward friability and hemorrhage, occurring either spontaneously or on slight irritation. Acute painful necrotizing ulcerative inflammatory involvement sometimes occurs in the crevice formed at the junction of the enlarged gingiva and the contiguous tooth surfaces.

Fig. 18-20 Leukemic gingival enlargement. A, Leukemic gingival enlargement in a patient with acute myelocytic leukemia. Note that the enlargement is more prominent in the maxilla and is associated with greater plaque accumulation. B, Lingual view of gingival enlargement in a patient with subacute monocytic leukemia, showing a bulbous increase in size with discoloration and a smooth, shiny surface. Note the difference between the enlarged gingiva and the adjacent palatal mucosa.

Patients with leukemia may also have a simple chronic inflammation without the involvement of leukemic cells and may present with the same clinical and microscopic features seen in patients without the disease. Most cases reveal features of both simple chronic inflammation and a leukemic infiltrate.

True leukemic enlargement occurs commonly in acute leukemia but may also be seen in subacute leukemia. It seldom occurs in chronic leukemia.

HISTOPATHOLOGY. Gingival enlargements in leukemic patients show various degrees of chronic inflammation with mature leukocytes and areas of connective tissue infiltrated with a dense mass of immature and proliferating leukocytes, the specific nature of which varies with the type of leukemia. Engorged capillaries, edematous and degenerated connective tissue, and epithelium with various degrees of leukocytic infiltration and edema are found. Isolated surface areas of acute necrotizing inflammation with a pseudomembranous meshwork of fibrin, necrotic epithelial cells, polymorphonuclear neutrophils (PMNs), and bacteria are often seen.

Granulomatous Diseases

WEGENER'S GRANULOMATOSIS. Wegener's granulomatosis is a rare disease characterized by acute granulomatous necrotizing lesions of the respiratory tract, including nasal and oral defects. Renal lesions develop, and acute necrotizing vasculitis affects the blood vessels. The initial manifestations of Wegener's granulomatosis may involve the orofacial region and include oral mucosal ulceration, gingival enlargement, abnormal tooth mobility, exfoliation of teeth, and delayed healing response .20

Clinical Features. The granulomatous papillary enlargement is reddish purple and bleeds easily on stimulation.

Histopathology. Chronic inflammation occurs, with scattered giant cells and foci of acute inflammation and microabscesses covered by a thin acanthotic epithelium. Vascular changes have not been described, probably owing to the small size of the gingival blood vessels.[57]

The cause of Wegener's granulomatosis is unknown, but the condition is considered an immunologically mediated tissue injury.27 At one time the usual outcome was death from kidney failure within a few months, but more recently the use of immunosuppressive drugs has produced prolonged remissions in more than *90%* of cases.68

Sarcoidosis. Sarcoidosis is a granulomatous disease of unknown etiology. It starts in individuals in their twenties or thirties, affects predominantly blacks and can involve almost any organ, including the gingiva, where a red, smooth, painless enlargement may appear (Fig. *18-21).*

HISTOPATHOLOGY. Sarcoid granulomas consist of discrete, noncaseating whorls of epithelioid cells and multinucleated foreign-body–type giant cells with peripheral mononuclear cells.[99]

NEOPLASTIC ENLARGEMENT (GINGIVAL TUMORS

Only a brief description of some of the most common neoplastic and pseudoneoplastic lesions of the gingiva will be given. The reader is referred to texts on oral pathology for a more comprehensive coverage.87,99

Benign Tumors of the Gingiva

Epulis is a generic term used clinically to designate all discrete tumors and tumorlike masses of the gingiva. It

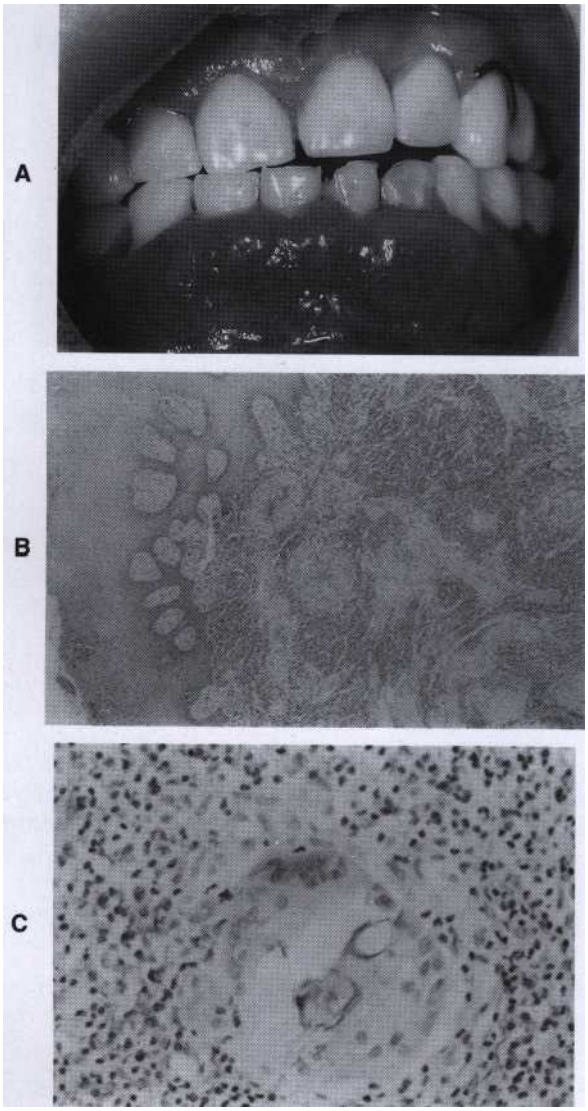

Fig. 18-21 A, Gingival enlargement in a case of sarcoidosis. Low power (B) and high-power (C) microscopic view of sarcoid granuloma. (Courtesy Dr. Silvia Oreamuno, San Jose, Costa Rica.)

serves to locate the tumor but not to describe it. Most lesions referred to as epulis are inflammatory rather than neoplastic.

Neoplasms account for a comparatively small proportion of gingival enlargements and make up a small percentage of the total number of oral neoplasms. In a survey of 257 oral tumors,[81] approximately 8% occurred on the gingiva. In another study[12] of 868 growths of the gingiva and palate, of which 57% were neoplastic and the remainder inflammatory, the following incidence of tumors was noted: carcinoma, 11.0%; fibroma, 9.3%; giant cell tumor, 8.4%; papilloma, 7.3%, leukoplakia, 4.9%; mixed tumor (salivary gland type), 2.5%; angioma, 1.5%; osteofibroma, 1.3%; sarcoma, 0.5%; melanoma, 0.5%; myxoma, 0.45%; fibropapilloma, 0.4%; adenoma, 0.4%; and lipoma, 0.3%.

Fibroma. Fibromas of the gingiva arise from the gingival connective tissue or from the periodontal ligament. They are slow-growing, spherical tumors that tend to be firm and nodular but may be soft and vascular. Fibromas are usually pedunculated. Hard fibromas of the gingiva are rare; most of the lesions diagnosed clinically as fibromas are inflammatory enlargements.[103]

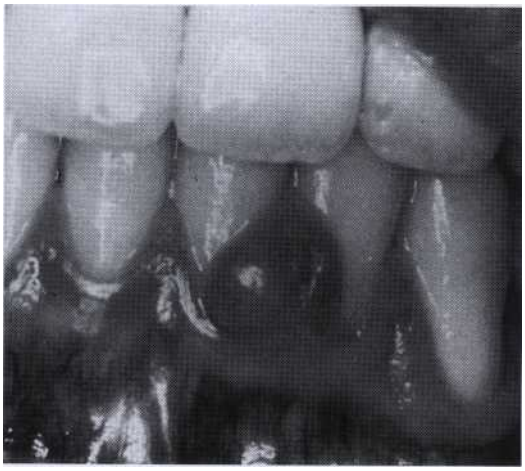

Fig. 18-22 Papilloma of the gingiva in a 26-year-old man.

Fig. 18-23 Gingival giant cell granuloma.

HISTOPATHOLOGY. Fibromas are composed of bundles of well-formed collagen fibers with a scattering of fibrocytes and a variable vascularity.

A so-called giant-cell fibroma contains multinucleated fibroblasts. In another variant mineralized tissue (bone, cementum-like material, dystrophic calcifications) may be found; this type of fibroma is called *peripheral ossifying fibroma.*

Papilloma. Papillomas are benign proliferations of surface epithelium associated with the human papillomavirus (HPV). Viral subtypes HPV-6 and HPV-11 have been found in most cases of oral papillomas. Gingival papillomas appear as solitary, wartlike or "cauliflower"-like protuberances (Fig. 18-22) and may be small and discrete or broad, hard elevations with minutely irregular surfaces.

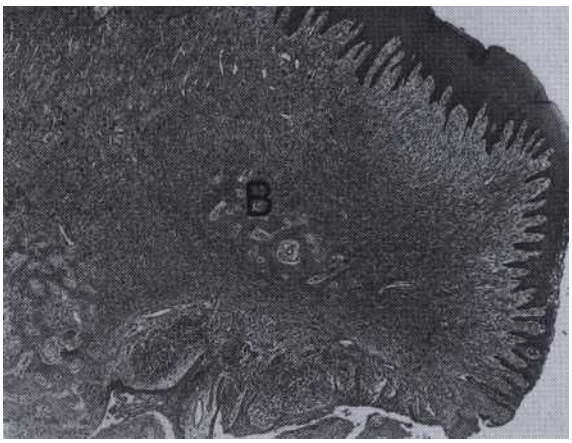

Fig. 18-24 Microscopic survey of peripheral giant cell reparative granuloma. Trabeculae of newly formed bone (B) are contained within the mass.

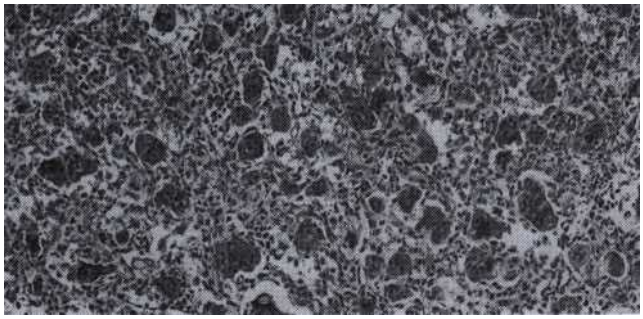

Fig. 18-25 High-power study of the lesion shown in Fig. 18-24 demonstrating the giant cells and intervening stroma that make up the major portion of the mass.

HISTOPATHOLOGY. The lesion consists of fingerlike projections of stratified squamous epithelium, often hyperkeratotic, with a central core of fibrovascular connective tissue.

Peripheral Giant Cell Granuloma. Giant cell lesions of the gingiva arise interdentally or from the gingival margin, occur most frequently on the labial surface, and may be sessile or pedunculated. They vary in appearance from smooth, regularly outlined masses to irregularly shaped, multilobulated protuberances with surface indentations (Fig. 18-23). Ulceration of the margin is occasionally seen. The lesions are painless, vary in size, and may cover several teeth. They may be firm or spongy, and the color varies from pink to deep red or purplish blue. There are no pathognomonic clinical features whereby these lesions can be differentiated from other forms of gingival enlargement. Microscopic examination is required for definitive diagnosis (Figs. 18-24 and 18-25).

In the past, giant cell lesions of the gingiva have been referred to as *peripheral reparative giant cell tumors.* These lesions, however, are essentially responses to local injury and not neoplasms; and their reparative nature has not been proven. Therefore they are now referred to as *peripheral giant cell granulomas.* The prefix peripheral is needed to differentiate them from comparable lesions that originate within the jawbone (central giant cell granulomas).

In some instances, the giant cell granuloma of the gingiva is locally invasive and causes destruction of the underlying bone (Fig. 18-26). Complete removal leads to uneventful recovery.

HISTOPATHOLOGY. The giant cell granuloma has numerous foci of multinuclear giant cells and hemosiderin particles in a connective tissue stroma. Areas of chronic inflammation are scattered throughout the lesion, with acute involvement occurring at the surface. The overlying epithelium is usually hyperplastic, with ulceration at the base. Bone formation occasionally occurs within the lesion (see Figs. 18-24 and 18-25).

Central Giant Cell Granuloma. These lesions arise within the jaws and produce central cavitation. They occasionally create a deformity of the jaw that makes the gingiva appear enlarged.

Mixed tumors, salivary gland type tumors, and plasmacytomas of the gingiva have also been described but are not often seen.

Leukoplakia. *Leukoplakia is* a strictly clinical term defined by the World Health Organization as a white patch or plaque that does not rub off and cannot be diagnosed as any other disease. The cause of leukoplakia remains obscure, although it is associated to the use of tobacco (smoke or smokeless). Other probable factors are *Candida albicans,* HPV-16 and HPV-18, and trauma. Leukoplakia of the gingiva varies in appearance from a grayish white, flattened, scaly lesion to a thick, irregularly shaped keratinous plaque (Fig. 18-27).

Most leukoplakias (80%) are benign, the remaining 20% are malignant or premalignant, and only 3% of these are invasive carcinomas.[37] Biopsy of all leukoplakias, selecting the most suspicious area, is necessary to arrive at a correct diagnosis and institute proper therapy.[37,87]

HISTOPATHOLOGY. Leukoplakia exhibits hyperkeratosis and acanthosis. Premalignant and malignant cases have a variable degree of atypical epithelial changes that may be mild, moderate, or severe, depending on the extent of involvement of the epithelial layers. When dysplastic changes involve all layers, it is diagnosed as a *carcinoma in situ,* and this may become invasive carcinoma when the basement membrane is breached.[37] Inflammatory involvement of the underlying connective tissue is a commonly associated finding.

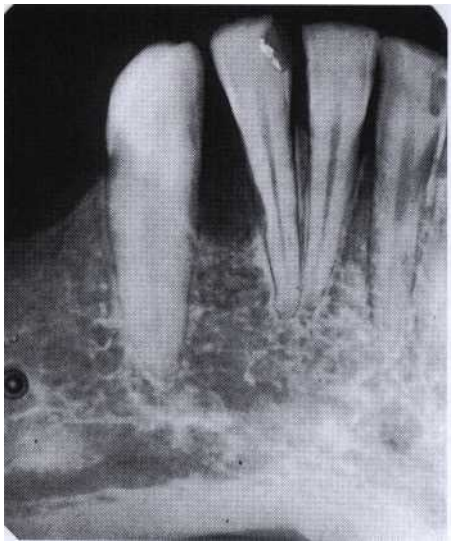

Fig. 18-26 Bone destruction in the interproximal space between the canine and lateral incisor caused by the extension of a peripheral giant cell reparative granuloma of the gingiva. (Courtesy Dr. Sam Toll.)

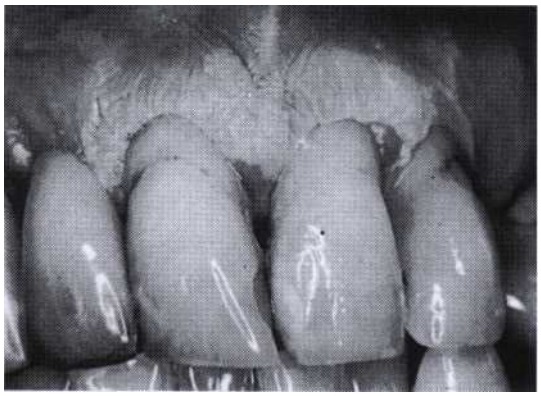

Fig. 18-27 Leukoplakia of the gingiva.

Gingival Cyst. Gingival cysts of microscopic proportions are common, but they seldom reach a clinically significant size.[84] When they do, they appear as localized enlargements that may involve the marginal and attached gingiva. They occur in the mandibular canine and premolar areas, most often on the lingual surface. They are painless, but with expansion, they may cause erosion of the surface of the alveolar bone. However, it should be differentiated from the lateral periodontal cyst (see Chapter 22), which arises within the alveolar bone, adjacent to the root, and is developmental in origin. The cysts develop from odontogenic epithelium or from surface or sulcular epithelium traumatically implanted in the area. Removal is followed by uneventful recovery.

Microscopically, a cyst cavity is lined by a thin, flattened epithelium with or without localized areas of thickening. Less frequently, the following types of epithelium can be found: unkeratinized stratified squamous epithelium, keratinized stratified squamous epithelium, and parakeratinized epithelium with palisading basal cells.[19]

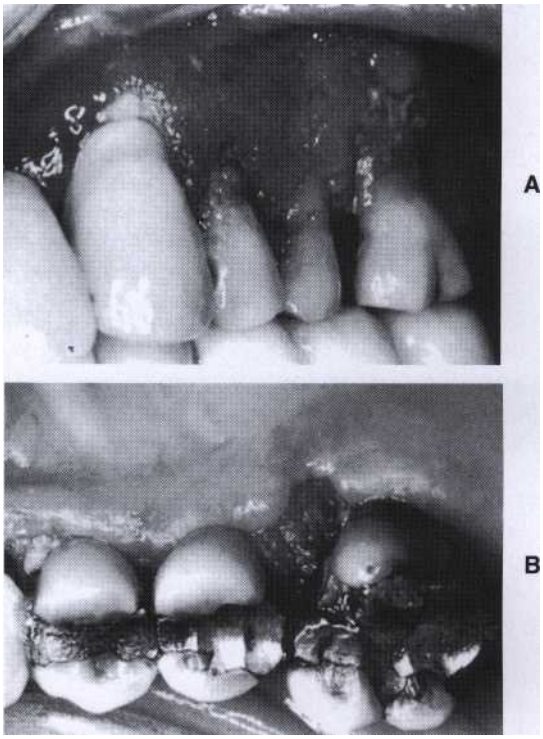

Fig. 18-29 Squamous cell carcinoma of the gingiva. A, Facial view. Note the extensive verrucous involvement. B, Palatal view. Note the mulberry-like tissue emerging between the second premolar and the first molar.

Other benign tumors have also been described as rare or infrequent findings in the gingiva. They include nevus,[13] myoblastoma,[43,61] hemangioma (Fig. 18-28),[12,121] neurilemoma,["] neurofibroma,[94] mucus-secreting cysts (mucoceles),[127] and ameloblastoma.[118]

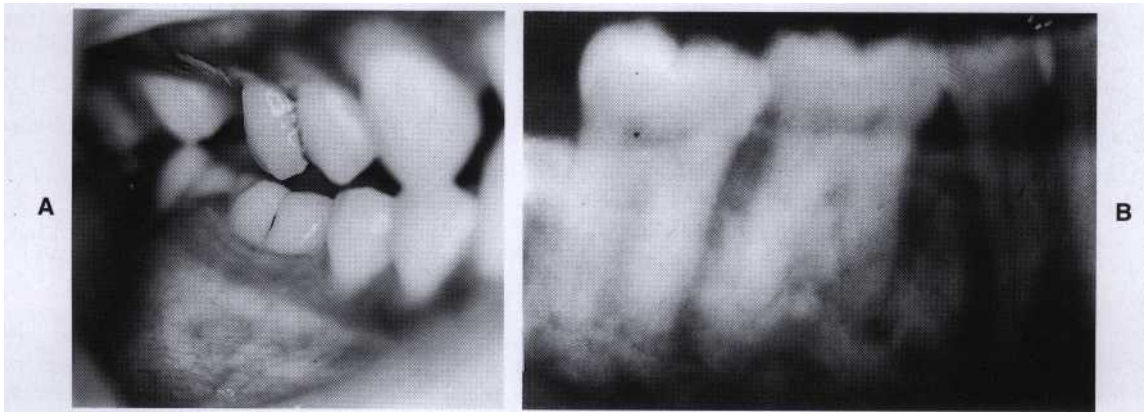

Fig. 18-30 A, Apparent gingival enlargement associated with bone augmentation in a case of fibrous dysplasia. B, Radiograph of the case shown in A, depicting a ground-glass, mottled radiographic pattern.

Malignant Tumors of the Gingiva

Carcinoma. Oral cancer accounts for less than 3% of all malignant tumors in the body but is the sixth most common cancer in males and the twelfth in females." The gingiva is not a frequent site of oral malignancy (6% of oral cancers").

Squamous cell carcinoma is the most common malignant tumor of the gingiva. It may be exophytic, presenting as an irregular outgrowth, or ulcerative, which appear as flat, erosive lesions. It is often symptom free, often going unnoticed until complicated by inflammatory changes that may mask the neoplasm but cause pain; sometimes it becomes evident after tooth extraction. They are locally invasive, involving the underlying bone and periodontal ligament of adjoining teeth and the adjacent mucosa (Fig. 18-29). Metastasis is usually confined to the region above the clavicle; however, more extensive involvement may include the lung, liver, or bone.

Malignant Melanoma. Malignant melanoma is a rare oral tumor that tends to occur in the hard palate and maxillary gingiva of older persons.87 It is usually darkly pigmented and is often preceded by the occurrence of localized pigmentation .25 It may be flat or nodular and is characterized by rapid growth and early metastasis. It arises from melanoblasts in the gingiva, cheek, or palate. Infiltration into the underlying bone and metastasis to cervical and axillary lymph nodes are common.

SARCOMA. Fibrosarcoma, lymphosarcoma, and reticulum cell sarcoma of the gingiva are rare; only isolated cases have been described in the literature.42,47,123 Kaposi's sarcoma often occurs in the oral cavity of patients with acquired immunodeficiency syndrome (AIDS), particularly in the palate and the gingiva (see Chapter 29).

METASTASIS. Tumor metastasis to the gingiva is not common. Such metastasis has been reported with various tumors, including adenocarcinoma of the colon,s5 lung carcinoma, primary hepatocellular carcinoma,125 renal cell carcinoma,18 hypernephroma,93 chondrosarcoma,122 and testicular tumor.36

The low incidence of oral malignancy should not mislead the clinician. *Ulcerations that do not respond to therapy in the usual manner, as well as all gingival tumors and tumorlike lesions must be biopsied and submitted for microscopic diagnosis* (see Chapter 30).

The reader is referred to oral pathology textbooks" for more complete information on benign and malignant tumors of the gingiva.

FALSE ENLARGEMENT

False enlargements are not true enlargements of the gingival tissues but may appear as such as a result of increases in size of the underlying osseous or dental tissues. The gingiva usually presents with no abnormal clinical features except the massive increase in size of the area.

Underlying Osseous Lesions

Enlargement of the bone subjacent to the gingival area occurs most commonly in tori and exostoses, but it can also occur in Paget's disease, fibrous dysplasia, cherubism, central giant cell granuloma, ameloblastoma, osteoma, and osteosarcoma. One example of this type of enlargement is shown in Fig. 18-30. In this case a fibrous dysplasia (florid type) in a 38-year-old black female induced an osseous enlargement in the mandibular molar area that appeared as a gingival enlargement. The gingival tissue can appear normal or may have unrelated inflammatory changes.

Underlying Dental Tissues

During the various stages of eruption, particularly of the primary dentition, the labial gingiva may show a bulbous marginal distortion caused by superimposition of the bulk of the gingiva on the normal prominence of the enamel in the gingival half of the crown. This enlargement has been termed *developmental enlargement* and often persists until the junctional epithelium has migrated from the enamel to the cementoenamel junction.

In a strict sense, developmental gingival enlargements are physiologic and ordinarily present no problems. However, when such enlargement is complicated by mar-

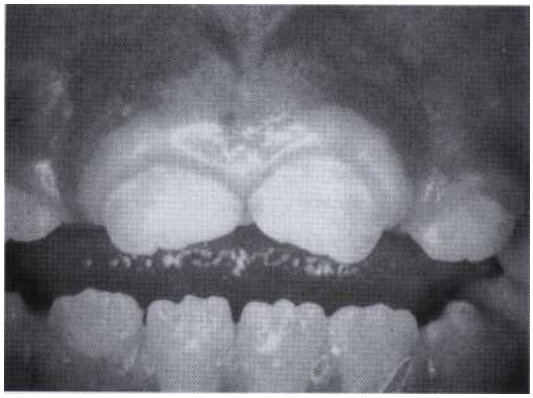

Fig. 18-31 Developmental gingival enlargement. The normal bulbous contour of the gingiva around the incompletely erupted anterior teeth is accentuated by chronic inflammation.

ginal inflammation, the composite picture gives the impression of extensive gingival enlargement (Fig. 18-31). Treatment to alleviate the marginal inflammation, rather than resection of the enlargement, is sufficient in these cases.

NECROTIZING ULCERATIVE GINGIVITIS

Necrotizing ulcerative gingivitis (NUG) is an inflammatory destructive disease of the gingiva, which presents characteristic signs and symptoms.

Clinical Features

Classification. NUG most often occurs as an acute disease. NUG often undergoes a diminution in severity, leading to a subacute stage with milder clinical symptoms. The disease may sometimes subside spontaneously without treatment. Such patients generally have a history of repeated remissions and exacerbations. Recurrence of the condition in previously treated patients is also frequent. Involvement may be limited to a single tooth or group of teeth (Fig. 19-1) or may be widespread throughout the mouth.

NUG can cause tissue destruction involving the supporting structures. When bone loss occurs the condition is called necrotizing ulcerative periodontitis (NUP) (see Chapter 27).

History. NUG is characterized by sudden onset, sometimes following an episode of debilitating disease or acute respiratory tract infection. A change in living habits, protracted work without adequate rest, and psychologic stress are frequent features of the patient's history.

Oral Signs. *Characteristic lesions are punched out, craterlike depressions at the crest of the interdental papillae,* subsequently extending to the marginal gingiva and rarely to the attached gingiva and oral mucosa. The surface of the gingival craters is covered by a *gray, pseudomembranous slough, demarcated from the remainder of the gingival mucosa by a pronounced linear erythema* (Color Fig. 19-1, A). In some instances, the lesions are denuded of the surface pseudomembrane, exposing the gingival margin, which is red, shiny, and hemorrhagic. The characteristic lesions may progressively destroy the gingiva and underlying periodontal tissues (Color Fig. 19-1, B).

Spontaneous gingival hemorrhage or pronounced bleeding on the slightest stimulation are additional characteristic

Fig. 19-1 Localized zone of necrotizing ulcerative gingivitis.

Fig. 19-2 Noma following necrotizing ulcerative gingivitis in a 50-year-old male with severe anemia.

clinical signs (Color Fig. *19-1,* C). Other signs often found are fetid odor and increased salivation.

NUG can occur in otherwise disease-free mouths or can be superimposed on chronic gingivitis (Color Fig. *19-1, D) or periodontal pockets.* However, it does not usually lead to periodontal pocket formation because the necrotic changes involve the junctional epithelium; a viable junctional epithelium is needed for pocket deepening (see Chapter *22).* It is rare in edentulous mouths, but isolated spherical lesions occasionally occur on the soft palate.

Oral Symptoms. The lesions are *extremely sensitive to touch,* and the patient often complains of a *constant radiating, gnawing pain* that is intensified by eating spicy or hot foods and chewing. There is a metallic foul taste, and the patient is conscious of an excessive amount of "pasty" saliva.

Extraoral and Systemic Signs and Symptoms. Patients are usually ambulatory and have a minimum of systemic complications. Local lymphadenopathy and a slight elevation in temperature are common features of the mild and moderate stages of the disease. In severe cases there may be marked systemic complications such as high fever, increased pulse rate, leukocytosis, loss of appetite, and general lassitude. Systemic reactions are more severe in children. Insomnia, constipation, gastrointestinal disorders, headache, and mental depression sometimes accompany the condition.

In very rare cases, severe sequelae such as noma or gangrenous stomatitis[2,3,19] (Fig. *19-2)* have been described.

Clinical Course. The clinical course is indefinite. If untreated, NUG may lead to NUP with a progressive destruction of the periodontium and denudation of the roots, accompanied by an increase in the severity of toxic systemic complications.

Pindborg and colleagues[53] have described the following stages in the progress of NUG: (1) only the tip of the interdental papilla is affected; (2) the lesion extends to marginal gingiva and causes punched-out papilla; (3) the attached gingiva is also affected; and (4) bone is exposed.

Horning and Cohen[33] extended the staging of these oral necrotizing diseases as follows:

Stage 1: Necrosis of the tip of the interdental papilla *(93%)**
Stage 2: Necrosis of the entire papilla *(19%)*
Stage 3: Necrosis extending to the gingival margin *(21%)*
Stage 4: Necrosis extending also to the attached gingiva *(1%)*
Stage 5: Necrosis extending into buccal or labial mucosa *(6%)*
Stage 6: Necrosis exposing alveolar bone (1%)
Stage 7: Necrosis perforating skin of cheek (0%)

According to Horning and Cohen, stage 1 is NUG, stage *2* may be either NUG or NUP because attachment loss may have occurred, stages *3* and 4 are NUP, stages 5 and *6* are necrotizing stomatitis, and stage 7 is noma.

* **Percent of cases found in Horning and Cohen series.**

Histopathology. Microscopically, the lesion is a nonspecific acute necrotizing inflammation of the gingival margin, involving both the stratified squamous epithelium and the underlying connective tissue. The surface epithelium is destroyed and is replaced by a meshwork of fibrin, necrotic epithelial cells, polymorphonuclear neutrophils (PMNs), and various types of microorganisms (Fig. 19-3). This is the zone that appears clinically as the surface pseudomembrane. At the immediate border of the necrotic pseudomembrane, the epithelium is edematous, and the individual cells exhibit varying degrees of hydropic degeneration. In addition, there is an infiltration of PMNs in the intercellular spaces.

The underlying connective tissue is markedly hyperemic, with numerous engorged capillaries and a dense infiltration of PMNs. This acutely inflamed zone appears clinically as the linear erythema beneath the surface pseudomembrane. Numerous plasma cells may appear in the periphery of the infiltrate; this is interpreted as an area of established chronic gingivitis on which the acute lesion became superimposed.[32]

The epithelium and connective tissue alterations decrease as the distance from the necrotic gingival margin increases, blending gradually with the uninvolved gingiva.

It is noteworthy that the microscopic appearance of NUG is nonspecific. Comparable changes result from trauma, chemical irritation, or the application of caustic medications.

Relation of Bacteria to the Characteristic Lesion

The light microscope and the electron microscope have been used to study the relationship of bacteria to the characteristic lesion of NUG. With the former, it appears that the exudate on the surface of the necrotic lesion contains microorganisms that morphologically resemble cocci, fusiform bacilli, and spirochetes.[74] The layer between the necrotic and the living tissue contains enormous numbers of fusiform bacilli and spirochetes, in addition to leukocytes and fibrin. Spirochetes and other bacteria',[12,17,38] invade the underlying living tissue.

Listgarten'' described the following four zones, which blend with each other and may not all be present in every case:

Zone 1: Bacterial zone, the most superficial, consists of varied bacteria, including a few spirochetes of the small, medium, and large types.

Zone 2: Neutrophil-rich zone contains numerous leukocytes, preponderantly neutrophils, with bacteria, including many spirochetes of various types, between the leukocytes.

Zone 3: Necrotic zone consists of disintegrated tissue cells, fibrillar material, remnants of collagen fibers, and numerous spirochetes of the medium and large types, with few other organisms.

Zone 4: Zone of spirochetal infiltration consists of well-preserved tissue infiltrated with medium and large spirochetes, without other organisms.

Spirochetes have been found as deep as 300 microns from the surface. The majority of spirochetes in the deeper zones are morphologically different from cultivated strains of *Treponema microdentium*. They occur in nonnecrotic tissue before other types of bacteria and may be present in high concentrations intercellularly in the epithelium adjacent to the ulcerated lesion and in the connective tissue.[31]

Bacterial Flora

Smears from the lesions (Fig. 19-4) present scattered bacteria, predominantly spirochetes and fusiform bacilli, desquamated epithelial cells, and occasional PMNs. A smear containing only spirochetes and fusiform bacilli is rarely seen. Usually these two organisms are seen with other oral spirochetes, vibrios, streptococci, and filamentous organisms. The spirochetal organisms form a light-staining, conspicuous, interlacing network throughout the microscopic field.

Electron microscopic studies indicate that the spirochetes may be classified into three morphologic groups: small (7% to 39% of the total spirochetes present); medium (43.9% to 90%); and large (0% to 20%).[35] It was also suggested that medium-size spirochetes are present in greater numbers in pooled scrapings from lesions of NUG and are found in greater percentages in deeper portions of the lesions.

Diagnosis

Diagnosis is based on clinical findings of gingival pain, ulceration, and bleeding. A bacterial smear is not necessary or definitive because the bacterial picture is not appreciably different from that in marginal gingivitis, periodontal pockets, pericoronitis, or primary herpetic gingivostomatitis.[59] Bacterial studies are useful, however, in the differential diagnosis of NUG and specific infections of the oral cavity such as diphtheria, thrush, actinomycosis, and streptococcal stomatitis.

Microscopic examination of a biopsy specimen is not sufficiently specific to be diagnostic. It can be used to differentiate NUG from specific infections such as tuberculosis or from neoplastic disease, but it does not differentiate between NUG and other necrotizing conditions of nonspecific origin, such as those produced by trauma or caustic medications.

Differential Diagnosis

NUG should be differentiated from other conditions that resemble it in some respects, such as herpetic gingivostomatitis (Table 19-1); chronic periodontitis; desquamative gingivitis (Table 19-2); streptococcal gingivostomatitis; aphthous stomatitis; gonococcal gingivostomatitis; diphtheritic and syphilitic lesions (Table 19-3); tuberculous gingival lesion; candidiasis, agranulocytosis, dermatoses (pemphigus, erythema multiforme, and lichen planus); and stomatitis venenata. See Chapter 21 for a description of most of these conditions.

Streptococcal gingivostomatitis[43] is a rare condition characterized by a diffuse erythema of the gingiva and other areas of the oral mucosa. In some instances it is confined

as a marginal erythema with marginal hemorrhage. Necrosis of the gingival margin is not a feature of this disease, and there is no notably fetid odor. Bacterial smears show a preponderance of streptococcal forms, which were identified as Streptococcus *viridans,* but more recent studies report it to be group A beta-hemolytic streptococcus.[39]

Agranulocytosis is characterized by a marked decrease in the number of circulating PMNs, lesions of the throat, and other mucous membranes, as well as ulceration and necrosis of the gingiva, which may resemble that of NUG. The oral condition in agranulocytosis is primarily necrotizing. Because of the diminished innate defense mechanisms in agranulocytosis, the clinical picture is not marked by the severe inflammatory reaction seen in NUG. Blood studies serve to differentiate between NUG and the gingival necrosis in agranulocytosis.

Vincent's angina is a fusospirochetal infection of the oropharynx and throat, as distinguished from NUG, which affects the marginal gingiva. In Vincent's angina, there is a painful membranous ulceration of the throat, with edema and hyperemic patches breaking down to form ulcers covered with pseudomembranous material. The process may extend to the larynx and middle ear.

TABLE 19-1

Differentiation between Necrotizing Ulcerative Gingivitis and Primary Herpetic Gingivostomatitis

Necrotizing Ulcerative Gingivitis	Primary Herpetic Gingivostomatitis
Etiology: Interaction between host and bacteria, most probably fusospirochetes	Specific viral etiology
Necrotizing condition	
Punched out gingival margin; pseudomembrane that peels off, leaving raw areas. Marginal gingiva affected; other oral tissues rarely affected	Diffuse erythema and vesicular eruption Vesicles rupture and leave slightly depressed oval or spherical ulcer Diffuse involvement of gingiva, may include buccal mucosa and lips
Uncommon in children	Occurs more frequently in children
No definite duration	Duration of 7 to 10 days
No demonstrated immunity	An acute episode results in some degree of immunity
Contagion not demonstrated	Contagious

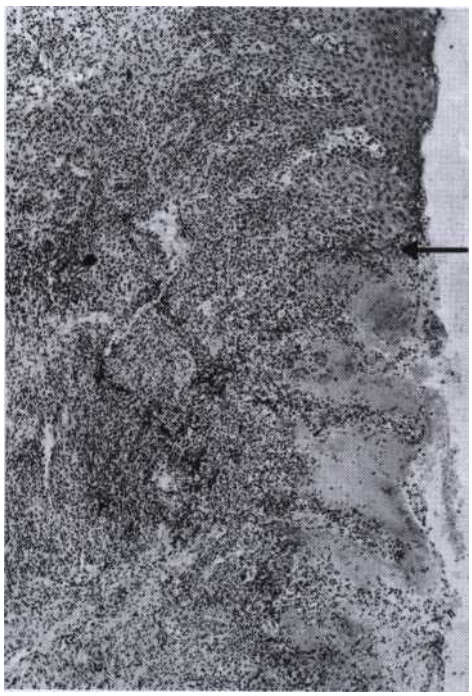

Fig. 19-3 Survey section of the gingiva in necrotizing ulcerative gingivitis. The portion of the section below the arrow shows ulceration and accumulation of leukocytes, fibrin, and necrotic tissue that form the gray marginal pseudomembrane.

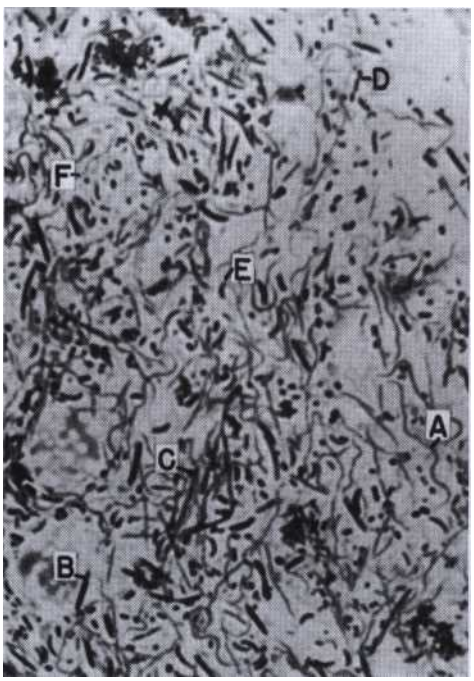

Fig. 19-4 Bacterial smear from lesion in necrotizing ulcerative gingivitis. A, Spirochete; *B, Bacillus fusiformis;* **C, filamentous organism** *(Actinomyces* or *Leptotrichia); D, Streptococcus; E, Vibrio; F, Treponema microdentium.*

TABLE 19-2

Differentiation among Necrotizing Ulcerative Gingivitis, Chronic Desquamative Gingivitis, and Chronic Periodontal Disease

Necrotizing Ulcerative Gingivitis	Desquamative Gingivitis	Chronic Destructive Periodontal Disease
Bacterial smears show fusospirochetal complex	Bacterial smears reveal numerous epithelial cells, few bacterial forms	Bacterial smears are variable
Marginal gingiva affected	Diffuse involvement of marginal and attached gingivae and other areas of oral mucosa	Marginal gingiva affected
Acute history	Chronic history	Chronic history
Painful	May or may not be painful	Painless if uncomplicated
Pseudomembrane	Patchy desquamation of gingival epithelium	No desquamation generally but purulent material may appear from pockets
Papillary and marginal necrotic lesions	Papillae do not undergo necrosis	Papillae do not undergo notable necrosis
Affects adults of both genders, occasionally children	Affects adults, most often women	Generally in adults, occasionally in children
Characteristic fetid odor	None	Some odor present but not strikingly fetid

TABLE 19-3

Differentiation among Necrotizing Ulcerative Gingivitis, Diphtheria, and Secondary Stage of Syphilis

Necrotizing Ulcerative Gingivitis	Diphtheria	Secondary Stage of Syphilis (Mucous Patch)
Etiology: interaction between host and bacteria, possibly fusospirochetes	Specific bacterial etiology: *Corynebacterium diphtheriae*	Specific bacterial etiology: *Treponema pallidum*
Affects marginal gingiva	Rarely affects marginal gingiva	Rarely affects marginal gingiva
Membrane removal easy	Membrane removal difficult	Membrane not detachable
Painful condition	Less painful	Minimal pain
Marginal gingiva affected	Throat, fauces, tonsils affected	Any part of mouth affected
Serologic findings normal	Serologic findings normal	Serologic findings abnormal (Wassermann, Kahn, Venereal Disease Research Laboratory [VDRL])
Immunity not conferred	Immunity conferred by an attack	Immunity not conferred
Doubtful contagiousness	Contagious	Only direct contact will communicate disease
Antibiotic therapy relieves symptoms	Antibiotic treatment has little effect	Antibiotic therapy has excellent results

NUG in leukemia is not produced by leukemia per se but may be the result of a reduction in host defense mechanisms seen with leukemia. However, NUG may be superimposed on gingival tissue alterations caused by leukemia. The differential diagnosis consists not in distinguishing between NUG and leukemic gingival changes, but rather in determining whether leukemia is a predisposing factor in a mouth with NUG. For example, if a patient with necrotizing involvement of the gingival margin also has generalized diffuse discoloration and edema of the attached gingiva, the possibility of an underlying, systemically induced gingival change should be considered. Leukemia is one of the conditions that would have to be ruled out (see Chapter 12).

NUG in acquired immunodeficiency syndrome (AIDS) has the same clinical features, although it follows a very destructive course leading to NUP with the loss of soft tissue, bone, and the formation of bony sequestra[29] (see Chapter 29).

Etiology

The Role of Bacteria.

Plaut[54] and Vincent,[" in 1894 and 1896, respectively, introduced the concept that NUG is caused by specific bacteria, namely a fusiform bacillus and a spirochetal organism.

Opinions still differ regarding whether bacteria are the primary causative factors in NUG. Several observations support this concept, including the fact that spirochetal organisms and fusiform bacilli are always found in the disease, with other organisms also involved. Rosebury and colleagues[59] described a fusospirochetal complex consist-

ing of T. *microdentium,* intermediate spirochetes, vibrios, fusiform bacilli, and filamentous organisms, in addition to several *Borrelia* species.

Loesche and colleagues40 described a predominant constant flora and a variable flora associated with NUG. The constant flora is composed of *prevotella intermedia,* in addition to the *fusobacteria, treponema,* and *selenomonas* species. The variable flora consists of a heterogeneous array of bacterial types.

Treatment with metronidazole results in a significant reduction of *Treponema* species, *prevotella intermedia,* and *fusobacteria* with resolution of the clinical symptoms. [16,40] Given the antibacterial spectrum of this drug, the anaerobic members of the flora mentioned are thought to be responsible for the symptoms.

These bacteriologic findings have been supported by immunologic data from Chung and colleagues.' These investigators reported increased immunoglobulin (IgG and IgM) antibody titers for medium-size spirochetes and *prevotella intermedia* in NUG patients compared with titers in those with chronic gingivitis and healthy controls. Cogen and colleagues10 described a depression in host defense mechanisms, particularly in MIN chemotaxis and phagocytosis, in NUG patients. For further details on the host-bacteria interactions in NUG, see Chapters 6, 8, and 9.

NUG has not been produced experimentally in humans or animals by inoculation of bacterial exudates from the lesions. Exudates from NUG produce fusospirochetal abscesses when inoculated subcutaneously in experimental animals, and the infection is freely transmissible in series.58 Local intracutaneous injection of a hyaluronidase- and chondroitinase-containing cell-free filtrate of oral microaerophilic diphtheroid bacilli aggravated spirochetal lesions that were produced by oral treponemes.[31] Only in one animal experiment has the transmission of lesions comparable with those seen in humans been reported.2

The specific cause of NUG has not been established. The prevalent opinion is that it is produced by a complex of bacterial organisms but requires underlying tissue changes to facilitate the pathogenic activity of the bacteria.

Local Predisposing Factors. Preexisting gingivitis, injury to the gingiva, and smoking are important predisposing factors. Although NUG may appear in an otherwise disease-free mouth, it most often occurs superimposed on preexisting chronic gingival disease and periodontal pockets. Deep periodontal pockets and pericoronal flaps are particularly vulnerable areas because they offer a favorable environment for the proliferation of anaerobic fusiform bacilli and spirochetes. Areas of the gingiva traumatized by opposing teeth in malocclusion, such as the palatal surface behind the maxillary incisors and the labial gingival surface of the mandibular incisors, are frequent sites of NUG.

The *relationship between NUG and smoking* has often been mentioned in the literature. Pindborg[52] reported that 98% of his patients with NUG were smokers and that the frequency of this disease increases with an increasing exposure to tobacco smoke. The effect of smoking on periodontal disease in general has been the subject of numerous studies in the past two decades, and it has been established that it is a high risk factor for this disease. For an in-depth consideration of this important topic see Chapter 14.

Systemic Predisposing Factors. NUG is often superimposed on gingival alterations caused by severe systemic disease.

NUTRITIONAL DEFICIENCY. Necrotizing gingivitis has been produced by giving animals nutritionally deficient diets.[7,36,46,73,76] Several researchers found an increase in the fusospirochetal flora in the mouths of the experimental animals, but the bacteria were regarded as opportunists, proliferating only when the tissues were altered by the deficiency. A poor diet has been mentioned as a predisposing factor in NUG and its sequelae in developing African countries, although the effects appear to be primarily in diminishing the effectiveness of the immune response.[19,20,33]

Nutritional deficiencies (e.g., vitamin C, vitamin [132]) accentuate the severity of the pathologic changes induced when the fusospirochetal bacterial complex is injected into animals .[68]

DEBILITATING DISEASE. Debilitating systemic disease may predispose the development of NUG. Included among such systemic disturbances are chronic diseases such as syphilis and cancer, severe gastrointestinal disorders such as ulcerative colitis, blood dyscrasias such as the leukemias and anemia, and acquired immunodeficiency syndrome (AIDS). Nutritional deficiency resulting from debilitating disease may be an additional predisposing factor. Experimentally induced leukopenia in animals may produce ulcerative gangrenous stomatitis.[46,71,72,75] Ulceronecrotic lesions appear in the gingival margins of hamsters exposed to total body irradiation[41]; these lesions can be prevented with systemic antibiotics.[42]

Psychosomatic Factors. Psychologic factors appear to be important in the etiology of NUG. The disease often occurs in association with stress situations (induction into the armed forces or school examinations).[26] Psychological disturbances,[27] as well as increased adrenocortical secretion,[64] are common in patients with the disease.

Significant correlation between disease incidence and two personality traits, dominance and abasement, suggests the presence of an NUG-prone personality.[23] The mechanisms whereby psychologic factors create or predispose to gingival damage have not been established, but alterations in digital and gingival capillary responses suggestive of increased autonomic nervous activity have been demonstrated in patients with NUG.[25]

Cogen-Cole and colleagues" suggested that a psychiatric disturbance (e.g., trait anxiety, depression, and psychopathic deviance) and the impact of negative life events (stress) may lead to activation of the hypothalamic-pituitary-adrenal axis. This results in elevation of serum and urine cortisol levels, which is associated with a depression of lymphocyte and PMN function that may predispose to NUG.

It can be concluded that opportunistic bacteria are the primary etiologic agents of NUG in patients that demonstrate immunosuppression. Stress, smoking and preexisting gingivitis are common predisposing factors.

Epidemiology and Prevalence

NUG often occurs in groups in an epidemic pattern. At one time, it was considered contagious, but this has not been substantiated.[61]

The prevalence of NUG appears to have been rather low in the United States and Europe before 1914. During World Wars I and II, numerous "epidemics" broke out among the Allied troops, but German soldiers did not seem to have been similarly affected. Similar epidemic-like outbreaks have occurred among civilian populations. In a study conducted at a dental clinic in Prague, Czech Republic, the following incidence of NUG was reported: 0.08% in patients between ages 15 and 19, 0.05% in those between ages 20 and 24, and 0.02% in those between ages 25 and 29.[6]

NUG occurs at all ages," with the highest incidence reported between ages 20 and 30[14,69] and ages 15 and 20 years.[67] It is not common in children in the United States, Canada, and Europe, but it has been reported in children from low socioeconomic groups in underdeveloped countries." In India, 54%[52] and 58%[53] of the patients in two studies were under age 10. In a random school population in Nigeria, NUG occurred in 11.3% of children between the ages of 2 and 6 years,[65] and in a Nigerian hospital population, it was present in 23% of children under age 10.[18] It has been reported in several members of the same family in low socioeconomic groups. NUG is more common in children with Down syndrome than in other children with mental deficiencies.[4]

Opinions differ as to whether it is more common during the winter,[50] summer, or fall'[67] or whether there is a peak seasonal incidence.[15]

Communicability

A distinction must be made between communicability and transmissibility when referring to the characteristics of disease. The term *transmissible* denotes a capacity for the maintenance of an infectious agent in successive passages through a susceptible animal hosts' The term *communicable* signifies a capacity for the maintenance of infection by natural modes of spread such as direct contact through drinking water, food, and eating utensils; via the airborne route; or by means of arthropod vectors. A disease that is communicable is described as *contagious.* It has been demonstrated that disease associated with the fusospirochetal bacterial complex is transmissible; *however, it has not been shown to be communicable or contagious.*

Attempts have been made to spread NUG from human to human, without success.[62] King[36] traumatized an area in his gingiva and introduced debris from a patient with a severe case of NUG. There was no response until he happened to fall ill shortly thereafter; subsequent to his illness, he observed the characteristic lesion in the experimental area. It may be inferred with reservation from this experiment that systemic debility is a prerequisite for the contagion of NUG.

It is a common impression that, because NUG often occurs in groups using the same kitchen facilities, the disease is spread by bacteria on eating utensils. Growth of fusospirochetal organisms requires carefully controlled conditions and an anaerobic environment; they do not ordinarily survive on eating utensils.[31]

The occurrence of the disease in epidemic-like outbreaks does not necessarily mean that it is contagious. The affected groups may be afflicted by the disease because of common predisposing factors rather than because of its spread from person to person. In all likelihood, both a predisposed immunocompromised host and the presence of appropriate bacteria are necessary for the production of this disease.

PRIMARY HERPETIC GINGIVOSTOMATITIS

Primary herpetic gingivostomatitis is an infection of the oral cavity caused by the herpes simplex virus type 1 (HSV-1).[15,44] It occurs most often in infants and children younger than 6 years of age[6,63] but it is also seen in adolescents and adults. It occurs with equal frequency in male and female patients. In most persons, however, the primary infection is asymptomatic.

After the primary infection, the virus ascends through sensory and autonomic nerves and persists in neuronal ganglia that innervate the site as latent HSV. In approximately one third of the world's population, secondary manifestations occur as a result of various stimuli such as sunlight, trauma, fever, or stress. These secondary manifestations include herpes labialis (Fig. 19-5), herpes genitalis, ocular herpes, and herpetic encephalitis.

Clinical Features

Oral Signs. The condition appears as a diffuse, erythematous, shiny involvement of the gingiva and the adjacent oral mucosa, with varying degrees of edema and gingival bleeding (see Color Fig. 19-1, E). In **its initial stage, it is characterized** by the presence of discrete, spherical gray vesicles (see Color Fig. 19-1, F), which may occur on the gingiva, labial and buccal mucosae,

Fig. 19-5 Cluster of herpetic vesicles (cold sores).

soft palate, pharynx, sublingual mucosa, and tongue (Fig. *19-6).* After approximately *24* hours the vesicles rupture and form painful, small ulcers with a red, elevated, halolike margin and a depressed, yellowish- or grayish-white central portion. These occur either in widely separated areas or in clusters where confluence occurs (Figs. *19-7* and *19-8).*

Occasionally, primary herpetic gingivitis may occur without overt vesiculation. Diffuse, erythematous, shiny discoloration and edematous enlargement of the gingivae with a tendency toward bleeding make up the clinical picture.

The course of the disease is limited to *7* to 10 days. The diffuse gingival erythema and edema that appear early in the disease persist for several days after the ulcerative lesions have healed. Scarring does not occur in the areas of healed ulcerations.

Oral Symptoms. The disease is accompanied by generalized "soreness" of the oral cavity, which interferes with eating and drinking. The ruptured vesicles are the focal sites of pain and are particularly sensitive to touch, thermal changes, foods such as condiments and fruit juices, and the action of coarse foods. In infants the disease is marked by irritability and refusal to take food.

Extraoral and Systemic Signs and Symptoms. Cervical adenitis, fever as high as 101° F to 105° F *(38.3° C* to *40.6° C),* and generalized malaise are common.

History. Recent acute infection is a common feature of the history of patients with primary herpetic gingivostomatitis. The condition often occurs during and immediately after an episode of such febrile diseases as pneumonia, meningitis, influenza, and typhoid. It also tends to occur during periods of anxiety, strain, or exhaustion, as well as during menstruation. A history of exposure to patients with herpetic infection of the oral cavity or lips may also be elicited. Primary herpetic gingivostomatitis often occurs in the early stage of infectious mononucleosis.[47]

Histopathology. The virus targets the epithelial cells, which show "ballooning degeneration" consisting of acantholysis, nuclear clearing and nuclear enlargement. These cells are called *Tzanck cells.* Infected cells fuse, forming multinucleated cells, and intercellular edema leads to formation of an intraepithelial vesicles that rupture and develop a secondary inflammatory response with a fibropurulent exudate.[48] Discrete ulcerations resulting from rupture of the vesicles have a central portion of acute inflammation, with varying degrees of purulent exudate, surrounded by a zone rich in engorged blood vessels.

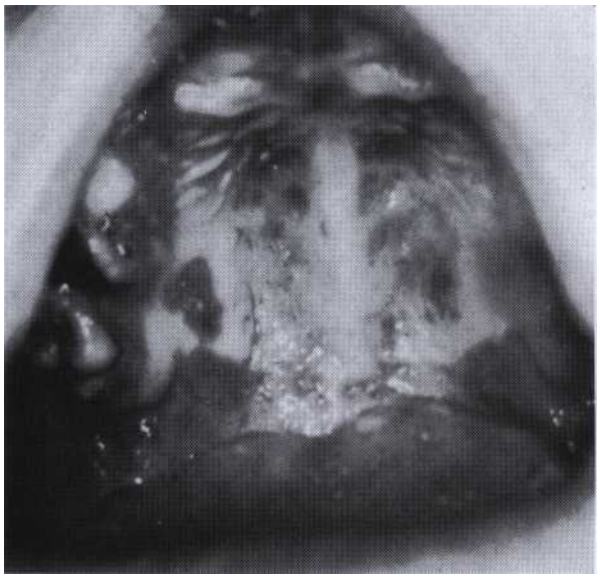

Fig. 19-7 Involvement of the palate in primary herpetic gingivostomatitis.

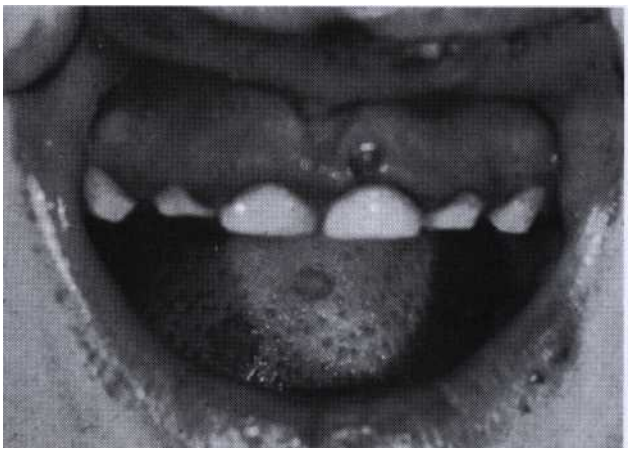

Fig. 19-6 Vesicles on the tongue in primary herpetic gingivostomatitis.

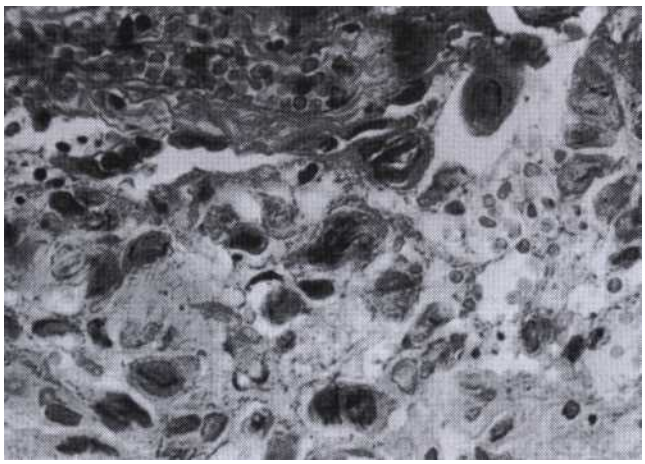

Fig. 19-8 Biopsy showing giant cells at base of herpetic lesion.

Diagnosis

The diagnosis is usually established from the patient's history and the clinical findings. Material may be obtained from the lesions and submitted to the laboratory for confirmatory tests, including virus culture and immunologic tests using monoclonal antibodies or DNA hybridization techniques.[6-24,55]

Differential Diagnosis

Primary herpetic gingivostomatitis should be differentiated from the following conditions. NUG can be differentiated in different ways (see Table 19-1).

Erythema multi forme can be differentiated because the vesicles in erythema multiforme are generally more extensive than those in primary herpetic gingivostomatitis and on rupture demonstrate a tendency toward pseudomembrane formation. In addition, in the former condition the tongue is usually markedly involved, with infection of the ruptured vesicles resulting in varying degrees of ulceration. Oral involvement in erythema multiforme may be accompanied by skin lesions. The duration of erythema multiforme may be comparable with that of primary herpetic gingivostomatitis, but prolonged involvement for a period of weeks is not uncommon.

Stevens-Johnson syndrome is a comparatively rare form of erythema multiforme, characterized by vesicular hemorrhagic lesions in the oral cavity, hemorrhagic ocular lesions, and bullous skin lesions.

Bullous lichen planus is a very rare and painful condition. It is characterized by large blisters on the tongue and cheek that rupture and undergo ulceration; it runs a prolonged, indefinite course. Patches of linear, gray, lacelike lesions of lichen planus are often interspersed among the bullous eruptions. Lichen planus involvement of the skin may coexist with the oral lesions and facilitate differential diagnosis.

Desquamative gingivitis is characterized by diffuse involvement of the gingiva, with varying degrees of "peeling" of the epithelial surface and exposure of the underlying tissue. It is a chronic condition (see Chapter 21).

Lesions of *recurrent aphthous stomatitis (RAS)*[21] Fig. 19-9) range from occasional small (0.5 to 1 cm in diameter), well-defined, round or ovoid, shallow ulcers with a yellowish-gray central area surrounded by an erythematous halo, which heal in 7 to 10 days without scarring, to larger (1 to 3 cm in diameter) oval or irregular ulcers, which persist for weeks and heal with scarring. The cause is unknown, although immunopathologic mecanisms appear to play a role. RAS is a different clinical entity from primary herpetic gingivostomatitis. The ulcerations may look the same in the two conditions, but diffuse erythematous involvement of the gingiva and acute toxic systemic symptoms do not occur in RAS.

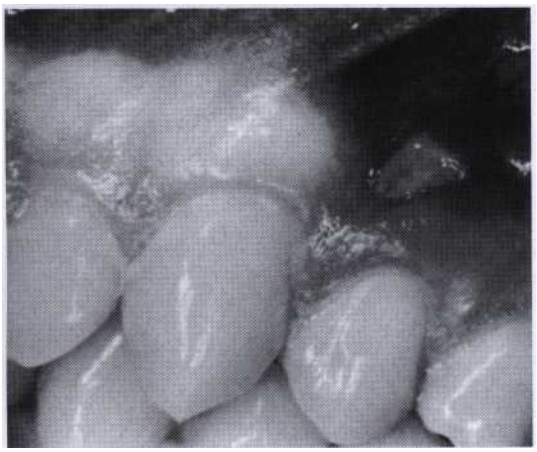

Fig. 19-9 Aphthous lesion in the mucobuccal fold. The depressed gray center is surrounded by an elevated red border.

Communicability

Primary herpetic gingivostomatitis is contagious.[8,39] Most adults have developed immunity to HSV as the result of infection during childhood, which in most instances is subclinical. For this reason acute herpetic gingivostomatitis usually occurs in infants and children. Although recurrent herpetic gingivostomatitis has been

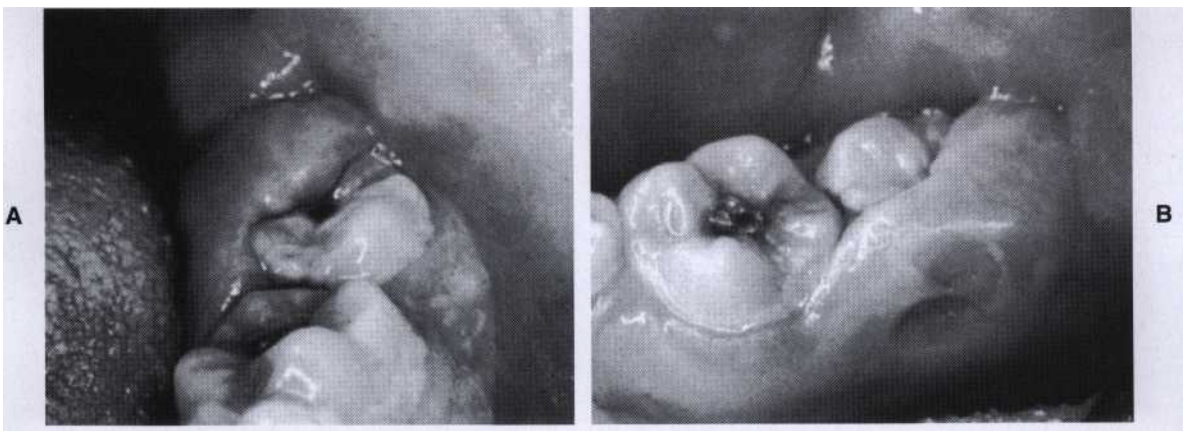

Fig. 19-10 Pericoronitis. A, Third molar partially covered by infected flap. B, Lingual view showing sinus draining from infected flap.

reported,[3°] it does not ordinarily recur unless immunity is destroyed by debilitating systemic disease. Secondary herpetic infection of the skin, such as herpes labialis, does recur.[b]

PERICORONITIS

The term *pericoronitis* refers to inflammation of the gingiva in relation to the crown of an incompletely erupted tooth (Fig. 19-10). It occurs most often in the mandibular third molar area. Pericoronitis may be acute, subacute, or chronic.

Clinical Features

The partially erupted or impacted mandibular third molar is the most common site of pericoronitis. The space between the crown of the tooth and the overlying gingival flap is an ideal area for the accumulation of food debris and bacterial growth. Even in patients with no clinical signs or symptoms, the gingival flap is often chronically inflamed and infected and has varying degrees of ulceration along its inner surface. Acute inflammatory involvement is a constant possibility.

Acute pericoronitis is identified by varying degrees of inflammatory involvement of the pericoronal flap and adjacent structures as well as systemic complications. The inflammatory fluid and cellular exudate increase the bulk of the flap, which then may interfere with complete closure of the jaws, and can be traumatized by contact with the opposing jaw, aggravating the inflammatory involvement.

The resultant clinical picture is that of a markedly red, swollen, suppurating lesion that is exquisitely tender, with radiating pains to the ear, throat, and floor of the mouth. The patient is extremely uncomfortable because of a foul taste and an inability to close the jaws, in addition to the pain. Swelling of the cheek in the region of the angle of **the jaw and lymphadenitis are** common findings. The patient may also have toxic systemic complications such as fever, leukocytosis, and malaise.

Complications

The involvement may become localized in the form of a pericoronal abscess. It may spread posteriorly into the oropharyngeal area and medially to the base of the tongue, making it difficult for the patient to swallow. Depending on the severity and extent of the infection, there is involvement of the submaxillary, posterior cervical, deep cervical, and retropharyngeal lymph nodes.[34,51] Peritonsillar abscess formation, cellulitis, and Ludwig's angina are infrequent but potential sequelae of acute pericoronitis.

Formation of the Gingival Margin
Normal Prominence of the Gingival Margin
TYPES OF GINGIVAL DISEASE
Chronic Marginal Gingivitis
Localized Gingival Recession
Acute Gingival Infections
TRAUMATIC CHANGES IN THE PERIODONTIUM
THE ORAL MUCOUS MEMBRANE IN CHILDHOOD DISEASES

The effects of periodontal disease observed in adults have their inception earlier in life. Gingival disease in the child may progress to jeopardize the periodontium of **the adult.**

The developing dentition and certain systemic metabolic patterns are peculiar to childhood. There are also gingival and periodontal disturbances that occur more often in childhood and are therefore identified with this period. Consequently, some degree of coherence is provided by considering gingival and periodontal problems in childhood and in adolescence separately. This chapter will cover gingival diseases; juvenile forms of periodontitis are covered in Chapter 28.

THE PERIODONTIUM OF THE DECIDUOUS DENTITION

The gingiva of the deciduous dentition is pale pink and firm and may be either smooth or stippled (stippling is found in 35% of children between ages 5 and 13 years)[26] (Fig. 20-1). The interdental gingiva is broad faciolingually and tends to be relatively narrow mesiodistally, in conformity with the contour of the approximal tooth surfaces. Its structure is comparable to that of the adult in that it consists of a facial papilla and a lingual papilla with an intervening depression, or col.

The mean gingival sulcus depth for the primary dentition is 2.1 mm ± 0.2 mm.[4] The width of the attached gingiva is greater in the incisor area, decreases over the cuspids, and increases again over premolars (primary molars) and permanent molars .z' The attached gingiva increases in width with age.

Microscopically, the stratified squamous epithelium of the gingiva presents well-differentiated rete pegs with a parakeratinized (Fig. 20-2) or keratinized surface, the latter correlated with stippling. The connective tissue is predominantly fibrillar, but the well-differentiated collagen bundles seen in the adult are not present in childhood. The epithelium covering the Col is a few cells thick and nonkeratinized.

The periodontal ligament of the deciduous teeth is wider than that of the permanent dentition. During eruption the principal fibers are parallel to the long axis of the teeth; the bundle arrangement seen in the adult dentition occurs when the teeth encounter their functional antagonists.

Radiographically, the alveolar bone in relation to the deciduous dentition shows a prominent lamina dura, both in the crypt stage and during eruption. The trabeculae of the alveolar bone are fewer but thicker than in the adult, and the marrow spaces tend to be larger. The crests of the interdental septa are flat.'

Oral flora and dental plaque in childhood are discussed in **Chapter 6.**

PHYSIOLOGIC GINGIVAL CHANGES ASSOCIATED WITH TOOTH ERUPTION

During the transition period in the development of the dentition, changes associated with eruption of the permanent teeth occur in the gingiva. It is important to recognize these physiologic changes and to differentiate them from the gingival disease that often accompanies tooth eruption.

Preemption Bulge

Before the crown appears in the oral cavity, the gingiva presents a bulge that is firm, may be slightly blanched, and conforms to the contour of the underlying crown.

Formation of the Gingival Margin

The marginal gingiva and sulcus develop as the crown penetrates the oral mucosa. In the course of eruption the gingival margin is usually edematous, rounded, and slightly reddened (Fig. 20-3).

Normal Prominence of the Gingival Margin

During the period of mixed dentition, it is normal for the marginal gingiva around the permanent teeth to be quite prominent, particularly in the maxillary anterior region. At this stage in tooth eruption the gingiva is still attached to the crown, and it appears prominent when superimposed on **the** bulk of the underlying enamel (Fig. 20-4).

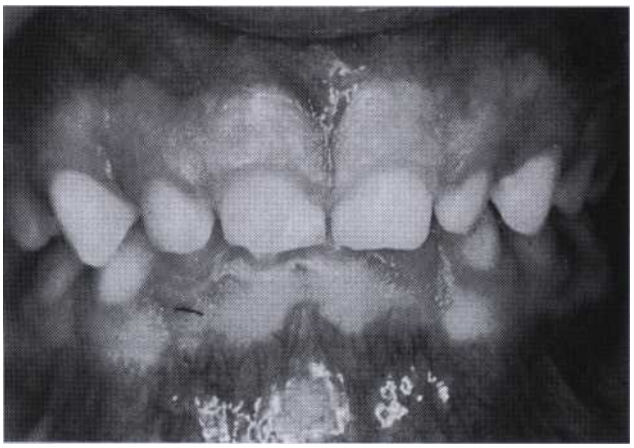

Fig. 20-1 Deciduous dentition with stippled gingiva.

TYPES OF GINGIVAL DISEASE

Chronic Marginal Gingivitis

Chronic marginal gingivitis is the most prevalent type of gingival change in childhood. The gingiva exhibits all the changes in color, size, consistency, and surface texture characteristic of chronic inflammation. A fiery red

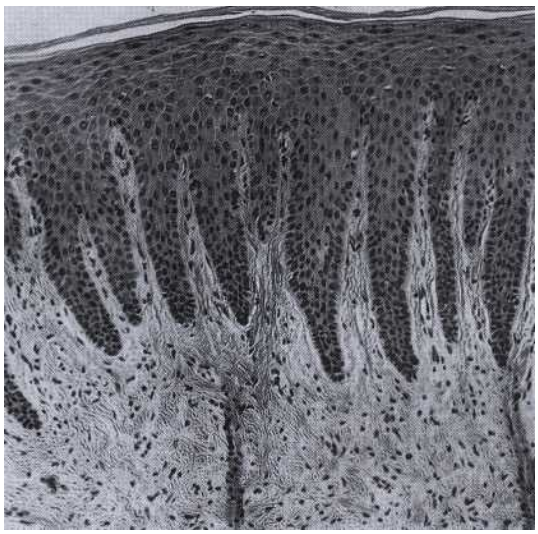

Fig. 20-2 Normal gingiva in a 4-year-old patient showing stratified squamous epithelium with rete pegs and surface keratinization. The papillary arrangement of the underlying connective tissue can also be seen.

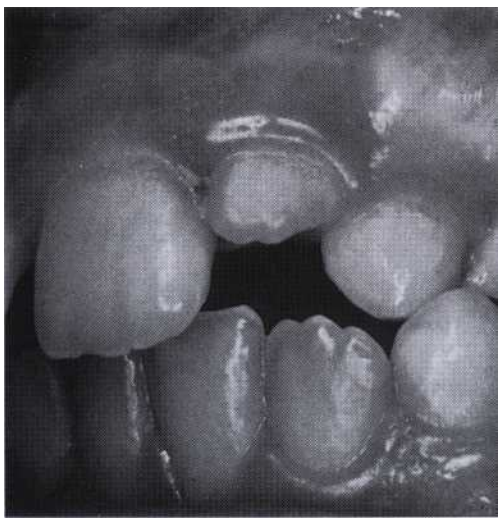

Fig. 20-3 Gingivitis associated with tooth eruption. Note the prominent rolled gingival margin, which is slightly inflamed and edematous around the erupting maxillary lateral incisor.

surface discoloration is often superimposed on underlying chronic changes. Gingival color change and swelling appear to be more common expressions of gingivitis in children than are bleeding and increased pocket depths

Etiology. In children, as in adults, the cause of gingivitis is plaque; local conditions such as *materia alba* and poor oral hygiene favor its accumulation (Fig. 20-5). In preschool children, however, the gingival response to bacterial plaque has been found to be markedly less than that in adults."," Dental plaque appears to form more rapidly in children age 8 to 12 years than in adults.

Calculus is uncommon in infants; it occurs in approximately 9% of children ages 4 to 6, in 18% of those ages 7 to 9, and in 33% to 43% of those ages 10 to 15. In children with cystic fibrosis, calculus formation is more common (occurring in 77% of those ages 7 to 9 and in 90% of those ages 10 to 15) and more severe; this is probably related to increased concentrations of phosphate, calcium, and protein in the saliva.[2°]

Gingivitis associated with tooth eruption is frequent and has given rise to the term eruption gingivitis. However, tooth eruption per se does not cause gingivitis. The inflammation results from plaque accumulation around erupting teeth. The initiation of gingivitis appears to be related to plaque accumulation rather than to tissue remodeling associated with eruption." Plaque retention around deciduous teeth facilitates plaque formation around juxtaposed permanent teeth." The inflammatory changes accentuate the normal prominence of the gingival margin and may create the impression of a marked gingival enlargement (Fig. 20-6).

Partially exfoliated, loose deciduous teeth often cause gingivitis. The eroded margin of partially resorbed teeth favors plaque accumulation, which causes gingival changes varying from slight discoloration and edema to abscess formation with suppuration. Other factors favoring plaque buildup are food impaction and *materia alba* accumulation around teeth partially destroyed by caries. Children often develop unilateral chewing habits to avoid loose or carious teeth, aggravating the accumulation of plaque on the nonchewing side.

Gingivitis occurs more often and with greater severity around malposed teeth because of their increased tendency to accumulate plaque and *materia alba.* Severe changes include gingival enlargement, bluish-red discoloration, ulceration (Fig. 20-7), and the formation of deep pockets from which pus can be expressed. Gingival health and contour are restored by correction of the malposition (Figs. 20-8 and 20-9); plaque elimination; and, when necessary, surgical removal of the enlarged gingiva.

Gingivitis is increased in children with *excessive overbite* and *overjet, nasal obstruction,* and *mouth-breathing habit.*

According to Maynard and Wilson," mucogingival problems start in the primary dentition as a consequence of developmental aberrations in eruption and deficiencies in the thickness of the periodontium. If there is also inadequate plaque control or excessive toothbrushing trauma, a mucogingival problem develops. However, the width of the attached gingiva increases with age, and these problems may resolve.

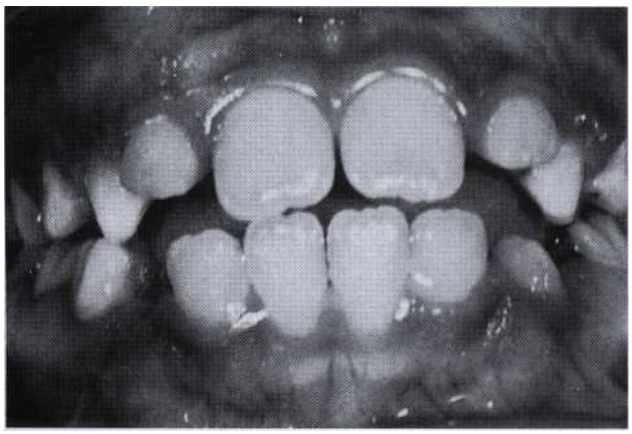

Fig. 20-4 Prominent marginal gingiva on the cervical third of partially erupted maxillary anterior teeth.

Fig. 20-5 Chronic marginal gingivitis associated with plaque and *materia olba.*

Fig. 20-6 Developmental gingival enlargement caused by inflammation superimposed on the normal prominence of the teeth at this stage of tooth eruption.

Histopathology. Chronic gingivitis in children[13,14] is characterized by loss of collagen in the area around the junctional epithelium, an important vascular component, and an infiltrate consisting mostly of lymphocytes and small numbers of polymorphonuclear leukocytes, plasma cells, monocytes, mast cells, fibroblasts, and endothelial cells.

The composition of the inflammatory infiltrate in gingivitis in children has given rise to controversy. According to Gillett and colleagues,' the inflammatory infiltrate is composed mostly of untransformed B lymphocytes, and the resulting clinical lesions are nondestructive and nonprogressive. This may also characterize the composition of the infiltrate in quiescent lesions in adults. According to Longhurst et al 13.14 and Seymour et al ,25 the infiltrate is predominantly composed of T cells that shift to B cells (plasma cells) when the lesion becomes destructive.

A higher prevalence and severity of gingivitis and gingival enlargement is found in the circumpubertal period; this form of gingivitis has been termed pubertal gingivitis. The most frequent manifestation is a significant increase in bleeding interdental sites." This inflammatory lesion may include a gingival enlargement as a result of hormonal changes that magnify the tissue response to dental plaque. It occurs in males and females and resolves partially after puberty (see Chapter 18).

Localized Gingival Recession

Gingival recession around individual teeth or groups of teeth is a common source of concern. The gingiva may be inflamed or free of disease, depending on the presence or absence of local irritants. There are many causes of gingival recession (see Chapter 17), but in children the position of the tooth in the arch is the most important.22 Gingival recession occurs on teeth in labial version (Fig. 20-10) and on those that are tilted or rotated so that the roots project labially. Anterior open bite increases the prevalence of gingival recession." The recession may be a transitional phase in tooth eruption and may correct itself when the teeth attain proper alignment, or it may be necessary to realign the teeth orthodontically.3

Acute Gingival Infections

Primary Herpetic Gingivostomatitis. This is the most common type of acute gingival infection in childhood and often occurs as a sequela of upper respiratory tract infection (see Chapter 19).

Candidiasis. This is a mycotic infection of the oral cavity caused by the fungus *Candida albicans.* For a complete discussion, see Chapter 21.

Necrotizing Ulcerative Gingivitis. The incidence of necrotizing ulcerative gingivitis (NUG) in childhood is low (see Chapter 19). In children living in areas

Fig. 20-7 Severe gingivitis associated with accumulation of plaque around malposed teeth.

Fig. 20-8 Gingival enlargement in relation to malposed maxillary lateral and canine teeth (left side).

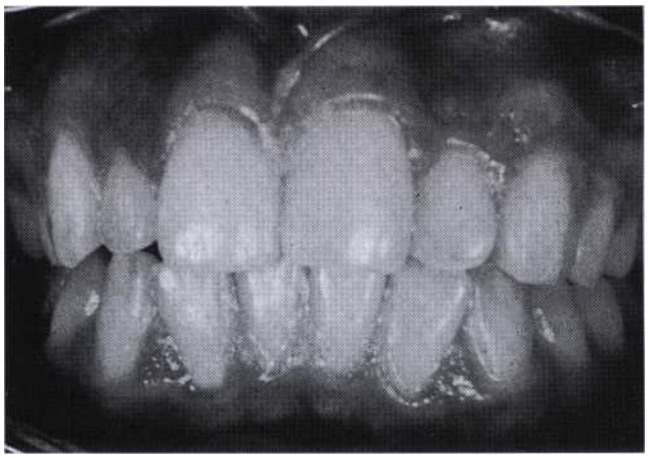

Fig. 20-9 Disappearance of the gingival enlargement shown in Fig. 20-8 after orthodontic correction of the malposed teeth.

Fig. 20-10 Gingival recession on labially positioned mandibular central incisors.

where chronic malnutrition is common and in children with Down syndrome, the incidence and severity of NUG are increased. [11,23] Primary herpetic gingivostomatitis, which is more common in childhood, is occasionally erroneously diagnosed as NUG.

TRAUMATIC CHANGES IN THE PERIODONTIUM

Traumatic changes may occur in the periodontal tissues of deciduous teeth under several conditions. In the process of shedding deciduous teeth, resorption of teeth and bone weakens the periodontal support so that the existing functional forces are injurious to the remaining supporting tissues.' Excessive occlusal forces may be produced by malalignment, mutilation, loss or extraction of teeth, or dental restorations. In the mixed dentition stage, the periodontium of the permanent teeth may be traumatized, because the permanent teeth bear an increased occlusal load when the adjacent deciduous teeth are shed. The periodontal ligament of an erupting permanent tooth may be injured by occlusal forces transmitted through the deciduous tooth it is replacing.9

Microscopically,[12,21] the least severe traumatic changes involve compression, ischemia, and hyalinization of the periodontal ligament. With severe injury there is crushing and necrosis of the periodontal ligament (see Chapter 24).

In most instances the injuries are repaired, and tooth loss does not result. However, traumatized teeth may be sore or loose. Repair may result in ankylosis of the tooth to the bone, fixing the tooth in situ. When the permanent dentition erupts, ankylosed deciduous teeth appear to be submerged.

THE ORAL MUCOUS MEMBRANE IN CHILDHOOD DISEASES

Some childhood diseases present specific alterations in the oral mucosa, including the gingival tissues. Among these are the communicable diseases, such as varicella (chickenpox), rubeola (measles), scarlatina (scarlet fever), and diphtheria. For a more thorough discussion of this topic, the reader is referred to books in oral and pediatric pathology.

MISCELLANEOUS

CHRONIC DESQUAMATIVE GINGIVITIS

Although first recognized and reported in 1894,[118] the term *chronic desquamative gingivitis* was coined in 1932 by Prinz[92] to describe a peculiar condition characterized by intense erythema, desquamation, and ulceration of the free and attached gingiva (Fig. 21-1). Patients may be asymptomatic, however, when symptomatic, their complaints range from a mild burning sensation to an intense pain. Approximately 50% of desquamative gingivitis cases are localized to the gingiva, although involvement of the gingiva plus other intraoral and even extraoral sites is not uncommon.[8s] Initially, the cause of this condition was unclear with a variety of possibilities suggested. Because most cases were diagnosed in women in the fourth to fifth decades of life (although desquamative gingivitis may occur as early as puberty or as late as the seventh or eighth decades), a hormonal derangement was suspected.* However, in 1960 McCarthy and colleagues[72] suggested that *desquamative gingivitis was not a specific disease entity, but a gingival response associated with a variety o f conditions.* This concept has been further supported by numerous immunopathologic studies.[57,86,97,113]

Use of clinical and laboratory parameters have revealed that approximately 75% of **desquamative gingivitis cases have** a dermatologic genesis. Cicatricial pemphigoid and lichen planus account for over 95% of the dermatologic cases.[85] However, many other mucocutaneous autoimmune conditions such as bullous pemphigoid, pemphigus vulgaris, linear immunoglobulin A (IgA), dermatitis herpetiformis, lupus erythematosus, and chronic ulcerative stomatitis can clinically manifest as desquamative gingivitis.[103]

Other conditions that must be considered in the differential diagnosis of desquamative gingivitis include chronic bacterial, fungal, and viral infections, as well as reactions to medications, mouthwashes, and chewing gum. Although less common, Crohn's disease, sarcoidosis, some leukemias, and even factitious lesions have also been reported to clinically present as desquamative gingivitis.[103,122]

* See references 37, 42, 75, 92, 114, 124, and 125.

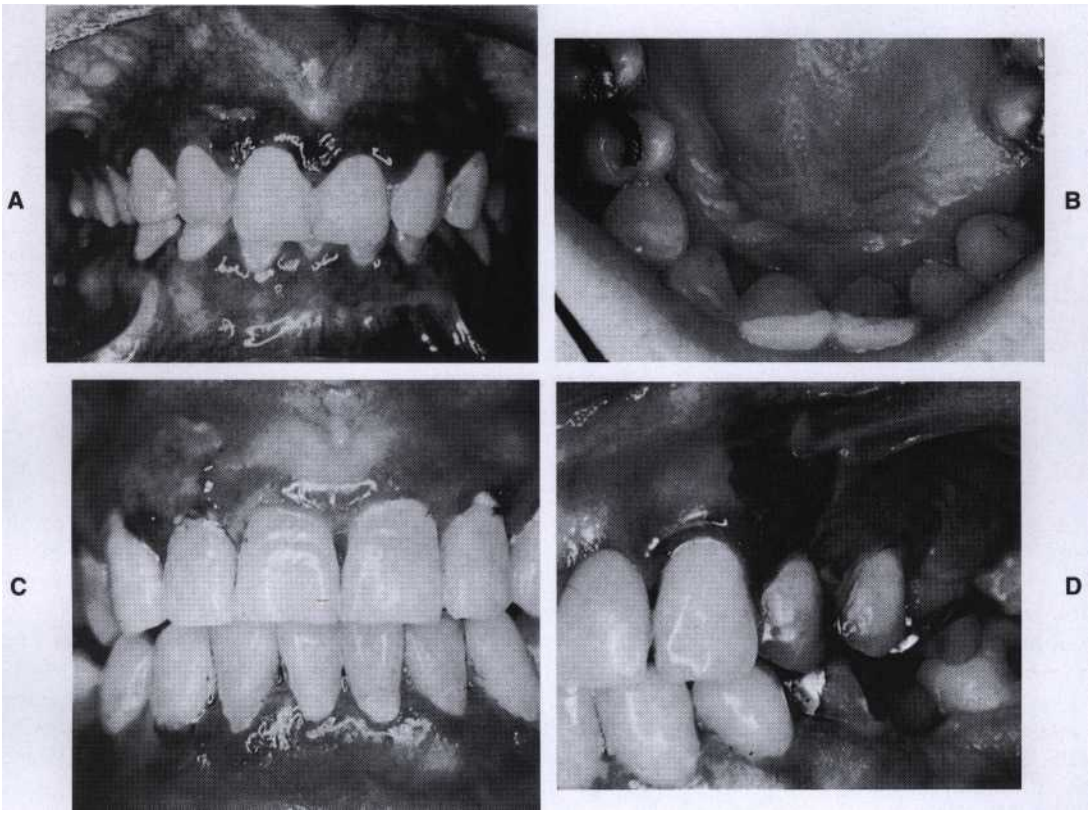

Fig. 21-1 Chronic desquamative gingivitis of varied severity. A, Moderate, with generalized edema and erythema associated with inflammation and exposure of underlying connective tissue. B, Lingual view of patient shown in A. Aside from slight marginal erythema, there is little evidence of change in the gingiva and adjacent mucosa. C, Severe, with scattered, irregularly shaped, denuded areas producing a mosaic appearance. Note the ulceration between the right maxillary lateral and canine teeth. D, Severe, with complete denudation of the epithelium and exposure of underlying erythematous inflamed connective tissue. (Courtesy Dr. Gerald Shklar, Boston, Mass.)

Therefore it is of paramount importance to ascertain the identity of the disease responsible for desquamative gingivitis to establish the appropriate therapeutic approach and management. To achieve this goal, the clinical examination has to be coupled with a thorough history, and routine histologic and immunofluorescent studies.[122] It should be mentioned, however, that despite this diagnostic approach, the cause of desquamative gingivitis cannot be elucidated in up to one third of the cases.[93]

DIAGNOSIS OF DESQUAMATIVE GINGIVITIS: A SYSTEMATIC APPROACH

The previous sections have made clear that *desquamative* gingivitis is only a clinical term that describes a peculiar clinical picture. This term is not a diagnosis per se and once it is rendered, a series of laboratory procedures should be used to arrive to a final diagnosis. Thus the success of any given therapeutic approach resides on the establishment of an accurate final diagnosis. The following represents a systematic approach to elucidate the disease triggering desquamative gingivitis. This approach is also illustrated in Fig 21-2.

Clinical History. A thorough clinical history is mandatory to begin the assessment of desquamative gingivitis. Data regarding the symptomatology associated with this condition, as well as its historical aspects (i.e., when did the lesion start, has it gotten worse, is there a habit that exacerbates the condition, etc.), provide the foundation for a thorough examination. Information regarding previous therapy that has been directed to alleviate the condition should also be documented.

Clinical Examination. Recognition of the pattern of distribution of the lesions (i.e., focal or multifocal, with or without confinement to the gingival tissues) provides leading information to begin the formulation of a differential diagnosis. In addition, a simple clinical maneuver such as Nikolsky's sign offers insight into the plausibility of the presence of a vesiculobullous disorder.

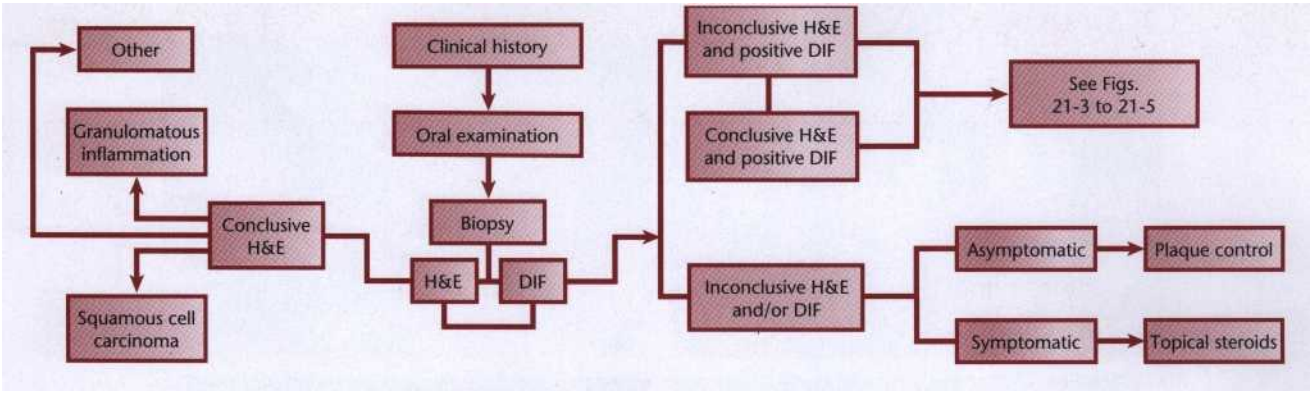

Fig. 21-2 Diagnostic approach for desquamative gingivitis.

Biopsy. Given the extent and number of lesions that may be present in a given individual, an incisional biopsy is the best alternative to begin the microscopic and immunological evaluation. An important consideration is selection of the biopsy site. A perilesional incisional biopsy should avoid areas of ulceration because necrosis and epithelial denudation severely hamper the diagnostic process. Once the tissue is excised from the oral cavity, the specimen can be bisected and then submitted for microscopic examination. Buffered formalin (10%) should be used to fix the tissue for conventional hematoxylin and eosin (H&E) evaluation. Michell's buffer (ammonium sulfate buffer, pH 7.0) is used as transport solution for immunofluorescent assessment. In general, an incisional biopsy of uninvolved (normal) mucosa will show the same immunofluorescent findings as the biopsy of the perilesional tissue. However, there are notable exceptions such as in lichen planus and subacute lupus erythematosus (Table 21-1) where only the lesional tissue will exhibit the corresponding immunologic markers.

Microscopic Examination. Approximately 5-ltm sections of formalin-fixed, paraffin embedded, tissue stained with conventional H&E are obtained for light microscopy examination.

Immunofluorescence. For direct immunofluorescence, unfixed frozen sections are incubated with a variety of fluorescein-labeled, anti-human serum (anti-IgG, anti-IgA, anti-IgM, anti-fibrin and anti-C3). With indirect immunofluorescence, unfixed frozen sections of oral or esophageal mucosa from an animal such as a monkey are first incubated with the patient's serum to allow attachment of any serum antibodies to the mucosal tissue. The tissue is then incubated with fluorescein-labeled anti-human serum (anti-IgG, anti-IgA, anti-IgM, anti-fibrin, and anti-C3). Immunofluorescence tests are positive if a fluorescent signal is observed either in the epithelium, its associated basement membrane or in the underlying connective tissue.

Management. Once the diagnosis is established, the dentist has to choose the optimum management for the patient. This is accomplished according to the following three factors: 1) practitioner's experience, 2) systemic impact of the disease, and 3) systemic complications of the medications.

A detailed consideration of these three factors dictates three different scenarios (Figs. 21-3 to 21-5). In the first one, the dental practitioner takes direct and exclusive responsibility for the treatment of the patient. Such is the case in erosive lichen planus that is responsive to topical steroids. In the second scenario, the dentist collaborates with another health care provider to concurrently evaluate and/or treat a patient. The classic example is seen in cicatricial pemphigoid where dentists and ophthalmologists work together. Although the dentist addresses the oral lesions, the ophthalmologist monitors the integrity of the ocular conjunctiva. The third and final scenario is when the patient is immediately referred to a dermatologist for further evaluation and treatment. This occurs in conditions where the systemic impact of the disease transcends the boundaries of the oral cavity and results in significant morbidity and even mortality. Pemphigus vulgaris is a clear example of a condition that once diagnosed by the dentist requires immediate referral to a dermatologist. In addition, the complications of chronically administered systemic medications that are indicated for the management of diseases such as pemphigus vulgaris or nonresponsive mucous membrane pemphigoid (e.g., diabetes mellitus, osteoporosis, methemoglobinemia, etc.) warrant the referral to a dermatologist or a specialist in internal medicine.

When oral treatment is provided, periodic evaluation is needed to monitor the response of the patient to the selected therapy. Initially, the patient should be evaluated at 2 to 4 weeks after beginning treatment to ensure that the condition is under control. This observation should continue until the patient is free of discomfort. Appointments every 3 to 6 months would then be appropriate. Adjustment to the doses of medication(s) used is expected to occur during this interval. Table 21-2 summarizes suggested contemporary therapeutic approaches commonly used to treat selected conditions that clinically present as desquamative gingivitis. It is clear that dentists play an important role in the diagnosis and management of desquamative gingivitis. The importance

Histopathologic, Direct, and Indirect Immunofluorescence Findings in Selected Conditions That May Present Clinically as Desquamative Gingivitis

		Direct Immunofluorescence		Indirect Immunofluorescence
Disease	**Histopathology**	**Biopsy Perilesional Mucosa**	**Biopsy Uninvolved Mucosa**	**Serum**
Pemphigus	Intraepithelial clefting above the basal cell layer. The basal cells have a **characteristic** "tombstone" appearance. Acantholysis is present.	Intercellular deposits in epithelium; IgG **in all cases,** C3 in most cases.	Same as perilesional mucosa.	Intercellular (IgG) antibodies in >_90% of cases.
Cicatricial pemphigoid	Subepithelial clefting with epithelial separation from the underlying lamina propria, leaving an intact basal layer.	Linear deposits of C3, with or without IgG at the basement membrane zone in almost all cases.	Same as perilesional mucosa.	Basement membrane zone (IgG) antibodies in 10% of cases.
Bullous pemphigoid	Subepithelial clefting with epithelial separation from the underlying lamina propria, leaving an intact basal layer.	Linear deposits of C3, with or without IgG at the basement membrane zone in almost all cases.	Same as perilesional mucosa.	Basement membrane zone (IgG) antibodies in 40% to 70% of cases.
Epidermolysis bullosa acquisita	Similar to bullous and **cicatricial pemphigoid.**	Linear deposits of IgG and C3 at the basement membrane zone in almost all cases.	Same as perilesional mucosa.	Basement membrane zone (IgG) antibodies in 25% of cases.
Lichen planus	Hyperkeratosis, hydropic degeneration of the basal layer, "saw-toothed" rete pegs. The lamina propria exhibits a dense, band-like infiltrate primarily of T lymphocytes. Colloid bodies are present.	Fibrilar deposits of fibrin at the dermal-epidermal junction.	Negative.	Negative.
Chronic ulcerative stomatitis	Similar to erosive lichen planus (hyperkeratosis, acanthosis, basal cell layer liquefaction, subepithelial clefting, and lympho-histiocytic chronic infiltrate in a bandlike configuration.	IgG deposits in nuclei of basal layer epithelial cells.	Same as perilesional mucosa.	ANA specific for basal cells of stratified squamous epithelium.
Linear IgA disease	Similar to erosive lichen planus.	Linear deposits of IgA at the basement membrane zone.	Same as perilesional mucosa.	IgA basement membrane zone (IgA) antibodies in 30% of cases.
Dermatitis herpetiformis	Collection of neutrophils, eosinophils, and fibrin in connective tissue papillae.	IgA deposits in dermal papillae in 85% of cases.	IgA deposits in dermal papillae in 100% of cases.	IgA endomysial antibodies in 70% of cases, gliadin antibodies in 30% of cases.

		Direct Immunofluorescence		Indirect Immunofluorescence
Disease	Histopathology	Biopsy Perilesional Mucosa	Biopsy Uninvolved Mucosa	Serum
Systemic lupus erythematosus	Hyperkeratosis, basal cell degeneration, epithelial atrophy, and perivascular inflammation.	Ig (G or M), with or without C3 deposits at dermal-epidermal junction.	Same as perilesional mucosa.	ANA in more than 95% of cases, DNA and ENA antibodies in more than 50% of cases.
Chronic cutaneous lupus erythematosus	Hyperkeratosis, basal cell degeneration, epithelial atrophy, and perivascular inflammation.	Ig (G or M), with or without C3 deposits at dermal-epidermal junction.	Negative.	Usually negative.
Subacute lupus erythematosus	Less inflammatory cell infiltrate than systemic and chronic cutaneous lupus erythematosus but with similar microscopic features.	Ig (G or M), with or without C3 deposits at dermal-epidermal junction in 60% of cases; granular IgG deposits in basal cell cytoplasm in 30% of cases.	Same as perilesional mucosa.	ANA in 60% to 90%, SS-A (Ro) in 80%, RF in 30%, and RNP in 10% of cases.

Modified from Rinaggio J, Neiders ME, Aguirre A, et al: Using immunofluorescence in the diagnosis of chronic ulcerative lesions of the oral mucosa. Compend 1999; 20:943.

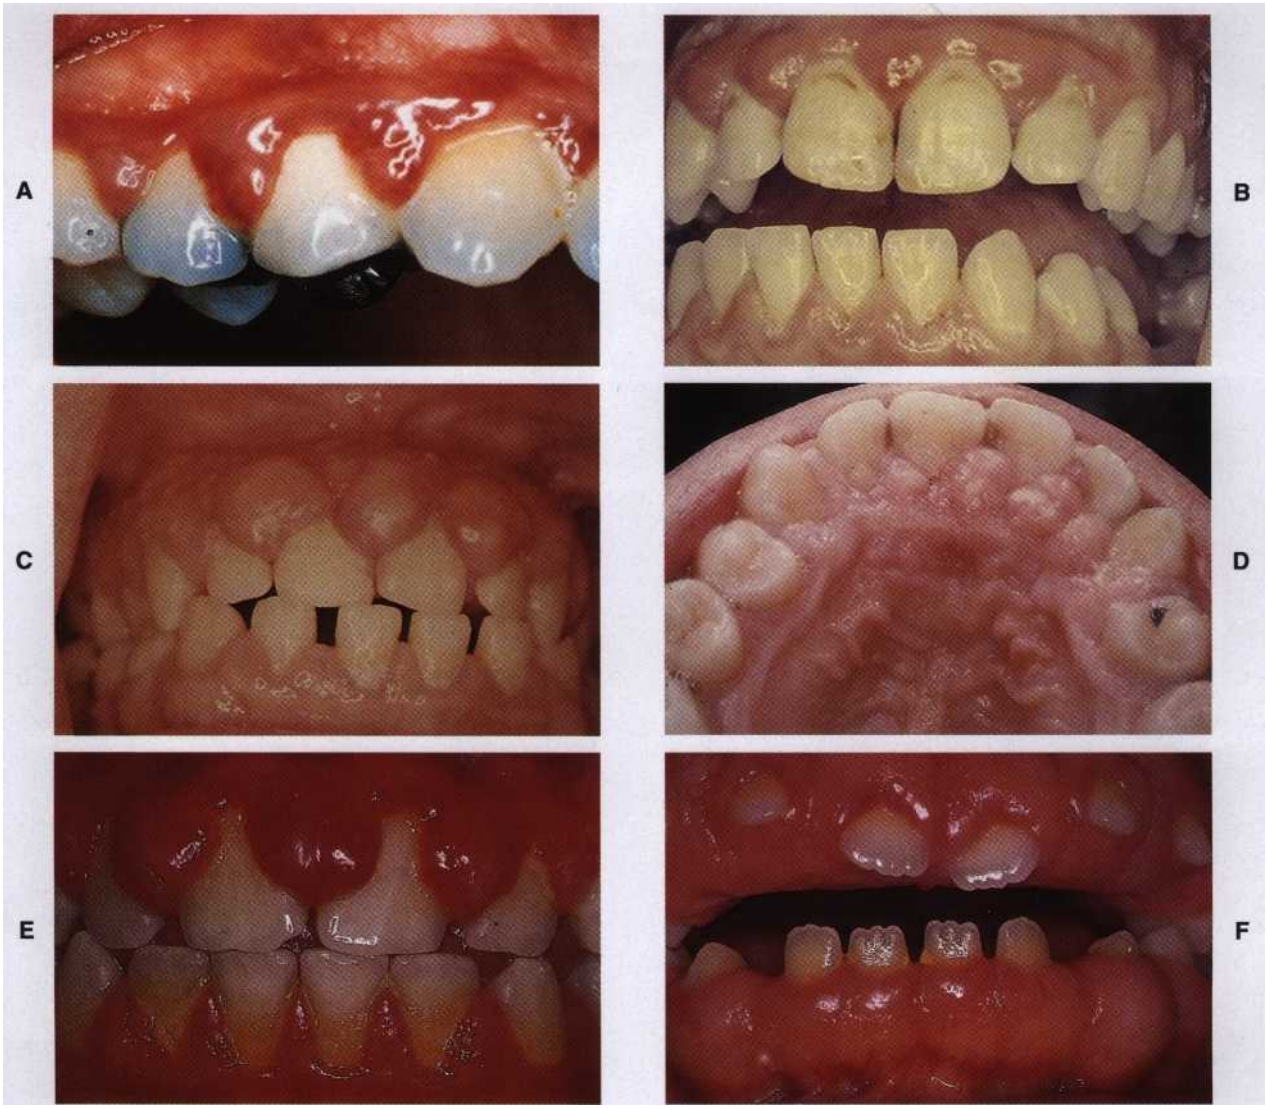
of being able to recognize and properly diagnose this condition is accentuated by the fact that a serious and life-threatening disease may initially manifest as desquamative gingivitis. The following is a discussion of the most common conditions presenting clinically as desquamative gingivitis.

DISEASES CLINICALLY PRESENTING AS DESQUAMATIVE GINGIVITIS

Lichen Planus

Lichen planus is a relatively common, chronic, dermatosis characterized by the presence of cutaneous violaceous papules that may coalesce to form plaques. The current evidence suggests that lichen planus is an immunologically mediated mucocutaneous disorder where host T lymphocytes play a central role .[1,48,7°] Although the oral cavity may present lichen planus lesions with a distinct clinical configuration and distribution, the clinical presentation sometimes may simulate other mucocutaneous disorders. Therefore a clinical diagnosis of oral lichen planus should be accompanied by a broad differential diagnosis. Numerous epidemiologic studies have shown that oral lichen planus presents in 0.1% to 4% of the population." The majority of patients with oral lichen planus are middle-aged and older females with a 2:1 ratio of females to males. Although possible, children are rarely affected. In a dental setting, cutaneous lichen planus is observed in about one third of the patients diagnosed with oral lichen planus.[67] In contrast, two thirds of patients seen in dermatologic clinics exhibit oral lichen planus.[102]

Oral Lesions. Although there are several clinical forms of oral lichen planus (reticular, patch, atrophic, erosive and bullous), the most common are the reticular and erosive subtypes. The typical reticular lesions are asymptomatic, bilateral, and consist of interlacing white lines on the posterior region of the buccal mucosa. The lateral border and dorsum of the tongue, hard palate, alveolar ridge, and gingiva may also be affected. In addition, it is not unusual for the reticular lesions to have an erythematous background, a feature that is associated with the coexistence of candidiasis. Oral lichen planus lesions follow a chronic course and have alternating, unpredictable periods of quiescence and flares.



The erosive subtype of lichen planus is often associated with pain and clinically manifests as atrophic, erythematous areas. Fine white radiating striations are observed bordering the atrophic zones. These areas may be sensitive to heat, acid, and spicy foods (Color Fig. 21-1).

Gingival Lesions. Up to 10% of patients with oral lichen planus have lesions restricted to the gingival

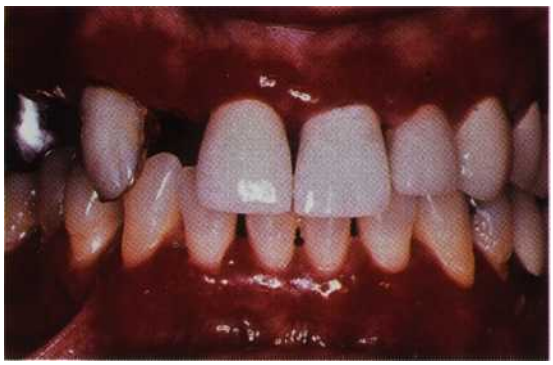
TABLE 21-2

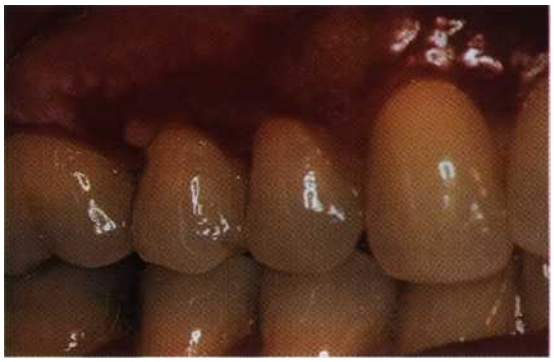
Accepted Contemporary Therapeutic Approaches Used to Treat Selected Conditions That Clinically Present as Desquamative Gingivitis

Disease	Therapy
Erosive Lichen Planus	Mild cases: Delivery of the therapeutic agent can be enhanced with the use of vacuum-formed custom trays. Rx.: Lidex (0.05% fluocinonide) gel Disp.: One tube 15 gm Sig.: Apply to affected area p.c. and h.s. Monitoring the oral cavity of the patient is warranted because candidiasis may develop after few weeks of use of topical steroids. Therefore concomitant use of an antifungal may be necessary. Rx.: Nystatin oral pastilles (100,000 IU) Disp.: 60 pastilles Sig.: Dissolve in mouth b.i.d. and then expectorate for 30 consecutive days Severe or refractory cases: Refer to dermatologist for management with systemic corticosteroids.
Cicatricial Pemphigoid	Mild cases: Rx.: Lidex (0.05% fluocinonide) gel Disp.: One tube 15 gm Sig.: Apply to affected area p.c. and h.s. Rx.: Temovate (0.05% clobetasol propionate) Disp.: One tube 15 gm Sig.: Apply to affected areas q.i.d. Severe or refractory cases: Refer to a dermatologist for management with prednisone (20-30 mg/day). Concomitant use of azathioprine may be needed. Dapsone, sulfonamide, and tetracycline are other alternatives.
Pemphigus	Refer to dermatologist for management with prednisone (20-30 mg/day). Concomitant use of azathioprine may be needed.
Chronic Ulcerative Stomatitis	Mild cases: Rx.: Lidex (0.05% fluocinonide) gel Disp.: One tube 15 gm Sig.: Apply to affected areas q.i.d. Rx.: Temovate (0.05% clobetasol propionate) Disp.: One tube 15 gm Sig.: Apply to affected areas q.i.d. Severe or refractory cases: Refer to dermatologist for management with hydroxychloroquinine sulfate (200-400 mg/day) and/or systemic corticosteroids.

tissue[102] that may occur as one or more types of four distinctive patterns:



1. *Keratotic lesions.* These raised white lesions may present as groups of individual papules, linear or reticulate lesions, or plaquelike configurations (Fig. 21-6).
2. *Erosive or ulcerative lesions.* These extensive erythematous areas with a patchy distribution may present as focal or diffuse hemorrhagic areas. These lesions are exacerbated by slight trauma (e.g., toothbrushing) (Color Fig. 21-2).
3. *Vesicular or bullous lesions.* These raised, fluid-filled lesions are uncommon and short lived on the gingiva, quickly rupturing and leaving an ulceration.
4. *Atrophic lesions.* Atrophy of the gingival tissues with ensuing epithelial thinning results in erythema confined to the gingiva.



Color Fig. 21-5 Pemphigus vulgaris of the gingiva. Clinical appearance of a patient with pemphigus vulgaris presenting oral lesions confined to the gingiva. The clinical diagnosis was consistent with desquamative gingivitis. (Courtesy Dr. Beatriz Aldape, National Autonomous University of Mexico, Mexico City, Mexico).

Color *Fig. 21-9* Erythema multiforme. Large, shallow, and painful ulcers involving the labial and buccal mucosae. Hemorrhagic crusting of the mandibular vermilion border of the lips is observed. (Courtesy Dr. Stuart Fischman, Buffalo, N.Y)

Color Fig. 21-10 Plasma cell gingivitis. The gingiva presents a band of moderate to severe inflammation reminiscent of desquamative gingivitis.

Color *Fig. 21-11* Graft versus host disease in a recipient of an allogenic bone marrow transplant. The maxillary gingiva exhibits features consistent with desquamative gingivitis. (Courtesy Dr. Linda Lee, University of Toronto, Toronto, Ontario.)

Color Fig. *21-12* Wegener's granulomatosis affecting the gingival tissues. The classic "strawberry gums" appearance of the mandibular gingiva is seen in this patient. A slight resemblance with desquamative gingivitis is evident.

Fig. 21-6 Lichen planus. Unusual papular appearance of lichen planus on the gingiva.

Histopathology. Microscopically, three main features characterize oral lichen planus: (1) hyperkeratosis or parakeratosis, (2) hydropic degeneration of the basal layer, and (3) a dense, bandlike infiltrate primarily of T lymphocytes in the lamina propria (Fig. 21-7). Classically, the epithelial rete ridges have a "saw-tooth" configuration. Hydropic degeneration of the basal layer of the epithelium may be sufficiently extensive that the epithelium becomes thin and atrophic or detaches off the underlying connective tissue and produces either a subepithelial vesicle or an ulcer. Colloid bodies (Civatte bodies) are often seen at the epithelium-connective tissue interface. A microscopic diagnosis of oral lichen planus is straightforward in the keratotic lesions, and biopsy specimens should be obtained from these areas if possible. However, these classic histologic features may be obscured in the areas of ulceration, making a conclusive diagnosis of oral lichen planus difficult based solely on conventional microscopy.

Electron microscopic studies indicate that lichen planus can be divided into three stages: (1) degeneration of the cytoplasm of the epithelial cells, (2) loss of collagen fibers in the superficial lamina propria, and (3) degeneration and necrosis of the basal and parabasal layers of the epithelium. The superficial lamina propria is also degenerated and necrotic, and the basement lamina is no longer visible. Separation of the basal lamina from the basal cell layer is an early manifestation of lichen planus.[106]

It is noteworthy that oral lesions of lichen planus may change in pattern, and in certain unusual cases, a second or even a third biopsy may be necessary to arrive at a definitive diagnosis. More importantly, controversy exists about the malignant potential of oral lichen planus. In some studies, it has been estimated that oral cancer emerges in 0.4 to 5.6% of patients with oral lichen planus.[46,47,112] In contrast, other researchers reject or question the connection between oral lichen planus and oral cancer.[32,65] In spite of this controversy, biopsy and close follow-up are warranted in these patients.

Immunopathology. Direct immunofluorescence of both lesional and perilesional oral lichen planus biopsy specimens reveal linear-fibrilar deposits of fibrin in the basement membrane zone (Fig. 21-8), along with scattered immunoglobulin-staining cytoid bodies in the upper areas of the lamina propria (Fig. 21-9). Serum tests using indirect immunofluorescence are negative in lichen planus.

Differential Diagnosis. The classic clinical presentation of oral lichen planus can be simulated by other conditions mainly, lichenoid mucositis. When an erosive component is present, lupus erythematosus and chronic ulcerative stomatitis should be included in the differential diagnosis. In the event that oral lichen planus is confined to the gingival tissues (erosive oral lichen planus), the identification of fine white radiating striations bordering the erosive areas support a clinical diagnosis of oral lichen planus. If the white striations are absent, the differential diagnosis should primarily include cicatricial pemphigoid and pemphigus vulgaris. Other less common possibilities encompass linear IgA and chronic ulcerative stomatitis.

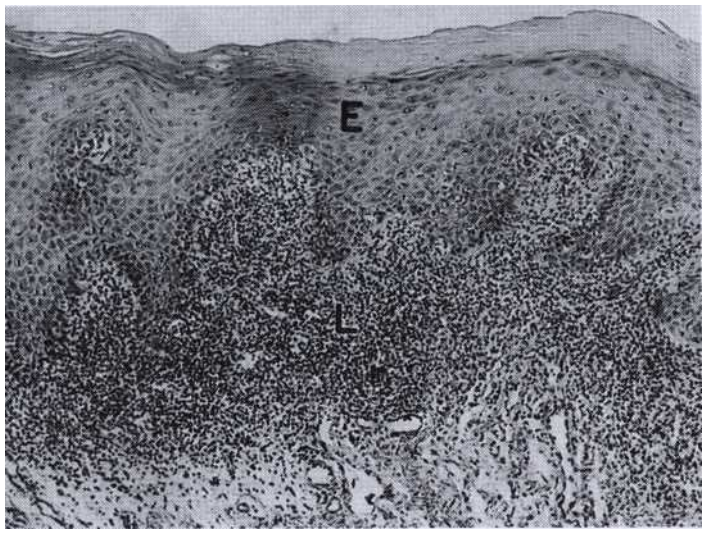

Fig. 21-7 Microscopic appearance of lichen planus. Biopsy specimen from a gingival lesion showing hyperkeratosis and acanthosis of the epithelium (E), as well as extension of rete pegs. There i5 dense, bandlike lymphocytic infiltrate in the lamina propria (L) confined to a broad zone immediately beneath the epithelium.

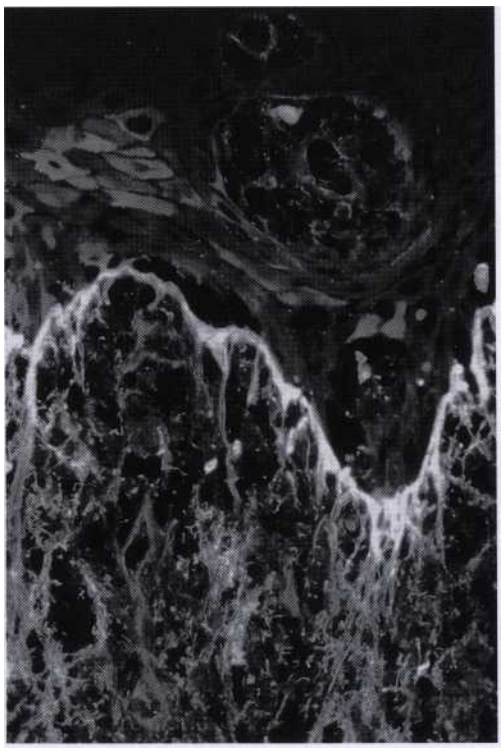

Fig. 21-8 Direct immunofluorescence of lichen planus. Fibrin deposits along the basement membrane of the epithelium.

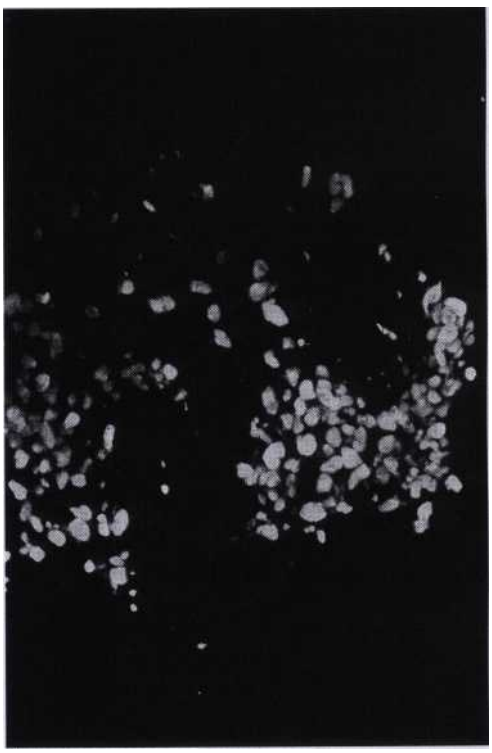

Fig. 21-9 Direct immunofluorescence of lichen planus. Clusters of cytoid bodies exhibiting IgM deposits in the lamina propria.

Therapy. The keratotic lesions of oral lichen planus are asymptomatic and do not require treatment once the microscopic diagnosis is established. However, follow-up of the patient every 6 to 12 months is warranted to monitor suspicious clinical changes and the emergence of an erosive component.

In contrast, the erosive, bullous, or ulcerative lesions of oral lichen planus are treated with high-potency topical steroid such as 0.05% fluocinonide ointment (Lidex, three times daily). Lidex can also be mixed 1:1 with carboxymethyl cellulose (Orabase) paste or other adhesive ointment. Intralesional injections of triamcinolone acetonide (10 to 20 mg) or short-term regimens of 40 mg prednisone daily for 5 days followed by 10 to 20 mg daily for an additional 2 weeks have also been employed in more severe cases.[85] Because of the potential side effects, administration of systemic steroids should be prescribed and monitored by a dermatologist. Other treatment modalities (e.g., retinoids, hydroxychloroquine, cyclosporine, and free gingival grafts) have also been used.[85] Because candidiasis is often associated with symptomatic oral lichen planus, antifungal therapy should be considered.[14,39]

Pemphigoid

The term *pemphigoid* applies to a number of cutaneous, immune-mediated, subepithelial bullous diseases that are characterized by a separation of the basement membrane zone (bullous pemphigoid, mucous membrane pemphigoid and pemphigoid [herpes] gestationis).[89-101] Among these conditions, bullous pemphigoid and mucous membrane pemphigoid (also known as *benign mucous membrane pemphigoid* and *cicatricial pemphigoid)* have received considerable attention. Current molecular findings on these two diseases have made clear that they are separate entities.[101] However, there is considerable histologic and immunopathologic overlap between them to the point that their differentiation may be impossible on these two criteria.[89] In many occasions, the clinical findings are probably the best cognitive element to discriminate them. Accordingly, the term *bullous pemphigoid* is preferred when the disease is nonscarring and mainly affects the skin. The term *cicatricial pemphigoid is* favored when scarring occurs and the disease is mainly confined to mucous membranes (although scarring may be absent in some subtypes of mucous membrane pemphigoid).[119] Until more research allows better understanding of this family of diseases, bullous pemphigoid and mucous membrane pemphigoid will be discussed separately.

Bullous Pemphigoid. Bullous pemphigoid is a chronic, autoimmune, subepidermal, bullous disease with tense bullae that rupture and become flaccid in the skin. Oral involvement occurs in about a third of the patients.[110] Although the skin lesions clinically resemble those of pemphigus, the microscopic picture is quite distinct. There is no evidence of acantholysis, and the developing vesicles are subepithelial rather than intraepithelial. The epithelium separates from the underlying connective tissue at the basement membrane zone. Electron microscopic studies show an actual horizontal splitting or replication of the basal lamina. The separating epithelium remains relatively intact, and the basal layer is present and appears to be regular. The two major antigenic determinants for bullous pemphigoid **are the** 230-kDa protein plaque known as BP1 and the 180-kDa collagen-like transmembrane protein BP2.[79,98]

IMMUNOFLUORESCENCE. Immunologically, bullous pemphigoid is characterized by IgG and C3 immune deposits along epithelial basement membranes and circulating IgG antibodies to the epithelial basement membrane.[52,82] Direct immunofluoresence is positive in 90% to 100% of these patients, whereas indirect immunofluorescence is positive in 40% to 70% of affected patients.[83]

ORAL LESIONS. Oral lesions have been reported to occur secondarily in up to 40% of the cases. There is an erosive or desquamative gingivitis presentation and occasional vesicular or bullous lesions.[110]

THERAPY. Because its etiologic factors are unknown, treatment of bullous pemphigoid is designed to control its signs and symptoms.[52,82] The primary treatment is a moderate dose of systemic prednisone. Steroid-sparing strategies (prednisone plus other immunomodulator drugs) are used when high doses of steroids are needed or the steroid alone fails to control the disease.[29] For localized lesions of bullous pemphigoid, high-potency topical steroids or tetracycline with or without nicotinamide can be effective.[84]

Mucous Membrane Pemphigoid (Cicatricial Pemphigoid). Mucous membrane pemphigoid, also known as *cicatricial pemphigoid, is* a chronic, vesiculobullous autoimmune disorder of unknown cause that predominantly affects women in the fifth decade of life. Although rare, it has been reported in young children.[101] Cicatricial pemphigoid involves the oral cavity, conjunctiva, and the mucosa of the nose, vagina, rectum, esophagus, and urethra. However, in about 20% of cases, the skin may also be involved. Recent investigations have suggested that cicatricial pemphigoid encompasses a group of heterogeneous conditions with distinct clinical and molecular features.[26,76,99] An elaborate cascade of events is involved in the pathogenesis of cicatricial pemphigoid. Initially, antigen/antibody complexing occurs at the basement membrane zone and is followed by complement activation and subsequent leukocyte recruitment. Next, proteolytic enzymes are released and dissolve or cleave the basement membrane zone, usually at the level of the lamina lucida.[34] The two major antigenic determinants for cicatricial pemphigoid are bullous pemphigoid 1 and 2 (BP1 and BP2). Most cases of cicatricial pemphigoid are the result of an immune response directed against BP2 and less commonly against BP1 and epiligrin (laminin-5, a lamina lucida protein in the basement membrane of the stratified epithelium).[5-26] Current research strongly suggests that there are at least five subtypes of cicatricial pemphigoid (oral pemphigoid, anti-epiligrin pemphigoid, anti-BP antigen mucosal pemphigoid, ocular pemphigoid and multiple antigens pemphigoid).[101]

OCULAR LESIONS. In cases presenting first to the dentist (mainly desquamative gingivitis), the eyes are affected in approximately 25% of the patients.[83] In contrast, in cases presenting first to the dermatologist, 66% of the patients present conjunctival lesions, where in ophthalmic studies, 100% of the patients have ocular involvement.[38,61,71] The initial lesion is characterized by unilateral conjunctivitis that becomes bilateral within 2 years. Subsequently, there may be adhesions of eyelid to eyeball (symblepharon) (Fig. 21-10). Adhesions at the edges of the eyelids (ankyloblepharon) may lead to a narrowing of the palpebral fissure. Small vesicular lesions may develop on the conjunctiva, which may eventually produce scarring, corneal damage, and blindness.

ORAL LESIONS. The most characteristic feature of oral involvement is the presence of desquamative gingivitis (Color Fig. 21-3) with typical areas of erythema, desquamation, ulceration, and vesiculation, of the attached gingiva.[40,109] Vesiculobullous lesions may occur elsewhere in the mouth.[40] The bullae tend to have a relatively thick roof and rupture in 2 to 3 days, leaving irregularly shaped areas of ulceration. Healing of the lesions may take up to 3 weeks or longer.

HISTOPATHOLOGY. The microscopic appearance of the oral lesions, although not completely diagnostic for mucous membrane pemphigoid, is sufficiently distinctive that a tentative diagnosis can be considered. A striking subepithelial vesiculation with the epithelium separated from the underlying lamina propria leaves an intact basal layer (Fig. 21-11). The separation of the epithelium and the connective tissue occurs at the basement membrane zone. Electron microscopic studies demonstrate a split in the basal lamina.[116] A mixed inflammatory infiltrate (lymphocytes, plasma cells, neutrophils, and scarce eosinophils) is observed in the underlying fibrous connective tissue.

IMMUNOFLUORESCENCE. Positive immunofluorescence findings along the basement membrane area has been reported by both direct and indirect immunofluorescence.[21,51,16] In biopsy tests by direct immunofluorescence, the main immunoreactants are IgG and C3, which are confined to the basement membrane (Fig. 21-12). Recent studies indicate that a positive indirect immunofluorescence is rare in these patients (<25%).[84] The lack of indirect immunofluorescence findings may be due to an earlier diagnosis of mucous membrane pemphigoid that results in the identification of patients with less extensive disease.[1-59] In any event, circulating autoantibodies do not appear to play a role in the pathogenesis of the disease.

DIFFERENTIAL DIAGNOSIS. Several disease entities present with similar clinical and histologic (subepithelial bulla) features.[31] These include bullous pemphigoid, bullous lichen planus, dermatitis herpetiformis, linear IgA, erythema multiforme, herpes gestationis, and epidermolysis bullosa acquisita.

Pemphigus may be confined to the oral cavity in its early stage, and the vesicular and ulcerative lesions may resemble those of mucous membrane pemphigoid. An erosive or desquamative gingivitis may also be seen in pemphigus as a rare manifestation. Biopsy studies can quickly rule out pemphigus by revealing the absence or presence of acantholytic changes. In erythema multiforme, there are obvious vesiculobullous lesions, but the onset is usually acute rather than chronic, labial involvement is severe, and the gingivae are usually not affected. Desquamative gingivitis is an unusual finding in erythema multiforme, although occasional vesicular lesions may develop. A biopsy study of an oral lesion reveals an unusual degeneration of the upper stratum spinosum, characteristically seen in oral erythema multiforme lesions.

Fig. 21-10 Mucous membrane pemphigoid. Characteristic ocular lesion (symblepharon) in a patient presenting with cicatricial pemphigoid. (Courtesy Dr. Carl Allen; Ohio State University, Columbus, Ohio)

Cicatricial pemphigoid must be differentiated from epidermolysis bullosa acquisita, which can present with similar histopathology and immunopathology. When the biopsy is treated with salt to separate the dermis from the epidermis, basement membrane immunodeposits occur on the epidermal side in pemphigoid and the dermal side in epidermolysis bullosa acquisita.[33]

THERAPY. Topical steroids are the mainstay of treatment for mucous membrane pemphigoid, in particular when localized lesions are present. Fluocinonide (0.05%) and clobetasol propionate (0.05%) in an adhesive vehicle can be used three times a day for up to 6 months.[101] When the oral lesions of mucous membrane pemphigoids are confined to the gingival tissues, topical corticosteroids are effectively delivered with vacuum-formed custom trays or veneers."' Optimal oral hygiene is essential because local irritants on the tooth surface result in an exaggerated gingival inflammatory response. Gingival irritation from any dental prosthesis should also be minimized. If the disease is not severe and symptoms are mild, systemic corticosteroids may be omitted. If ocular involvement exists, systemic corticosteroids are indicated.

When lesions do not respond to steroids, systemic Dapsone (4-4'diaminodiphenylsulfone) has proven to be effective.[22,36,76,81] Because of the systemic side effects to

this drug including hemolysis and methemaglobulinemia, particularly in patients with glucose-6-phosphate dehydrogenase deficiency, referral to a dermatologist is often indicated.$' Some authors have also advocated sulfonamides and tetracycline; surgery, although not a treatment for mucous membrane pemphigoid, is used in some cases to prevent blindness as well as esophageal and upper airways stenosis. 101

Pemphigus Vulgaris

The pemphigus diseases are a group of autoimmune bullous disorders that produce cutaneous and/or mucous membranes blisters (Fig. 21-13). Pemphigus vulgaris is the most common of the pemphigus diseases (pemphigus vulgaris, pemphigus foliaceous, pemphigus vegetants, and pemphigus erythematosus)." Pemphigus vulgaris is a potentially lethal chronic condition (10% mortality rate) with a worldwide incidence of 0.1 to 0.5 cases per year per 100,000 individuals. 9,96 A predilection in women, usually after the fourth decade of life, has been observed 96 However, pemphigus vulgaris has also been reported in unusually young children and even in newborns 20.96.120 The epidermal and/or mucous membrane blisters occur when the cell to cell adhesion structures are damaged by the action of circulating and in vivo binding of autoantibodies to the pemphigus vulgaris antigen, a cell surface glycoprotein present in keratinocytes. This pemphigus vulgaris glycoprotein is a member of the desmoglein (DSG) subfamily of the cadherin superfamily of cell to cell adhesion molecules, which is present in desmosomes. 58 Recent evidence suggests that DSG3, the gene coding for pemphigus vulgaris is located in chromosome 18. Most cases of pemphigus vulgaris are idiopathic; however, medications such as penicillamine and captopril can produce drug-induced pemphigus, which is usually reversible on withdrawal of the causative drug. Paraneoplastic pemphigus is antigenically distinct from pemphigus vulgaris and is associated with underlying malignancies."

In approximately *60%* of patients with pemphigus vulgaris, the oral lesions are the first sign of the disease and may herald the dermatologic involvement by a year or more.[111]

Oral Lesions. Oral lesions of pemphigus range from small vesicles to large bullae. When the bullae rupture, they leave extensive areas of ulceration (Color Fig. *21-4).* Virtually, any region of the oral cavity can be involved, but multiple lesions often develop at sites of irritation or trauma. The soft palate is more often involved (80%), followed by the buccal mucosa *(46%),* ventral aspect or dorsum of tongue *(20%),* and lower labial mucosa (10%). Oral lesions of pemphigus vulgaris are confined less often to the gingival tissues.[55] In these cases a clinical diagnosis of erosive gingivitis or desquamative gingivitis is seen as the sole manifestation of oral pemphigus (Color Fig. *21-5).*

Histopathology. Lesions of pemphigus demonstrate a characteristic intraepithelial separation, which occurs above the basal cell layer. The intraepithelial vesiculation begins as a microscopic alteration (Fig. *21-14)* and gradually results in a grossly visible, fluid-filled bulla. Occasionally, the entire superficial layers of epithelium are lost, leaving only the basal cells attached to the underlying lamina propria, conferring a characteristic "tombstone" appearance to the epithelial cells. Acantholysis, a separation of the epithelial cells of the lower stratum spinosum, takes place and is characterized by the presence of round rather than polyhedral epithelial cells. The intercellular bridges are lost, and the nuclei are large and hyperchromatic.[25,60,123] The underlying connective tissue usually presents as a mild to moderate chronic inflammatory cell infiltrate. As the vesicle or bulla ruptures, the ulcerated lesion becomes infiltrated with polymorphonuclear leukocytes, and the surface may show suppuration.

Cytology. Cytology smears of oral pemphigus lesions represent a preliminary test and should not replace the histologic and immunopathologic examinations. Cytologic examination may be used as corroborating evidence for a definitive diagnosis. A positive smear reveals large numbers of rounded acantholytic cells with serrated borders and large, hyperchromatic nuclei.[12,104]

Electron Microscopy. Electron microscopic studies indicate that breakdown of the epithelial intercellular cement substance is the first stage in the development of acantholysis. Other investigations suggest that the destruction starts in the tonofilaments[45] or in the desmosomes[107] (Fig. *21-15).*

Immunofluorescence. The presence of autoantibodies can be demonstrated in the oral mucosa of patients with oral pemphigus by the use of immunofluorescent techniques. For direct immunofluorescence, perilesional unfixed frozen sections are incubated with fluorescein-labeled human anti-IgG. In indirect immunofluorescence, unfixed frozen sections of oral or esophageal mucosa from an animal such as a monkey is first incubated with the patient's serum to allow attachment of any serum antibodies to the mucosal tissue. The tissue is then incubated with fluorescein-labeled, antihuman IgG serum. The test is positive if immunofluorescence is observed in the intercellular spaces of the stratified squamous epithelium of the mucosa (Fig. *21-16).* The indirect technique is less sensitive than the direct technique and may be negative in early stages of the disease, particularly in localized forms. However, in most cases, the indirect immunofluorescence titers are valuable to monitor disease activity and are of prognostic value.

Differential Diagnosis. The oral lesions of pemphigus vulgaris may be similar to those seen in erythema multiforme. In erythema multiforme however, recurrent active episodes of comparatively short duration are followed by long intervals free of skin or oral lesions. Erythema multiforme affects the lips with consid-

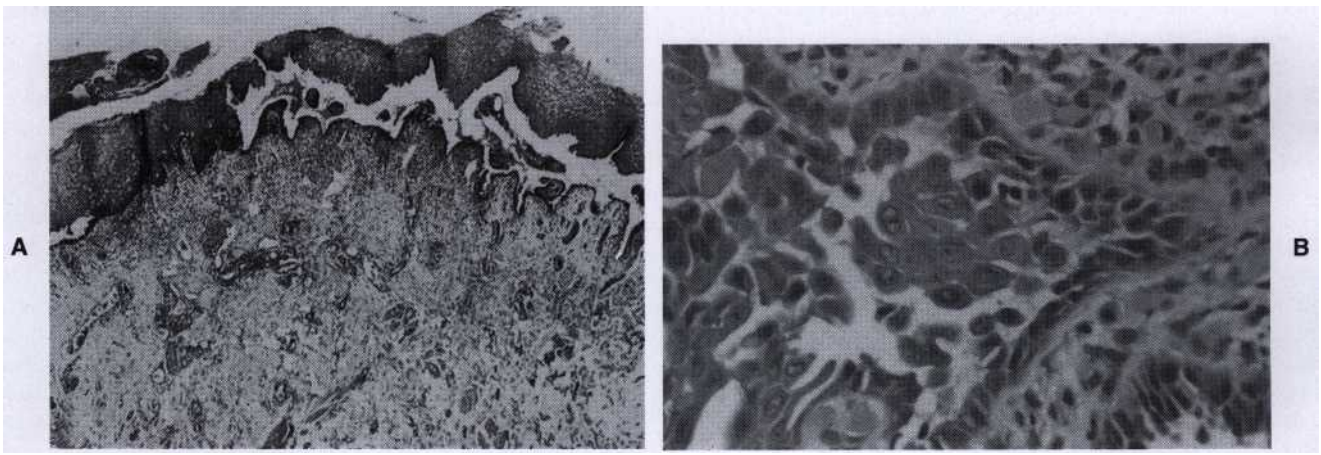

Fig. 21-14 Microscopic features of pemphigus vulgaris. A, Oral mucosa showing acantholysis and an intraepithelial vesicle. B, Detailed view of an intraepithelial vesicle in pemphigus vulgaris.

erable severity. Microscopic examination with conventional H&E and direct immunofluorescence can discriminate oral lesions of pemphigus from those of erythema multiforme. Pemphigus vulgaris will show characteristic intraepithelial clefting at the basal-spinous cell layers interface with acantholysis, whereas erythema multiforme shows microvesiculation of the superficial epithelial layers and numerous necrotic keratinocytes. Pemphigus vulgaris shows an intercellular and intraepithelial signal with direct immunofluorescence. In contrast, erythema multiforme exhibits negative immunofluorescence.

Pemphigoid may clinically resemble pemphigus when it is confined to the mouth. Microscopic examination and direct immunofluorescence studies are needed to establish a correct diagnosis. Bullous pemphigoid and mucous membrane pemphigoid exhibit detachment of the epithelium from the underlying connective tissue ("lifting off"), instead of the acantholysic lesion characteristic of pemphigus.

Bullous lichen planus must also be considered in the differential diagnosis. The primary lesion of pemphigus may be of a bullous character, followed by erosion with associated pain and discomfort. In lichen planus, however, the characteristic reticular lesions are invariably found associated with the bullae. Microscopic examination and direct immunofluorescence studies are necessary to differentiate this condition from pemphigus. Bullous lichen planus shows separation of the epithelium form the underlying fibrous connective tissue, "sawtooth" rete pegs and a bandlike chronic inflammatory infiltrate in the lamina propria. Direct immunofluorescence reveals linear fibrilar deposits of fibrin in the basement membrane of bullous lichen planus, whereas pemphigus vulgaris has intercellular immunoglobulin deposition within the epithelium.

If the oral lesions of pemphigus vulgaris are restricted to the gingival tissues, erosive lichen planus, pemphigoid, linear IgA, and chronic ulcerative stomatitis should be ruled out.

Therapy. The main therapy for pemphigus vulgaris is systemic corticosteroid therapy with or without the addition of other immunosuppressive agents.[111] Initially, when only steroids were employed, high initial and maintenance doses of steroids were necessary to control the disease.[62] Currently, if the patient responds well to corticosteroids, the dosage can be gradually reduced, but a low-maintenance dosage is usually necessary to prevent or minimize the recurrence of lesions. Many dermatologists monitor the dose of steroids by periodic indirect immunofluorescence for changes in titer. Increasing titers are often associated with an impending exacerbation and warrant an increase of the steroid dose. A decrease in the indirect immunofluorescence titer justifies a reduction of the steroid dose.[83] In patients not responsive to corticosteroids or who gradually adapt to them, "steroid-sparing" therapies are used. They consist of combinations of steroids plus other medications such as azathioprine, cyclophosphamide, cyclosporine, dapsone, gold, methotrexate, photoplasmaphoresis, and plasmaphoresis.[84]

The maintenance phase aims to control the disease with the lowest dose of medication. To minimize the risk of morbidity associated with the long-term use of steroids, alternate-day steroid therapy, steroid-sparing drugs, and topical steroids can be combined. Since topical steroids may promote the development of candidiasis, topical antifungal medication may be also needed.[68]

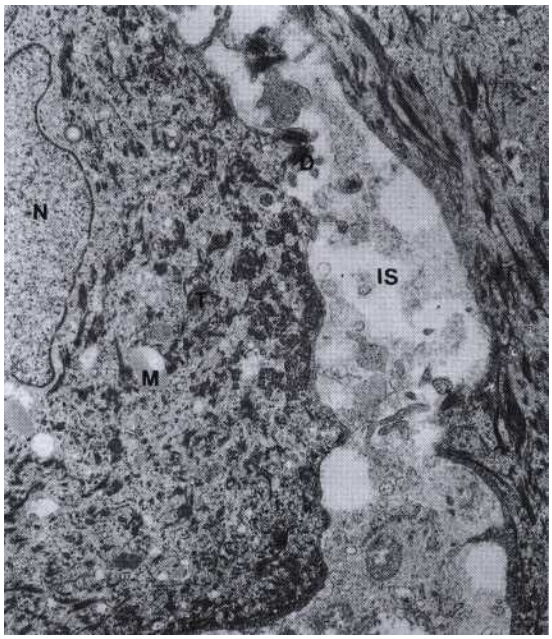

Fig. 21-15 Oral pemphigus. Electron micrograph of acantholytic cells showing the disappearance of desmosomes (D) and the separation of cells by widening of the intercellular space (IS). Tonofibrils (T) show clumping, and mitochondria (M) are degenerating. The nucleus (N) demonstrates on intact membrane.

Fig. 21-16 Direct immunofluorescence of oral pemphigus. A positive intercellualr signal for IgG deposition is seen in the entire keratinized stratified epithelium.

Minimization of oral irritation is important in patients with oral pemphigus vulgaris. Optimal oral hygiene is essential, because there is usually widespread involvement of the marginal and attached gingivae in pemphigus vulgaris, as well as other areas of the mouth, which can be exacerbated by plaque-associated gingivitis and periodontitis. Periodontal care is an important issue of the overall management of patients with pemphigus vulgaris. To prevent flare-ups, patients in the maintenance phase should receive prednisone before professional oral prophylaxis and periodontal surgery.[96] In addition, attention should be given to the fit and design of removable prosthetic appliances, as even slight irritation from these prostheses can cause severe inflammation with vesiculation and ulceration.

Chronic Ulcerative Stomatitis

Chronic ulcerative stomatitis was first reported in 1990.[49] Clinically, this condition presents with chronic oral ulcerations and has a predilection for women in their fourth decade of life. The erosions and ulcerations present predominantly in the oral cavity, with only few cases exhibiting cutaneous lesions.[19,63,121]

Oral Lesions. Painful, solitary small blisters and erosions with surrounding erythema are present mainly on the gingiva and the lateral border of the tongue. Because of the magnitude and clinic features of the gingival lesions, a diagnosis of desquamative gingivitis is considered (Color Fig. 21-6). The hard palate may also present similar lesions.

Histopathology. The microscopic features of chronic ulcerative stomatitis are similar to those observed in erosive lichen planus. Hyperkeratosis, acanthosis, and liquefaction of the basal cell layer with areas of subepithelial clefting are prominent features of the epithelium. The underlying lamina propria exhibits a lymphohistiocytic chronic infiltrate in a band-like configuration.

Immunofluorescence. Direct immunofluorescence of normal and perilesional tissues reveal typical stratified epithelium-specific antinuclear antibodies (SES-ANA). These are nuclear deposits of IgG with a speckled pattern, mainly in the basal cell layer of the normal epithelium (Fig. 21-17). In addition, fibrin deposits are visualized at the epithelial-connective tissue interface. Indirect immunofluorescence studies also reveal the presence of SES-ANA.

Differential Diagnosis. Chronic ulcerative stomatitis is clinically similar to erosive lichen. Pemphigus vulgaris, cicatricial pemphigoid, linear IgA, bullous pemphigoid, and lupus erythematosus have to be included in the clinical differential diagnosis. Microscopic examination usually reduces the number of possibilities to chronic ulcerative stomatitis, linear IgA dermatosis, and erosive lichen planus. Direct and indirect immunofluorescence are needed to arrive at the correct diagnosis.

Treatment. For mild cases, topical steroids (fluocinonide, clobetasol propionate) and topical tetracycline may produce clinical improvement; however, recurrences are common.[64] For severe cases, a high dose of systemic corticosteroids is needed to achieve remission. Unfortunately, reduction of the corticosteroids doses results in relapse of the lesions. Hydroxychloroquinine sulfate at a dosage of 200 to 400 mg per day seems to be the treatment of choice to produce complete, long-lasting remission.[10,21,49] However, a recent long-term follow-up study demonstrated that a combined therapy (small doses of corticosteroids and chloroquine) may be required, as the initial good response to chloroquine ceases after several months or even years of treatment.[19]

Linear IgA Disease (Linear IgA Dermatosis)

Linear IgA disease (LAD), also known as *linear IgA dermatosis, is* an uncommon mucocutaneous disorder with predilection in women. It clinically presents as a pruritic vesiculobullous rash usually during middle to late age, although younger individuals may be affected. Characteristic plaques or crops with an annular presentation surrounded by a peripheral rim of blisters affect the skin of the upper and lower trunk, shoulders, groin, and lower limbs. The face and perineum may also be affected. Mucosal involvement, including the oral mucosa, ranges from 50% to 100% of the cases published.[23,50]

LAD may mimic lichen planus both clinically and histologically. Immunofluorescent studies are needed to establish the correct diagnosis.

Oral Lesions. Oral manifestations of LAD consist of vesicles, painful ulcerations or erosions, and erosive gingivitis/cheilitis. The hard and soft palates are more commonly affected. Tonsillar pillars, buccal mucosa, tongue, and gingiva follow in frequency. Rarely, oral lesions may be the only manifestation of LAD for several years before the presentation of cutaneous lesions." In addition, oral lesions of LAD have been clinically reported as desquamative gingivitis (Color Fig. 21-7).[90,91]

Histopathology. The microscopic features of LAD are similar to those observed in erosive lichen planus.

Immunofluorescence. Linear deposits of IgA are observed at the epithelial-connective tissue interface. They differ from the granular pattern observed in dermatitis herpetiformis.

Differential Diagnosis. The differential diagnosis of LAD includes erosive lichen planus, chronic ulcerative stomatitis, pemphigus vulgaris, bullous pemphigoid, and lupus erythematosus. Microscopic examination and immunofluorescence studies are necessary to establish the correct diagnosis.

Treatment. The primary treatment for LAD is a combination of sulfones and dapsone. Small amounts of prednisone (10 to 30 mg per day) can be added if the initial response is inadequate." Alternatively, tetracycline (2 g per day) combined with nicotinamide (1.5 g per day) have shown promising results.$$

Dermatitis Herpetiformis

Dermatitis herpetiformis is a chronic condition that usually develops in young adults (ages 20 to 30 years) and has a slight predilection for males.30 Although its cause is still unclear, all patients have gluten enteropathy, which can be severe in about two thirds of the individuals affected and mild or subclinical in the remaining third. In severe cases, patients may complain of dysphagia, weakness, diarrhea, and weight loss.71 Clinically, dermatitis herpetiformis presents with bilateral and symmetric pruritic papules or vesicles predominantly restricted to the extensor surfaces of the extremities. The sacrum, buttocks, and occasionally the face, as well as the oral cavity may be also affected.[13,30] The name "herpetic" derives from the initial presentation of this disease, where clusters of vesicles or papules arise on the skin. These vesicles or papules eventually resolve and are followed by hyperpigmentation of the skin, which ultimately wanes. The oral lesions of dermatitis herpetiformis are characterized by the presence of painful ulcerations preceded by the collapse of ephemeral vesicles or bullae.

Microscopic examination of the initial lesions of dermatitis herpetiformis reveals focal aggregates of neutrophils and eosinophils amidst deposits of fibrin at the apices of the dermal pegs.[126] Direct immunofluorescence show that IgA and C3 are present at the dermal papillary apices. These findings are present in perilesional and normal, uninvolved tissue. In contrast, biopsies taken from lesional sites may fail to exhibit IgA or C3, resulting in false negatives.[126] Although no circulating autoantibodies to epithelial basement membrane are present in dermatitis herpetiformis, close to 80% of the individuals affected have anti-endomysial and gliadin antibodies."

Lupus Erythematosus

Lupus erythematosus is an autoimmune disease with three different clinical presentations: systemic, chronic cutaneous, and subacute cutaneous.

Systemic Lupus Erythematosus. Systemic lupus erythematosus (SLE) is a severe disease with predilection for females (10:1) that affects vital organs such as kidneys and heart, as well as the skin and mucosa. Its diagnosis is usually hampered by an insidious presentation during the early stages of the disease. However, fever, weight loss, and arthritis are common. The classic cutaneous lesions are characterized by the presence of a rash on the malar area with a butterfly distribution (Fig. 21-18). The oral lesions of SLE are usually ulcerative or lichen planus-like. Oral ulcerations present in 36% of SLE patients. In about 4% of these patients, hyperkeratotic plaques reminiscent of lichen planus appear on the buccal mucosa and palate.'-' In extremely rare instances, lupus erythematosus may occur on the oral mucous membrane without skin lesions. Direct immunofluorescence of the perilesional and normal tissue reveals immunoglobulins and C3 deposits at the dermal-epidermal interface. Antinuclear antibodies (ANA) are present in more than 95% of cases, whereas deoxyribonucleic acid (DNA) and extractable nuclear antigen (ENA) antibodies are present in more than 50% of the cases.

Chronic Cutaneous Lupus Erythematosus. Chronic cutaneous lupus erythematosus (CCLE) usually has no systemic signs or symptoms, with lesions being limited to skin or mucosal surfaces. The skin lesions are referred to as *discoid lupus erythematosus (DLE).* It is im-

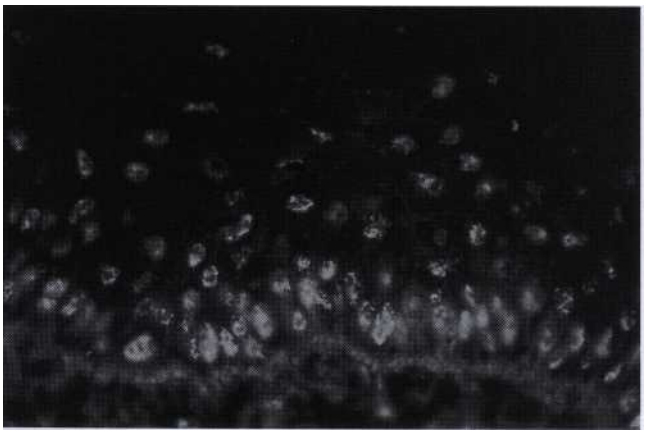

Fig. 21-17 Immunofluorescence of chronic ulcerative stomatitis. Nuclear deposits of IgG are prominent in the basal cell layer and fade towards the superficial epithelial layers. (Courtesy Dr. Douglas Damm; University of Kentucky, Lexington, Ky.).

Fig. 21-18 Lupus erythematosus showing "butterfly" distribution of lesions on the face and crusting of the lips.

portant to recognize that the term DLE refers to a specific skin lesion, not a subset of SLE. The term DLE merely describes the chronic scarring, atrophy-producing lesion that may develop hyperpigmentation or hypopigmentation of the healing area. In contrast, the subacute cutaneous lupus erythematosus skin lesions do not produce scarring and/or atrophy.[16]

In the oral cavity, about 9% of patients with CCLE present lichen planus-like plaques on the palate and buccal mucosa.[4,15] The lesions are usually localized and at their borders, numerous dilated blood vessels in a radial arrangement may extend into the surrounding tissue, coupled with whitish, pinhead papules. In the early stages the center of the lesion is slightly depressed and eroded and is covered with a bluish-red epithelial surface showing scarring. In older lesions the erythematous border becomes less elevated and is transformed into a whitish or bluish-white peripheral zone of thickened epithelium. White lines with the same diverging radial arrangement replace the dilated vessels. On the tongue the disease occurs as circumscribed, smooth, reddened areas in which the papillae are lost or as patches with a whitish sheen resembling leukoplakia.

On the lip the lesions are somewhat similar to those in the mouth, and in most cases the lip is involved by direct extension from perioral skin lesions. Localized patches may be present, or the entire lip may be involved. Early in the disease the lip is swollen, bluish-red, and often everted. The lip lesions may be covered with adherent scales and crusts, which remain localized and are rarely diffuse. At the margins of the patches, dilated capillaries or fine, branching radial lines may be seen. The lip is tender and sensitive, and on removal of the adherent scales, bleeding from the raw surface is noted. Depressed scars may follow healing of the deeper lesions. The gingiva may be affected and clinically present as desquamative gingivitis (Color Fig. 21-8).

Periods of activity and quiescence occur. The lesions enlarge by peripheral extension and are accompanied by fresh erosions and superficial ulcerations, followed by atrophic changes. Some burning sensation occurs in the erosions and deeper ulcerations.

Histopathology. The histopathology of the oral lesions consists of hyperkeratosis or parakeratosis, alternated acanthosis and atrophy, and hydropic degeneration of the basal layer of the epithelium. In addition, the lamina propria exhibits a chronic inflammatory cell infiltrate similar to that observed in lichen planus. However, a more diffuse, and deeper inflammatory infiltrate with a perivascular pattern is observed.[16,18]

Direct immunofluorescence of lesional tissue reveals immunoglobulins and *C3* deposits at the dermal-epidermal junction of the lesional or perilesional tissue but not in normal tissue. This seems to differentiate SLE from DLE. Indirect immunofluorescence reveals the presence of ANAs in more than 95% of these patients, whereas DNA- and ENA-circulating antibodies are present in more than 50% of cases.

Subacute Cutaneous Lupus Erythematosus. Subacute cutaneous lupus erythematosus (SCLE) has been used to describe a group of patients who have a characteristic cutaneous lesion that has similarities to DLE but lacks the development of scarring and atrophy." In addition, arthritis/arthralgia, low-grade fever, malaise and myalgia may present in up to 50% of SCLE patients.[16,17] Direct immunofluorescence reveals immunoglobulins and *C3* deposits at the dermal-epidermal junction in 60% of cases, and granular IgG deposits in the cytoplasm of basal cells in *30%* of cases. About 80% of patients with SCLE have Ro (SSA) antibodies to nuclear antigens, whereas 25% to *30%* have La (SSB) antibodies to nuclear antigens. Rheumatoid factor is positive in about *30%* of these patients, ANA is positive in 60% to 90%, and 10% of cases have anti-ribonucleoprotein (anti-RNP) antibodies to nuclear antigens.

Differential Diagnosis. Diagnosis usually depends on the identification of the accompanying skin lesions. The diagnosis of DLE confined to the oral cavity is very difficult to make, but microscopic studies may suggest the characteristic histopathology.[3] Erosive lichen planus, erythema multiforme, and pemphigus vulgaris may sometimes simulate the lesions observed in lupus erythematosus. Biopsy studies (H&E and direct immunofluorescence) aid in differentiating between lupus erythematosus and other erosive diseases.

Treatment. The therapy for SLE is dependent on the severity and extent of the disease. Cutaneous rashes are treated with topical steroids, sunscreens, and hydroxychloroquinine. For arthritis and mild pleuritis, nonsteroidal antiinflamatory agents or hydroxychloroquinine are used. For severe systemic organ involvement, moderate-to-high doses of prednisone are effective. For severe cases of SLE or when side effects to prednisone develop, immunosuppressive drugs such as cytotoxic drugs (cyclophosphamide and azathioprine) and plasmaphoresis alone or in conjunction with steroids are useful.[84] For CCLE, topical steroids are effective to manage the cutaneous and oral lesions. For cases resistant to topical therapy, systemic antimalarial drugs may be used with good results.[83]

Erythema Multiforme

Erythema multiforme is an acute bullous and/or macular inflammatory mucocutaneous disease where a series of immunopathologic mechanisms occur.[34] It is believed that the genesis of ulcerative lesions affecting the skin and mucosa resides in the development of immune complex vasculitis. This is followed by complement fixation leading to leukocytoclastic destruction of vascular walls and small vessel occlusion. The culmination of these events produces ischemic necrosis of the epithelium and underlying connective tissue.[34] Target or "iris" lesions with central clearing, are the "hallmark" of erythema multiforme. It may be a mild condition (erythema multiforme minor), or it may be a severe, possibly life-threatening condition (erythema

multiforme major or Stevens-Johnson syndrome). Erythema multiforme minor lasts approximately 4 weeks and exhibits a moderate cutaneous and mucosal involvement. Stevens-Johnson syndrome may last a month or longer and involves the skin, conjunctiva, oral mucosa, and genitalia, requiring a more aggressive therapy. Toxic epidermal necrolysis is considered by some researchers as the most severe form of erythema multiforme; however, other investigators feel that they are unrelated entities.' The three most common etiologic factors for the development of erythema multiforme are (1) herpes simplex infection, (2) mycoplasma infection, and (3) drug reactions. The most common causative drugs are sulfonamides, penicillins, phenylbutazone, and phenytoin.[115]

Oral lesions in erythema multiforme are common and present in more than 70% of patients with skin involvement.[35,66,73] However, in rare instances, erythema multiforme may be confined to the mouth.[69,103]

Oral Lesions. The oral lesions consist of multiple, large, shallow, painful ulcers with an erythematous border. They may affect the entire oral mucosa in approximately 20% of erythema multiforme patients. The lesions are so painful that chewing and swallowing are impaired (Color Fig. 21-9). The buccal mucosa and tongue are the most commonly affected sites, followed by the labial mucosa. Less commonly affected are the floor of the mouth, hard and soft palate, and the gingiva.[35] There are rare instances in which erythema multiforme may be confined exclusively to the gingival tissues, resulting in a clinical diagnosis of desquamative gingivitis.[8] Hemorrhagic crusting of the vermilion border of the lips is not uncommon. The presence of hemorrhagic crusting of the lips is helpful in arriving at a clinical diagnosis of erythema multiforme.

Histopathology. A wide spectrum of tissue changes occur in erythema multiforme. In several cases, the value of the microscopic examination is to rule out other conditions. Some of the most common microscopic findings of erythema multiforme include liquefaction degeneration of the upper epithelium and the development of intraepithelial microvesicles, but without the acantholysis that occurs in pemphigus.[105] In addition, acanthosis, pseudoepitheliomatous hyperplasia, and necrotic keratinocytes are observed in the epithelium. Degenerative changes also occur in the basement membrane. In some cases, the junction between the epithelium and the lamina propria is indistinct due to a dense inflammatory cell infiltrate. Edema of the lamina propria, vascular dilation, and congestion are also present. Deeper layers of the connective tissue stroma exhibit a perivascular chronic inflammatory cell infiltrate. Nonetheless, neutrophils and esosinophils may also be present.

Immunofluorescence. Immunofluorescence examination is negative in erythema multiforme. Its value resides in ruling out other vesiculo-bullous and ulcerative disorders.

Treatment. There is no specific treatment for erythema multiforme. Some cases may even resolve spontaneously, and erythematous lesions may require no treatment. In contrast, patients exhibiting bullous or ulcerative lesions require intervention. For mild symptoms, systemic and local antihistamines coupled to topical anesthetics and debridement of lesions with an oxygenating agent is adequate. In patients with severe symptoms, corticosteroids are considered the drug of choice although, its use is controversial and not completely accepted.[85]

DRUG ERUPTIONS

An **increase in the incidence** of skin and oral manifestations of hypersensitivity to drugs has been noted since the advent of the sulfonamides, barbiturates, and various antibiotics. The eruptive skin and oral lesions are attributed to the fact that the drug acts as an allergen, either alone or in combination, sensitizing the tissues and then causing the allergic reaction.

Eruptions in the oral cavity resulting from sensitivity to drugs that have been taken by mouth or parenterally are termed *stomatitis medicamentosa.* The local reaction from the use of a medicament in the oral cavity (e.g., an aspirin burn or the stomatitis resulting from topical penicillin) is referred to as *stomatitis venenata* or *contact stomatitis.* Such changes may result either from the irritating local action of the drug or from drug sensitivity. In many cases, skin eruptions may accompany the oral lesions.

In general, drug eruptions in the oral cavity are multiform. Vesicular and bullous lesions occur most commonly, but pigmented or nonpigmented macular lesions are also often observed. Erosions, often followed by deep ulceration with purpuric lesions, may also occur. The lesions are seen in different areas of the oral cavity, with the gingiva often affected.[41]

The development of gingival lesions due to contact allergy to mercurial compounds present in dental amalgam has been clearly documented.[53] Because of financial considerations, biopsy and patch testing may be indicated before the indiscriminate replacement of dental amalgam restorations. Similarly, desquamative gingivitis has been reported with the use of tartar control toothpaste. Pyrophosphates and flavoring agents have been identified as the main causative agents of this unusual condition.[2a] Oral reactions to cinnamon compounds (cinnamon oil, cinnamic acid and cinnamic aldehyde) used to mask the taste of pyrophosphates in tartar control toothpaste, include an intense erythema of the attached gingival tissues characteristic of plasma cell gingivitis (Color Fig. 21-10).[2,54] A thorough clinical history usually discloses the source of the gingival disturbance. Elimination of the offending agent (e.g., tartar control toothpaste) leads to resolution of the gingival lesions within a week. **Challenge with the offending agent leads to recurrence of the oral** lesions.

MISCELLANEOUS

Another group of heterogeneous conditions may masquerade as desquamative gingivitis. Factitious lesions, candidiasis, graft vs. host disease, Wegener's granulomatosis, foreign body gingivitis, Kindler syndrome, and even squamous cell carcinoma can divert the attention of the clinician and result in a diagnostic challenge. Factitious lesions are consciously and intentionally produced injuries without a clear motive, although, guilt, seeking sympathy, or monetary compensation may be the driving forces behind this abnormal behavior. Factitious desquamative gingivitis has been reported in the literature and may be very difficult to diagnose and become apparent only after extensive and costly laboratory tests fail to reveal the genesis of the lesions." Rarely, candidiasis may be limited to the gingival tissues and may simulate desquamative gingivitis (Fig. 21-19). Graft vs. host disease may occur in recipients of allogenic bone marrow transplants where oral lesions may occasionally resemble desquamative gingivitis (Color Fig. 21-11). Wegener's granulomatous is a systemic disease that may initially present with striking alterations that are confined to the gingival tissues. Classically, the gingival tissues exhibit erythema and enlargement and are typically described as "strawberry gums" (Color Fig. 21-12).[24] Foreign body gingivitis is clinically characterized by red or red and white chronic lesions that may be painful and are reminiscent of desquamative gingivitis. This condition does not have a gingival site predilection and is more common in women approaching the fifth decade of life. Microscopic analysis reveals small (<5 ~tm in diameter) foreign bodies associated with a chronic inflammatory cell response that may exhibit granulomatous and lichenoid characteristics. Energy dispersive x-ray microanalysis has revealed that in this condition, most foreign bodies are of dental material origin (more specifically abrasives and restorative material)."," Kindler syndrome (cutaneous neonatal bullae, poikiloderma, photosensitivity, and acral atrophy) may also present with oral lesions that are clinically consistent with desquamative gingivitis.[94] Failure to properly and systematically evaluate a patient with a clinical condition that is consistent with desquamative gingivitis can lead to unpleasant outcomes. This is particularly true when therapy for a putative desquamative gingivitis is established before a biopsy of the lesional tissue is obtained. Every year we see in our laboratory at least two examples of clinically diagnosed desquamative gingivitis where microscopic and immunofluorescence studies were not performed to rule out the genesis of the gingival lesions. In those cases, the patients have been either "carefully" followed-up or placed on topical steroids for several months (Fig. 21-20). The lack of response of the gingival tissues impels the clinician to obtain a biopsy, which reveals that the gingival lesions are bona fide squamous cell carcinomas. Thus the clinician should be alert to the possibility of squamous cell carcinoma of the gingival tissues presenting initially as desquamative gingivitis.

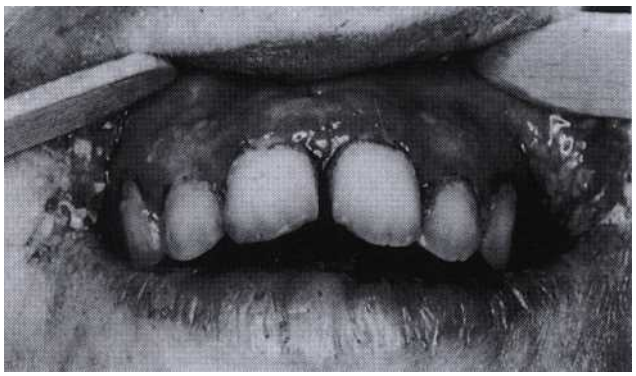

Fig. 21-19 Chronic candidiasis involving the gingiva in an 18-year-old woman.

Fig. 21-20 Squamous cell carcinoma masquerading as desquamative gingivitis.

PERIODONTAL DISEASE ACTIVITY
SITE SPECIFICITY
PULP CHANGES ASSOCIATED WITH PERIODONTAL POCKETS
RELATION OF ATTACHMENT LOSS AND BONE LOSS TO POCKET DEPTH
AREA BETWEEN THE BASE OF THE POCKET AND THE ALVEOLAR BONE
RELATIONSHIP OF THE PERIODONTAL POCKET TO BONE
- **Differences between Infrabony and Suprabony Pockets**

PERIODONTAL ABSCESS
PERIODONTAL CYST

The periodontal pocket, defined as a pathologically deepened gingival sulcus, is one of the most important clinical features of periodontal disease.[11] All different types of periodontitis, outlined in Chapter 4, share histopathologic features such as tissue changes in the periodontal pocket, mechanisms of tissue destruction, and healing mechanisms. They differ, however, in their etiology, natural history, progression, and response to therapy.[36]

CLASSIFICATION

Deepening of the gingival sulcus may occur by coronal movement of the gingival margin, apical displacement of the gingival attachment, or a combination of the two processes (Fig. 22-1). Pockets can be classified as follows:

Gingival pocket (pseudo pocket): This type of pocket is formed by gingival enlargement without destruction of the underlying periodontal tissues. The sulcus is deepened because of the increased bulk of the gingiva (Fig. 22-2, A).

Periodontal pocket: This type of pocket occurs with destruction of the supporting periodontal tissues. Progressive pocket deepening leads to destruction of the supporting periodontal tissues and loosening and exfoliation of the teeth. The remainder of this chapter refers to this type of pocket.

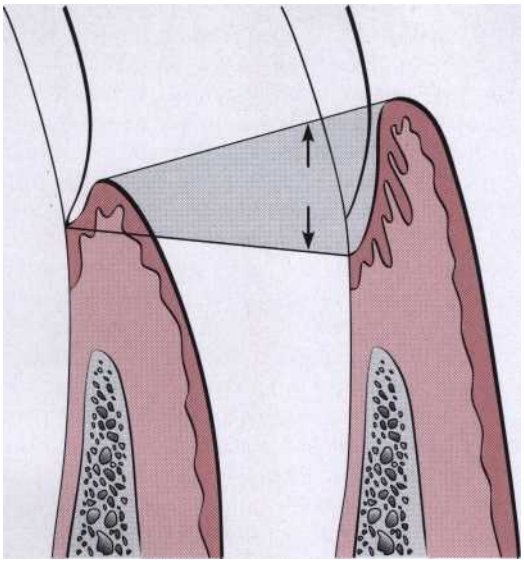

Fig. 22-1 Illustration of pocket formation indicating expansion in two directions (arrows) from the normal gingival sulcus (left) to the periodontal pocket (right).

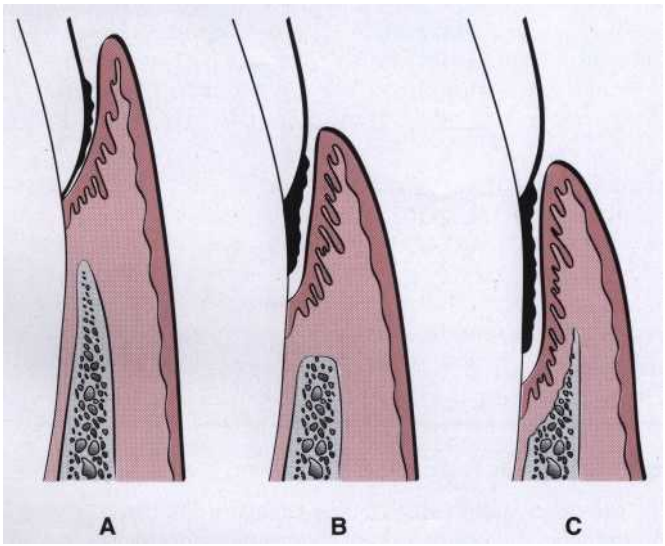

Fig. 22-2 Different types of periodontal pockets. A, Gingival pocket. There is no destruction of the supporting periodontal tissues. B, Suprabony pocket. The base of the pocket is coronal to the level of the underlying bone. Bone loss is horizontal. C, Intrabony pocket. The base of the pocket is apical to the level of the adjacent bone. Bone loss is vertical.

Two types of periodontal pockets exist:

Suprabony (supracrestal or supraalveolar), in which the bottom of the pocket is coronal to the underlying alveolar bone (Fig. 22-2, B).

Intrabony (infrabony, subcrestal or intraalveolar), in which the bottom of the pocket is apical to the level of the adjacent alveolar bone. In this second type, the lateral pocket wall lies between the tooth surface and the alveolar bone (Fig. 22-2, C).

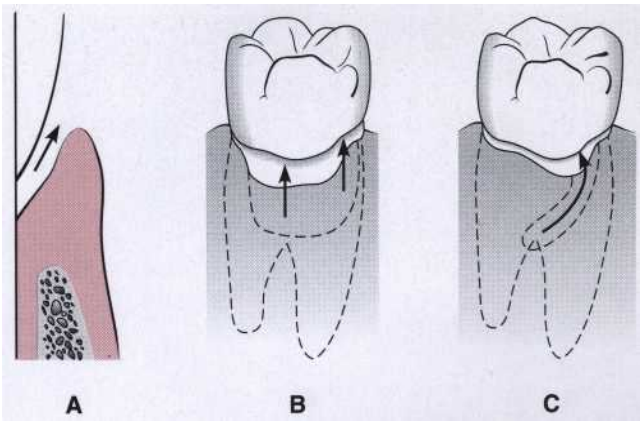

Fig. 22-3 Classification of pockets according to involved tooth surfaces. A, Simple pocket. B, Compound pocket. C, Complex pocket.

Pockets can involve one, two, or more tooth surfaces and can be of different depths and types on different surfaces of the same tooth and on approximating surfaces of the same interdental space.[32,42] Pockets can also be spiral (i.e., originating on one tooth surface and twisting around the tooth to involve one or more additional surfaces) (Fig. 22-3). These types of pockets are most common in furcation areas.

CLINICAL FEATURES

Clinical signs such as bluish-red, thickened marginal gingiva; a bluish-red vertical zone from the gingival margin to the alveolar mucosa; gingival bleeding, suppuration, or both; tooth mobility; and diastema formation and symptoms such as localized pain or pain "deep in the bone" are suggestive of the presence of periodontal pockets. The only reliable method of locating periodontal pockets and determining their extent is careful probing of the gingival margin along each tooth surface (Fig. 22-4 and Table 22-1). On the basis of depth alone, however, it is sometimes difficult to differentiate between a deep normal sulcus and a shallow periodontal pocket. In such borderline cases, pathologic changes in the gingiva distinguish the two conditions.

For a more detailed discussion of the clinical aspects of periodontal pockets, see Chapter 30.

PATHOGENESIS

The initial lesion in the development of periodontitis is the inflammation of the gingiva in response to a bacterial challenge. Changes involved in the transition from the normal gingival sulcus to the pathologic periodontal pocket are associated with different proportions of bacterial cells in dental plaque. Healthy gingiva is associated with few microorganisms, mostly coccoid cells and straight rods. Diseased gingiva is associated with increased numbers of spirochetes and motile rods.[44,45,47] However, the microbiota of diseased sites cannot be used as a predictor of future attachment or bone loss because their presence alone is not sufficient for disease to start or progress.[39]

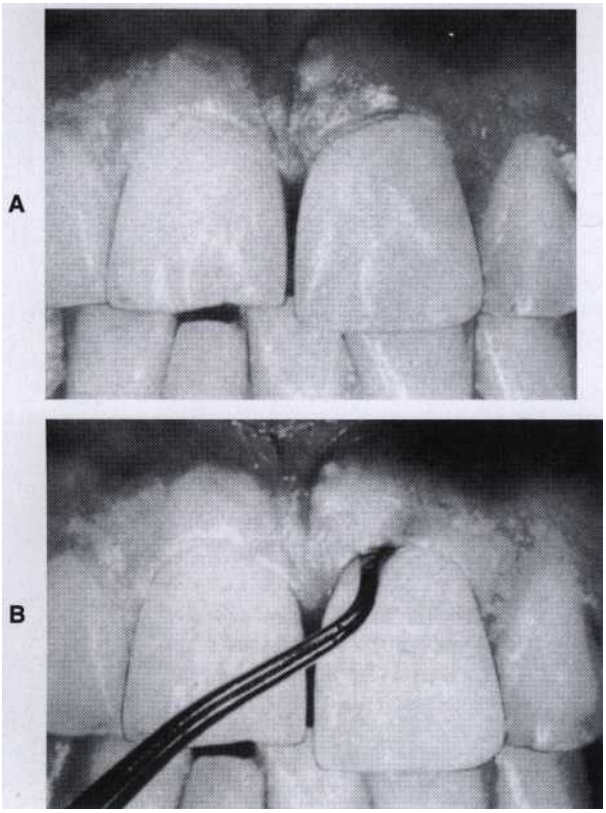

Fig. 22-4 A, Extrusion of the central incisor and diastema associated with the periodontal pocket. B, The entire length of the periodontal probe inserted to the base of the periodontal pocket in the central incisor.

Pocket formation starts as an inflammatory change in the connective tissue wall of the gingival sulcus. The cellular and fluid inflammatory exudate causes degeneration of the surrounding connective tissue, including the gingival fibers. Just apical to the junctional epithelium, collagen fibers are destroyed[21,65] and the area becomes occupied by inflammatory cells and edema.

Two mechanisms are considered to be associated with collagen loss: (1) collagenases and other enzymes secreted by various cells in healthy and inflamed tissue such as fibroblasts,[78] polymorphonuclear leukocytes,[77] and macrophages[57] become extracellular and destroy collagen; these enzymes that degrade collagen and other matrix macromolecules into small peptides are called *matrix metalloproteinases*[79]; (2) fibroblasts phagocytize collagen fibers by extending cytoplasmic processes to the ligament-cementum interface and degrade the inserted collagen fibrils and the fibrils of the cementum matrix.[21,22]

As a consequence of the loss of collagen, the apical cells of the junctional epithelium proliferate along the root, extending fingerlike projections two or three cells in thickness.

The coronal portion of the junctional epithelium detaches from the root as the apical portion migrates. As a result of inflammation, polymorphonuclear neutrophils (PMNs) invade the coronal end of the junctional epithelium in increasing numbers. The PMNs are not joined to one another or to the remaining

TABLE 22-1

Correlation *of* Clinical and Histopathologic Features *of* the Periodontal Pocket

Clinical Features	Histopathologic Features
1. The gingival wall of the periodontal pocket presents various degrees of bluish-red discoloration; flaccidity; a smooth, shiny surface; and pitting on pressure.	1. The discoloration is caused by circulatory stagnation; the flaccidity, by destruction of the gingival fibers and surrounding tissues; the smooth, shiny surface, by the atrophy of the epithelium and edema; the pitting on pressure, by edema and degeneration.
2. Less frequently, the gingival wall may be pink and firm.	2. In such cases, fibrotic changes predominate over exudation and degeneration, particularly in relation to the outer surface of the pocket wall. However, despite the external appearance of health, the inner wall of the pocket invariably presents some degeneration and is often ulcerated (see Fig. 22-13).
3. Bleeding is elicited by gently probing the soft tissue wall of the pocket.	3. Ease of bleeding results from increased vascularity, thinning and degeneration of the epithelium, and the proximity of the engorged vessels to the inner surface.
4. When explored with a probe, the inner aspect of the periodontal pocket is generally painful.	4. Pain on tactile stimulation is due to ulceration of the inner aspect of the pocket wall.
5. In many cases, pus may be expressed by applying digital pressure.	5. Pus occurs in pockets with suppurative inflammation of the inner wall.

epithelial cells by desmosomes. When the relative volume of PMNs reaches approximately 60% or more of the junctional epithelium, the tissue loses cohesiveness and detaches from the tooth surface. Thus the sulcus bottom shifts apically, and the oral sulcular epithelium occupies a gradually increasing portion of the sulcular (pocket) lining.[66]

The initial deepening of the pocket has been described as occurring between the junctional epithelium and the tooth[33,34,65] or by an intraepithelial cleavage within the junctional epithelium.[10,24,46,78]

Extension of the junctional epithelium along the root requires the presence of healthy epithelial cells. Marked degeneration or necrosis of the junctional epithelium retards rather than accelerates pocket formation. Degenerative changes seen in the junctional epithelium at the base of periodontal pockets are usually less severe than those in the epithelium of the lateral pocket wall. Because migration of the junctional epithelium requires healthy, viable cells, it is reasonable to assume that the degenerative changes seen in this area occur after the junctional epithelium reaches its position on the cementum.

The degree of leukocyte infiltration of the junctional epithelium is independent of the volume of inflamed connective tissue, and thus this process may occur in gingiva with only slight signs of clinical inflammation.[65]

With continued inflammation, the gingiva increases in bulk, and the crest of the gingival margin extends coronally. The junctional epithelium continues to migrate along the root and separate from it. The epithelium of the lateral wall of the pocket proliferates to form bulbous, cordlike extensions into the inflamed connective tissue. Leukocytes and edema from the inflamed connective tissue infiltrate the epithelium lining the pocket, resulting in various degrees of degeneration and necrosis.

The transformation of a gingival sulcus into a periodontal pocket creates an area where plaque removal becomes impossible, and the following feedback mechanism is established:

Plaque → Gingival inflammation → Pocket formation → → More plaque formation

The rationale for pocket reduction is based on the need to eliminate areas of plaque accumulation.

HISTOPATHOLOGY

Changes occurring in the initial stages of gingival inflammation are presented in Chapter 16. Once the pocket is formed, several microscopic features are present, as discussed in the following sections.

Soft Tissue Wall

The connective tissue is edematous and densely infiltrated with plasma cells (approximately 80%),[86] lymphocytes, and a scattering of PMNs. The blood vessels are increased in number, dilated, and engorged, particularly in the subepithelial connective tissue layer.[11] The connective tissue exhibits varying degrees of degeneration. Single or multiple necrotic foci are occasionally present.[56] In addition to exudative and degenerative changes, the connective tissue shows proliferation of the endothelial cells, with newly formed capillaries, fibroblasts, and collagen fibers (Fig. 22-5).

The junctional epithelium at the base of the pocket is usually much shorter than that of a normal sulcus. Although marked variations are found as to length, width, and condition of the epithelial cells, usually the coronoapical length of the junctional epithelium is reduced to only 50 to 100 μm.[15] The cells may be well formed and in good condition or may exhibit slight to marked degeneration (Fig. 22-6).

The most severe degenerative changes in the periodontal pocket occur along the lateral wall (Fig. 22-7). The epithelium of the lateral wall of the pocket presents striking proliferative and degenerative changes. Epithelial buds or interlacing cords of epithelial cells project from the lateral wall into the adjacent inflamed connective tissue and may extend farther apically than the junctional epithelium. These epithelial projections, as well as the remainder of the lateral epithelium, are densely infiltrated by leukocytes and edema from the inflamed connective tissue. The cells undergo vacuolar degeneration and rupture to form vesicles. Progressive degeneration and necrosis of the epithelium lead to ulceration of the lateral wall, exposure of the underlying inflamed connective tissue, and suppuration. In some cases, acute inflammation is superimposed on the underlying chronic changes.

A comparative study of gingival histopathologic changes in rapidly progressive (aggressive) and adult periodontitis (chronic)[39] revealed more pronounced degenerative changes in the epithelium of aggressive cases with more open intercellular spaces, with microclefts and necrotic areas.

The severity of the degenerative changes is not necessarily related to pocket depth. Ulceration of the lateral wall may occur in shallow pockets, and deep pockets are occasionally observed in which the lateral epithelium is relatively intact or shows only slight degeneration.

The epithelium at the gingival crest of a periodontal pocket is generally intact and thickened, with prominent rete pegs.

A detailed electron microscopic study of the pocket epithelium in experimentally induced pockets in dogs has been performed by Miiller-Glauser and Schroder.53

Bacterial Invasion. Bacterial invasion of the apical and lateral areas of the pocket wall has been described in

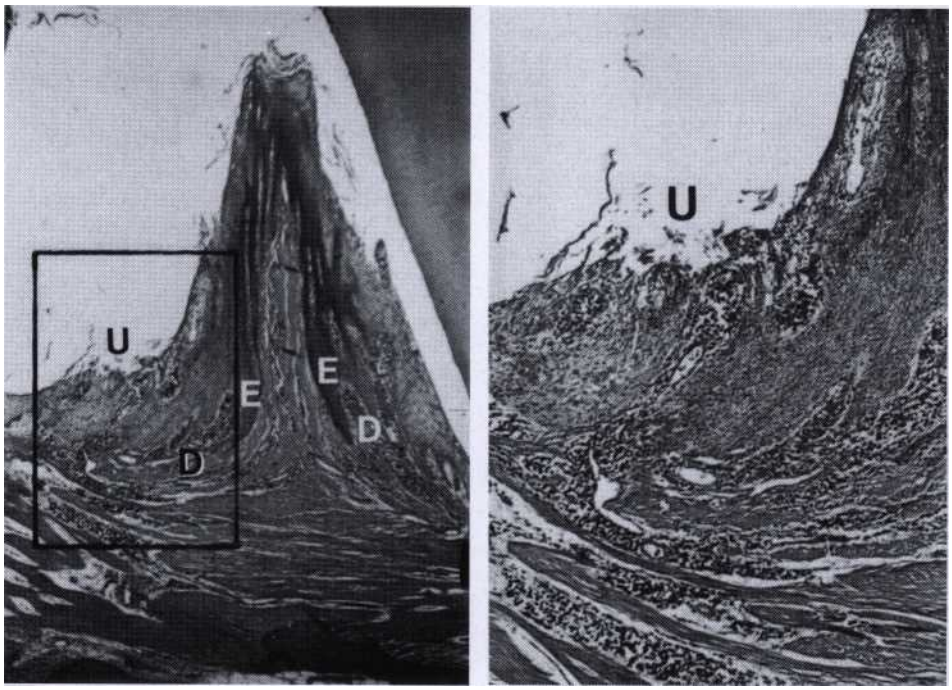

Fig. 22-5 *Left,* Interdental papilla with suprabony pockets on proximal tooth surfaces. human chronic periodontitis. Filaments, rods, and coccoid organisms with predominant gram-negative cell walls have been found in intercellular spaces of the epithelium.[27,28] Hillmann et al[39] have reported the presence of *Porphyromonas gingivalis* and *Prevotella intermedia* in the gingiva of aggressive periodontitis cases. *Actinobacillus actinomycetemcomitans* has also been found in the tissues.[17-51,63]

Bacteria may invade the intercellular space under exfoliating epithelial cells, but they are also found between deeper epithelial cells and accumulating on the basement lamina. Some bacteria traverse the basement lamina and invade the subepithelial connective tissue[64] (Figs. 22-8 and 22-9).

The presence of bacteria in the gingival tissues has been interpreted by different investigators as bacterial invasion or as passive translocation of plaque bacteria. This important point has significant clinicopathologic implications and has not yet been clarified.[18,43,47]

Microtopography of the Gingival Wall of the Pocket

Scanning electron microscopy has permitted the description of several areas in the soft tissue wall of the pocket where different types of activity take place.[60] These areas are irregularly oval or elongated and adjacent to one another and measure about 50 to 200 ttm. These findings suggest that the pocket wall is constantly changing as a

Magnification x800.

result of the interaction between the host and the bacteria. The following areas have been noted:

1. *Areas of relative quiescence,* showing a relatively flat surface with minor depressions and mounds and occasional shedding of cells (Fig. *22-10, A).*
2. *Areas of bacterial accumulation,* which appear as depressions on the epithelial surface, with abundant debris and bacterial clumps penetrating into the enlarged intercellular spaces. These bacteria are mainly cocci, rods, and filaments, with a few spirochetes (see Fig. *22-10, B).*
3. *Areas of emergence of leukocytes,* where leukocytes appear in the pocket wall through holes located in the intercellular spaces (Fig. *22-11).*
4. *Areas of leukocyte-bacteria interaction,* where numerous leukocytes are present and covered with bacteria in an apparent process of phagocytosis. Bacterial plaque associated with the epithelium is seen either as an organized matrix covered by a fibrin-like material in contact with the surface of cells or as bacteria penetrating into the intercellular spaces (see Fig. *22-10, C).*
5. *Areas of intense epithelial desquamation,* which consist of semi-attached and folded epithelial squames, sometimes partially covered with bacteria (Fig. *22-10, D).*
6. *Areas of ulceration,* with exposed connective tissue (Fig. *22-12).*
7. *Areas of hemorrhage,* with numerous erythrocytes.

The transition from one area to another could be postulated as follows: bacteria accumulate in previously quiescent areas, triggering the emergence of leukocytes and

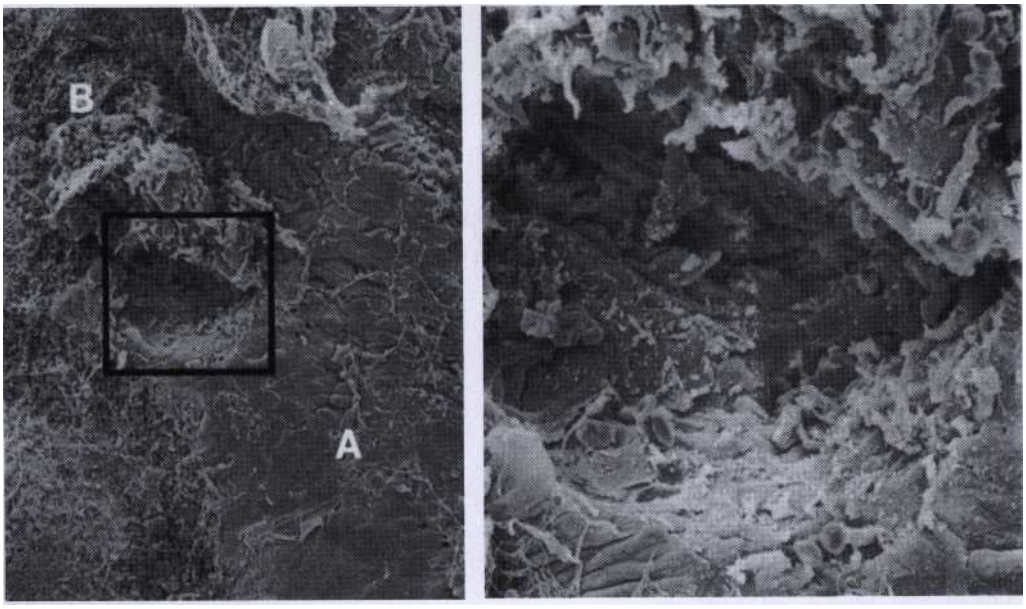

Fig. 22-12 *Left,* **Area of ulceration in the lateral wall of a deep periodontal pocket in a human specimen. A, Surface of pocket epithelium in a quiescent state; 8, area of hemorrhage. the leukocyte-bacteria interaction. This would lead to intense epithelial desquamation and finally to ulceration and hemorrhage.

Periodontal Pockets as Healing Lesions

Periodontal pockets are chronic inflammatory lesions and as such are constantly undergoing repair. Complete healing does not occur because of the persistence of the bacterial attack, which continues to stimulate an inflammatory response, causing degeneration of the new tissue elements formed in the continuous effort at repair.

The condition of the soft tissue wall of the periodontal pocket results from the interplay of the destructive and constructive tissue changes. Their balance determines clinical features such as color, **consistency, and surface texture of the pocket wall.** If the inflammatory fluid and cellular exudate predominate, the pocket wall is bluish-red, soft, spongy, and friable, with a smooth, shiny surface. If there is a relative predominance of newly formed connective tissue cells and fibers, the pocket wall is more firm and pink. At the clinical level, the former condition is generally referred to as an *edematous pocket wall* and the latter as a *fibrotic pocket wall* (see Chapter 30).

Edematous and fibrotic pockets represent opposite extremes of the same pathologic process, not different disease entities. They are subject to constant modification, depending on the relative predominance of exudative and constructive changes.

Fibrotic pocket walls may be misleading because they do not necessarily reflect what is taking place throughout the pocket wall. The most severe degenerative changes in periodontal tissues occur adjacent to the tooth surface and subgingival plaque. In some cases, inflammation and ulceration on the inside of the pocket are walled off by fibrous tissue on the outer aspect (Fig. 22-13). Outwardly the pocket appears pink and fibrotic, despite the inflammatory changes occurring within.

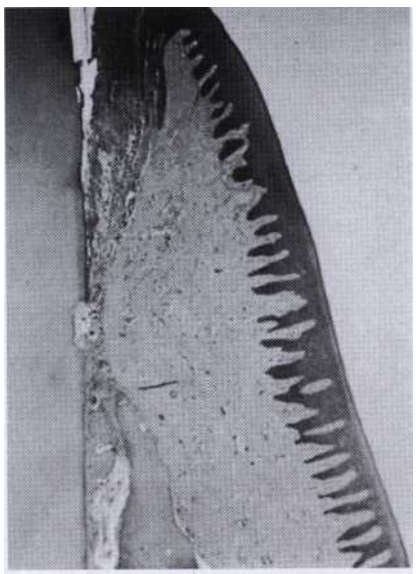

Fig. 22-13 Periodontal pocket wall. The inner half is inflamed and ulcerated; the outer half is densely collagenous.

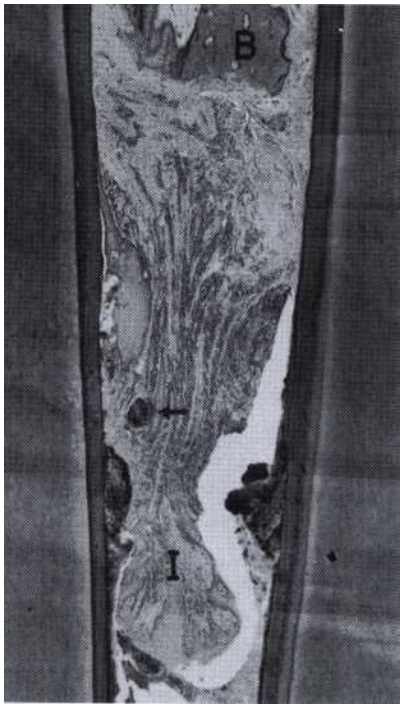

Fig. 22-14 Interdental papilla (1) with ulcerated suprabony periodontal pockets on its mesial and distal aspects. Calculus is present on the approximal tooth surfaces and within the gingiva (arrow). The bone i5 shown at 8.

Pocket Contents

Periodontal pockets contain debris consisting principally of microorganisms and their products (enzymes, endotoxins, and other metabolic products), gingival fluid, food remnants, salivary mucin, desquamated epithelial cells, and leukocytes. Plaque-covered calculus usually projects from the tooth surface (Fig. 22-14). Purulent exudate, if present, consists of living, degenerated, and necrotic leukocytes; living and dead bacteria; serum; and a scant amount of fibrin." The contents of periodontal pockets filtered free of organisms and debris have been demonstrated to be toxic when injected subcutaneously into experimental animals.35

Significance of Pus Formation. There is a tendency to overemphasize the importance of the purulent exudate and to equate it with severity of periodontal disease. Because it is a dramatic clinical finding, early observers assumed that it was responsible for the loosening and exfoliation of the teeth. Pus is *a common feature of periodontal disease, but it is only a secondary sign.* The presence of pus or the ease with which it can be expressed from the pocket merely reflects the nature of the inflarnmatory changes in the pocket wall. It is not an indication of the depth of the pocket or the severity of the destruction of the supporting tissues. Extensive pus formation may occur in shallow pockets, whereas deep pockets may exhibit little or no pus.

Localized accumulation of pus constitutes an abscess, which is discussed later in this chapter.

Root Surface Wall

The root surface wall of periodontal pockets often undergoes changes that are significant because they may perpetuate the periodontal infection, cause pain, and complicate periodontal treatment.

As the pocket deepens, collagen fibers embedded in the cementum are destroyed and cementum becomes exposed to the oral environment. Collagenous remnants of Sharpey's fibers in the cementum undergo degeneration, creating an environment favorable to the penetration of bacteria. Viable bacteria have been found in the roots of 87% of periodontally diseased noncarious teeth.[1] Bacterial penetration into the cementum can be found as deep as the cementodentinal junction[2,19] and may also enter the dentinal tubules (Fig. 22-15).[31]

*Pathologic granules*9 have been observed with optical and electron microscopy6,7 and may represent areas of collagen degeneration or areas where collagen fibrils have not been fully mineralized initially.

Penetration and growth of bacteria leads to fragmentation and breakdown of the cementum surface and result in areas of necrotic cementum, separated from the tooth by masses of bacteria (Fig. 22-16).

In addition, bacterial products such as endotoxins4-5 have also been detected in the cementum wall of periodontal pockets. When root fragments from teeth with periodontal disease are placed in tissue culture, they induce irreversible morphologic changes in the cells of the culture. Such changes are not produced by normal roots.37 Diseased root fragments also prevent the in vitro attachment of human gingival fibroblasts, whereas normal root surfaces allow the cells to attach freely.' When reimplanted in the oral mucosa of the patient, diseased root fragments induce an inflammatory response even if they are autoclaved.[48]

These changes are manifested clinically by softening of the cementum surface, which is usually asymptomatic but painful when a probe or explorer penetrates the area. They also constitute a possible reservoir for reinfection of the area after treatment. In the course of treatment, these necrotic areas are removed by root planing until a hard smooth surface is reached. Cementum is very thin in the cervical areas, and scaling and root planing often removes it entirely, exposing the underlying dentin. Sensitivity to cold may result until secondary dentin is formed by the pulp tissue.

The following changes may also occur in the root surface wall of periodontal pockets:

Decalcification and Remineralization of Cementum. Areas of *increased mineralization*9 are probably

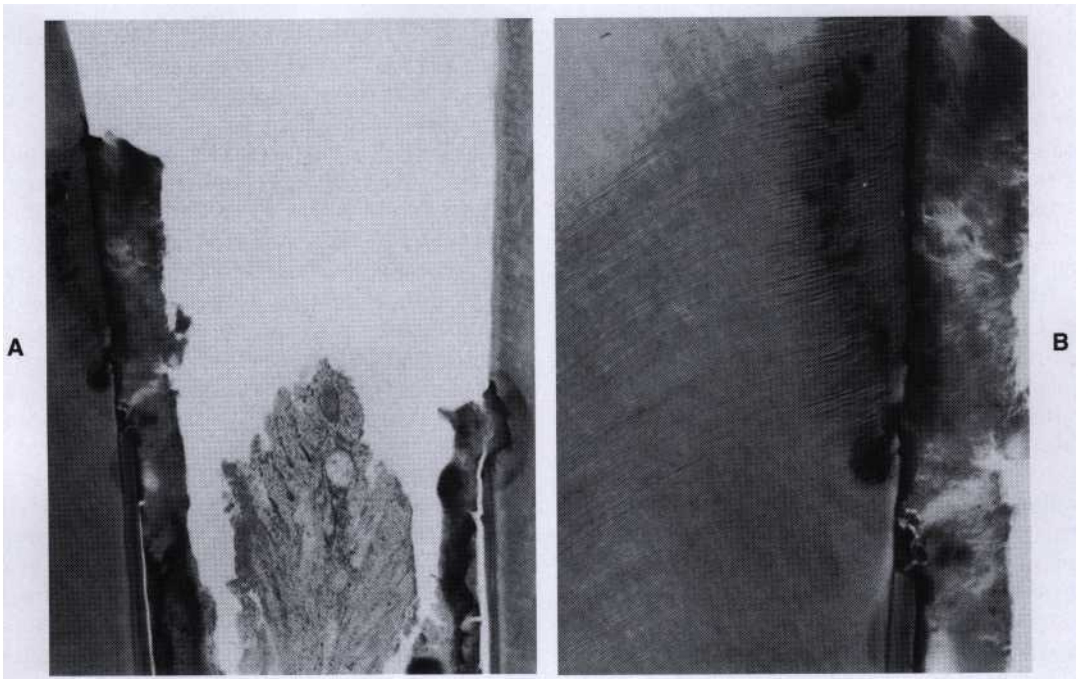

Fig. 22-15 Caries on root surfaces exposed by periodontal disease. A, Interdental space, showing inflamed gingiva and caries on proximal tooth surfaces. B, Caries of cementum and dentin, showing bacterial invasion of dentinal tubules. Note the filamentous structure of the dental plaque and darker staining of calculus adherent to the root.

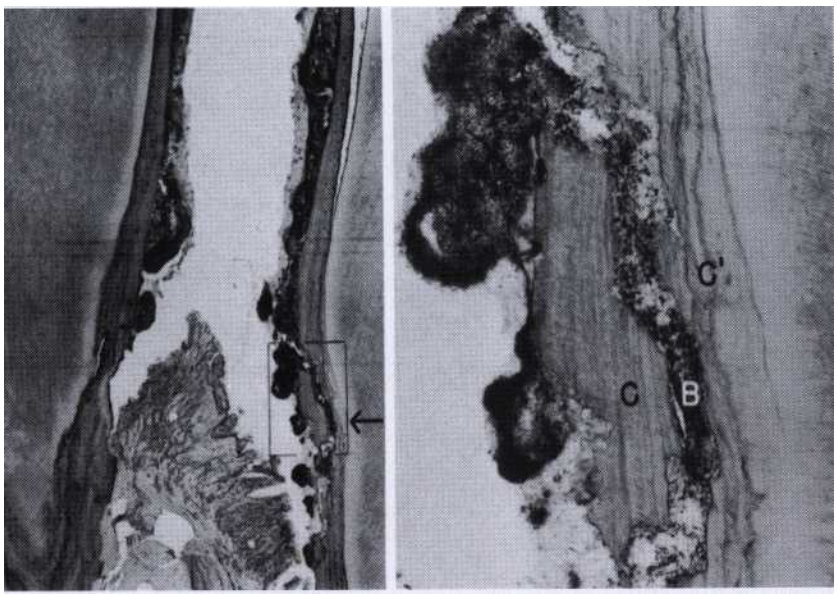

Fig. 22-16 *Left,* **Mesiodistal section through an interdental space in a patient with extensive periodontal destruction. An area of cementum necrosis is enclosed within the rectangle designated by the arrow.** *Right* **Detailed section of the rectangular area showing a necrotic fragment of cementum (C) separated from lamellated cementum (C) by clumps of bacteria (B).**

a result of an exchange, on exposure to the oral cavity, of minerals and organic components at the cementum-saliva interface. The mineral content of exposed cementum increases.[68] The following minerals are increased in diseased root surfaces: calcium,[54,71] magnesium,[54] phosphorus,[54] and fluoride.[54] Microhardness, however, remains unchanged.[59,85] The development of a highly mineralized superficial layer may increase the tooth resistance to decay.[3]

The hypermineralized zones are detectable by electron microscopy and are associated with increased perfection of the crystal structure and organic changes

suggestive of a subsurface cuticle.[68,69] These zones have also been seen in microradiographic studies" as a layer 10 to 20 /-tm thick, with areas as thick as 50 /,m. No decrease in mineralization was found in deeper areas, thereby indicating that increased mineralization does not come from adjacent areas. A loss of, or reduction in, the cross-banding of collagen near the cementum surface[29,30] and a subsurface condensation of organic material of exogenous origin[68] have also been reported.

Areas of demineralization are commonly related to root caries. Exposure to oral fluid and bacterial plaque results in proteolysis of the embedded remnants of Sharpey's fibers; the cementum may be softened and may undergo fragmentation and cavitation." Unlike enamel caries, root surface caries tend to progress around rather than into the tooth.[52] Active root caries lesions appear as well-defined yellowish or light-brown areas, are frequently covered by plaque, and have a softened or leathery consistency on probing.[26] Inactive lesions are well-defined darker lesions with a smooth surface and a harder consistency on probing.[26]

The dominant microorganism in root surface caries is *Actinomyces viscosus,*[16] although its specific responsibility in the development of the lesion has not been established.[26] Other bacteria such as *Actinomyces naeslundii, Streptococcus mutans, Streptococcus salivarius, Streptococcus sanguis,* and *Bacillus cereus* have been found to produce root caries in animal models. Quirynen et al[58] reported that when plaque levels and pocket depths fall after periodontal therapy (both conservative and surgical), a shift in oral bacteria occurs, leading to a reduction in periodontal pathogens and an increase in S. *mutans* and the development of root caries.

A prevalence rate study of root caries in 20- to 64-year-old individuals revealed that 42% had one or more root caries lesions and that these lesions tended to increase with age.[41]

The tooth may not be painful, but exploration of the root surface reveals the presence of a defect, and penetration of the involved area with a probe causes pain. Caries of the root, however, may lead to pulpitis, sensitivity to sweets and thermal changes, or severe pain. Pathologic exposure of the pulp occurs in severe cases. Root caries may be the cause of toothache in patients with periodontal disease and no evidence of coronal decay.

Caries of the cementum requires special attention when the pocket is treated. The necrotic cementum must be removed by scaling and root planing until firm tooth surface is reached, even if this entails extension into the dentin.

Areas of cellular resorption of cementum and dentin are common in roots unexposed by periodontal disease (see Figs. 2-16 and 22-16).[12] These areas are of no particular significance because they are symptom free, and as long as the root is covered by the periodontal ligament, they are apt to undergo repair. However, if the root is exposed by progressive pocket formation before repair of such areas occurs, these appear as isolated cavitations that penetrate into the dentin. These areas can be differentiated from caries of the cementum by their clear-cut outline and hard surface. They may be sources of considerable pain, requiring the placement of a restoration.

Surface Morphology of the Tooth Wall of Periodontal Pockets. This topic has been studied by several authors.[8,13,40,61,62,82] The following zones can be found in the bottom of a periodontal pocket (Fig. 22-17):

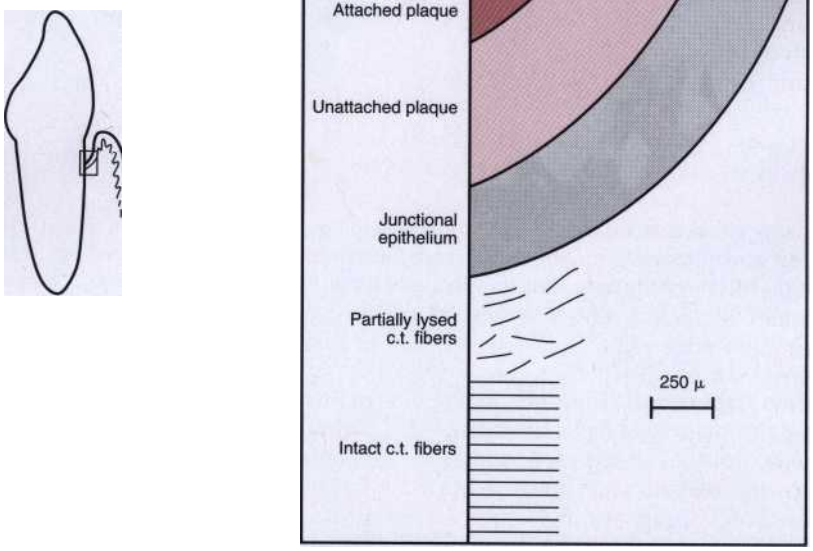

Fig. 22-17 Diagram of the area at the bottom of a pocket.

1. *Cementum covered by calculus,* where all the changes described in the preceding paragraphs can be found.
2. *Attached plaque,* which covers calculus and extends apically from it to a variable degree, probably 100 to 500 gym.
3. *The zone of unattached plaque* that surrounds attached plaque and extends apically to it.
4. The zone where the *junctional epithelium is attached to the tooth.* The extension of this zone, which in normal sulci is more than 500 Am, is usually reduced in periodontal pockets to less than 100 Am.
5. Apical to the junctional epithelium, there may be *a zone of semidestroyed connective tissue fibers* (see "Pathogenesis").

Areas 3, 4, and 5 compose the so-called *plaque-free zone* seen in extracted teeth. The total width of the plaque-free zone varies according to the type of tooth (it is wider in molars than in incisors) and the depth of the pocket (it is narrower in deeper pockets).61 It is important to remember that the term *plaque-free zone* refers only to attached plaque because unattached plaque contains a variety of gram-positive cocci and various gram-negative morphotypes including cocci, rods, filaments, fusiforms, and spirochetes. The most apical zone contain predominantly gram-negative rods and cocci.8o

PERIODONTAL DISEASE ACTIVITY

For many years the loss of attachment produced by periodontal disease was thought to be a slow but continuously progressive phenomenon. More recently, as a result of studies on the specificity of plaque bacteria, the concept of periodontal disease activity has evolved.

According to this concept, periodontal pockets go through periods of exacerbation and quiescence, resulting from episodic bursts of activity followed by periods of remission. *Periods o f quiescence* are characterized by a reduced inflammatory response and little or no loss of bone and connective tissue attachment. A buildup of unattached plaque, with its gram-negative, motile, and anaerobic bacteria (see Chapter 6), starts a *period o f exacerbation* in which bone and connective tissue attachment are lost and the pocket deepens. This period may last for days, weeks, or months and is eventually followed by a period of remission or quiescence in which gram-positive bacteria proliferate and a more stable condition is established. Based on a study Of I^{125} absorptiometry, McHenry and colleagues have confirmed that bone loss in untreated periodontal disease occurs in an episodic manner.[49]

These periods of quiescence and exacerbation are also known as *periods of activity* and *inactivity*. Clinically, active periods show bleeding, either spontaneously or with probing, and greater amounts of gingival exudate. Histologically, the pocket epithelium appears thin and ulcerated, and an infiltrate composed predominantly of plasma cells,z0 polymorphonuclear leukocytes,57 or both are seen. Bacterial samples from the pocket lumen, analyzed with darkfield microscopy, show high proportions of motile organisms and spirochetes.47 Over time, loss of bone should be detected radiographically.

Methods to detect periods of activity or inactivity are currently being investigated (see Chapter 34).

SITE SPECIFICITY

Periodontal destruction does not occur in all parts of the mouth at the same time but rather on a few teeth at a time or even only some aspects of some teeth at any given time. This is referred to as the *site specificity* of periodontal disease. It is very common to find sites of periodontal destruction next to sites with little or no destruction. Therefore the severity of periodontitis increases by the development of new disease sites, the increased breakdown of existing sites, or both.

PULP CHANGES ASSOCIATED WITH PERIODONTAL POCKETS

The spread of infection from periodontal pockets may cause pathologic changes in the pulp. Such changes may give rise to painful symptoms or adversely affect the response of the pulp to restorative procedures. Involvement of the pulp in periodontal disease occurs through either the apical foramen or the lateral canals in the root after infection spreads from the pocket through the periodontal ligament. Atrophic and inflammatory pulpal changes occur in such cases (see also Chapters 64 and 65).

RELATION OF ATTACHMENT LOSS AND BONE LOSS TO POCKET DEPTH

Pocket formation causes loss of attachment of the gingiva and denudation of the root surface. The severity of the attachment loss is generally, but not always, correlated with the depth of the pocket. This is because the degree of attachment loss depends on the location of the base of the pocket on the root surface, whereas the pocket depth is the distance between the base of the pocket and the crest of the gingival margin. Pockets of the same depth may be associated with different degrees of attachment loss (Fig. *22-18),* and pockets of different depths may be associated with the same amount of attachment loss (Fig. *22-19).*

Severity of bone loss is generally, but not always, correlated with pocket depth. Extensive attachment and bone loss may be associated with shallow pockets if the

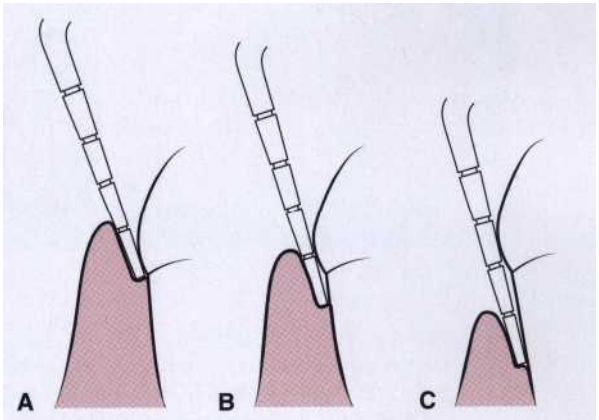

Fig. 22-18 Same pocket depth with different amounts of recession. A, Gingival pocket with no recession. B, Periodontal pocket of similar depth as in A, but with some degree of recession. C, Pocket depth same a5 in A and B, but with still more recession.

attachment loss is accompanied by recession of the gingival margin, and slight bone loss can occur with deep pockets.

AREA BETWEEN THE BASE OF THE POCKET AND THE ALVEOLAR BONE

Normally, the distance between the apical end of the functional epithelium and the alveolar bone is relatively constant. The distance between the apical extent of calculus and the alveolar crest in human periodontal pockets is most constant, having a mean length of 1.97 mm ± 33.16%.7S-$'

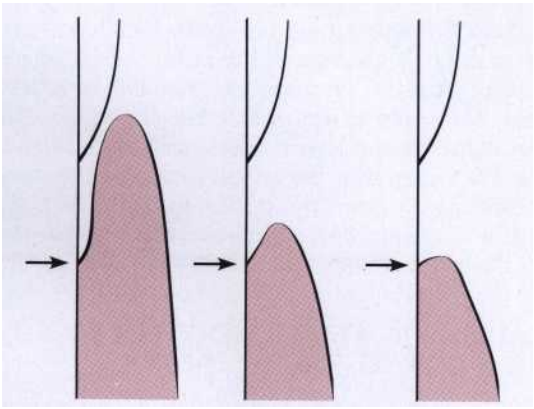

Fig. 22-19 Different pocket depths with the same amount of attachment loss. Arrows point to bottom of the pocket. The distance between the arrow and the cementoenamel junctions remains the same despite different pocket depths.

The distance from attached plaque to bone is never less than 0.5 mm and never more than 2.7 mm.[81,82] These findings suggest that the bone-resorbing activity induced by the bacteria is exerted within these distances. However, the finding of isolated bacteria, clumps of bacteria, or both in the connective tissue[64] and on the bone surface[28] may modify these considerations.

RELATIONSHIP OF THE PERIODONTAL POCKET TO BONE

In intrabony pockets, the base of the pocket is apical to the crest of the alveolar bone, and the pocket wall lies between the tooth and the bone. Intrabony pockets most often occur interproximally but may be located on the facial and lingual tooth surfaces. Most often the pocket spreads from the surface on which it originated to one or more contiguous surfaces. The suprabony pocket has its base coronal to the crest of the bone.

The inflammatory, proliferative, and degenerative changes in intrabony and suprabony pockets are the same, and both lead to destruction of the supporting periodontal tissues.

Differences between Intrabony and Suprabony Pockets

The principal differences between intrabony and suprabony pockets are the relationship of the soft tissue wall of the pocket to the alveolar bone, the pattern of bone destruction, and the direction of the transseptal fibers of the periodontal ligament[16] (Figs. 22-20 to 22-22).

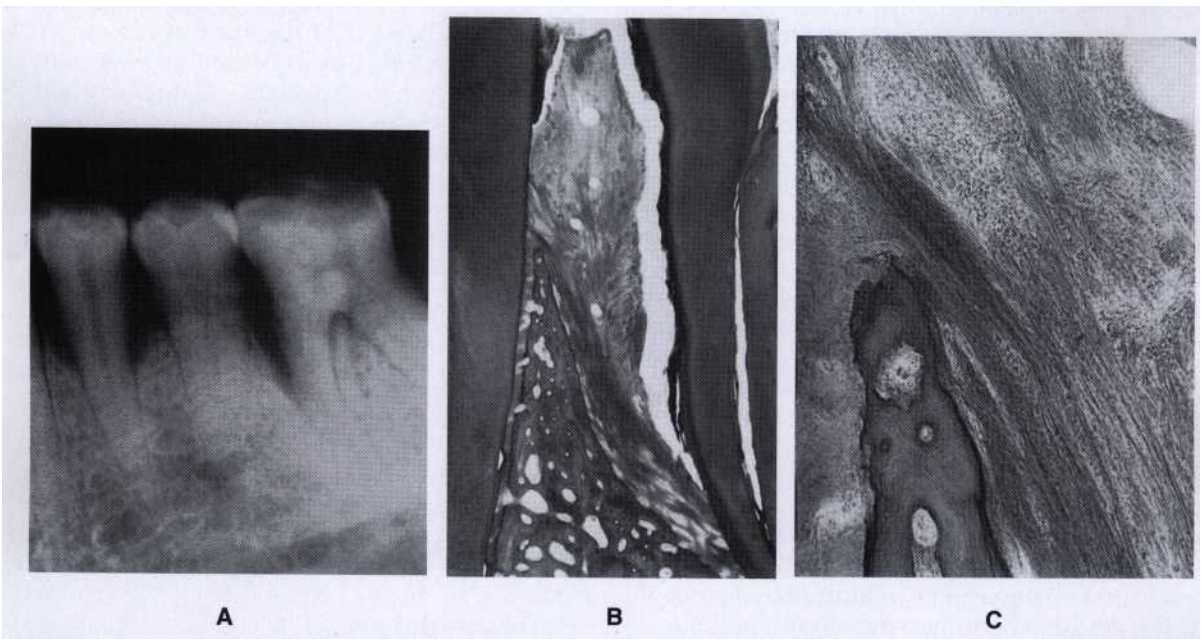

Fig. 22-20 Intrabony pocket on the mesial surface of a molar. A, Radiograph showing a deep angular defect on the mesial surface of the first molar. The bifurcation is also involved. Note the calculus on the mesial surface of the molar. B, Interdental space between the second premolar with a suprabony pocket *(left)* **and the first molar with an intrabony pocket. Note the transseptal fibers that extend from the base of the intrabony pocket along the bone to the root of the premolar, the relationship of the epithelial lining of the pocket to the transseptal fibers, and the calculus on the root. G, Transseptal fibers extending from the distal surface of the premolar over the crest of the bone into the infrabony pocket. Note the leukocytic infiltration of the transseptal fibers.**

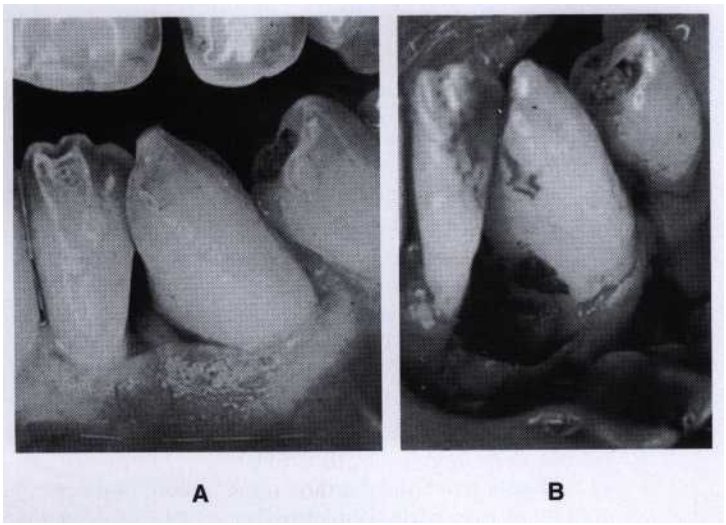

Fig. 22-21 Intrabony pocket on the mesial surface of the mandibular canine. A, Rolled gingival margin and space between gingiva and canine suggest the presence of a periodontal pocket. B, Flap reflected to show calculus on the root and a three-wall bone defect.

When loss of attachment and bone occur as a result of suprabony pockets, the alveolar crest and the periodontal ligament gradually attain a more apical position in relation to the tooth but retain their general morphology and architecture. This is usually associated with a horizontal pattern of bone loss. In intrabony pockets, the morphology of the alveolar crest changes completely with the formation of angular bony defects as a result of vertical bone loss. This may affect the function of the area. [14]

The distinguishing features of suprabony and intrabony pockets are summarized in Table 22-2. The morphologic features of the intrabony pocket are important because they necessitate modification in treatment techniques (see Chapters 62 and 63). The classification of intrabony pockets is discussed in Chapter 23.

Fig. 22-22 Two suprabony pockets in an interdental space between the maxillary cuspid and the lateral incisor. Note the normal horizontal arrangement of the transseptal fibers.

PERIODONTAL ABSCESS

A periodontal abscess is a localized purulent inflammation in the periodontal tissues (Fig. 22-23). It is also known as a *lateral* or *parietal abscess.* Abscesses localized in the gingiva, caused by injury to the outer surface of the gingiva, and not involving the supporting structures are called *gingival abscesses.* They may occur in the presence or absence of a periodontal pocket (see Chapter 18).

Periodontal abscess formation may occur in the following ways:

1. Extension of infection from a periodontal pocket deeply into the supporting periodontal tissues and localization of the suppurative inflammatory process along the lateral aspect of the root.
2. Lateral extension of inflammation from the inner surface of a periodontal pocket into the connective tissue of the pocket wall. Localization of the abscess results when drainage into the pocket space is impaired (Fig. 22-24).
3. In a pocket that describes a tortuous course around the root, a periodontal abscess may form in the culde-sac, the deep end of which is shut off from the surface.
4. Incomplete removal of calculus during treatment of a periodontal pocket. In this instance, the gingival wall shrinks, occluding the pocket orifice, and a periodontal abscess occurs in the sealed-off portion of **the pocket.**
5. A periodontal abscess may occur in the absence of periodontal disease after trauma to the tooth or perforation of the lateral wall of the root in endodontic therapy.

Periodontal abscesses are classified according to location as follows:

1. *Abscess in the supporting periodontal tissues* along the lateral aspect of the root. In this condition, a sinus generally occurs in the bone that extends laterally from the abscess to the external surface.
2. *Abscess in the soft tissue wall of a deep periodontal pocket.*

TABLE 22-2

Distinguishing Features of the Suprabony and Intrabony Pockets

Suprabony Pocket	Intrabony Pocket
1. The base of the pocket is coronal to the level of the alveolar bone.	The base of the pocket is apical to the crest of the alveolar bone so that the bone is adjacent to the soft tissue wall (see Fig. 22-2).
2. The pattern of destruction of the underlying bone is horizontal.	2. The bone destructive pattern is vertical (angular) (see Figs. 22-20 and 22-21).
3. Interproximally, the transseptal fibers that are restored during progressive periodontal disease are arranged horizontally in the space between the base of the pocket and the alveolar bone (see Fig. 22-22).	3. Interproximally, the transseptal fibers are oblique rather than horizontal. They extend from the cementum beneath the base of the pocket along the bone and over the crest to the cementum of the adjacent tooth (see Fig. 22-20).
4. On the facial and lingual surfaces, the periodontal ligament fibers beneath the pocket follow their normal horizontal-oblique course between the tooth and the bone.	4. On the facial and lingual surfaces, the periodontal ligament fibers follow the angular pattern of the adjacent bone. They extend from the cementum beneath the base of the pocket along the bone and over the crest to join with the outer periosteum.

Microscopically, an abscess is a localized accumulation of viable and nonviable PMNs within the periodontal pocket wall. The PMNs liberate enzymes that digest the cells and other tissue structures, forming the liquid product known as *pus,* which constitutes the center of the abscess. An acute inflammatory reaction surrounds the purulent area, and the overlying epithelium exhibits intracellular and extracellular edema and invasion of leukocytes (Fig. 22-25).

The localized acute abscess becomes a chronic abscess when its purulent content drains through a fistula into the outer gingival surface or into the periodontal pocket and the infection causing the abscess is not resolved.

Bacterial invasion of tissues has been reported in abscesses; the invading organisms were identified as gram-negative cocci, diplococci, fusiforms, and spirochetes.23 Invasive fungi were also found and were interpreted as being opportunistic invaders.23 Microorganisms that colonize the periodontal abscess have been reported to be primarily gram-negative anaerobic rods.55

PERIODONTAL CYST

The periodontal cyst is an uncommon lesion that produces localized destruction of the periodontal tissues along a lateral root surface, most often in the mandibular canine-premolar area.[25,11]

The following possible etiologies have been suggested:

1. Odontogenic cyst caused by proliferation of the epithelial rests of Malassez; the stimulus initiating the cellular activity is not known.
2. Lateral dentigerous cyst retained in the jaw after tooth eruption.
3. Primordial cyst of supernumerary tooth germ.
4. Stimulation of epithelial rests of the periodontal ligament by infection from a periodontal abscess or the pulp through an accessory root canal.

A periodontal cyst is usually asymptomatic and without grossly detectable changes, but it may present as a localized tender swelling. Radiographically, an interproximal periodontal cyst appears on the side of the root as a radiolucent area bordered by a radiopaque line. Its radiographic appearance cannot be differentiated from that of a periodontal abscess.

Microscopically, the cystic lining may be (1) a loosely arranged, nonkeratinized, thickened, proliferating epithelium; (2) a thin, nonkeratinized epithelium; or (3) an odontogenic keratocyst.[25]

Although periodontitis is an infectious disease of the gingival tissue, changes that occur in bone are crucial because the destruction of bone is responsible for tooth loss.

The height and density of the alveolar bone are normally maintained by an equilibrium, regulated by local and systemic influences[12-16] between bone formation and bone resorption. When resorption exceeds formation, bone height, density, or both are reduced.

The level of bone is the consequence of past pathologic experiences, whereas changes in the soft tissue of the pocket wall reflect the present inflammatory condition. Therefore the degree of bone loss is not necessarily correlated with the depth of periodontal pockets, severity of ulceration of the pocket wall, or presence or absence of pus.

BONE DESTRUCTION CAUSED BY EXTENSION OF GINGIVAL INFLAMMATION

The most common cause of bone destruction in periodontal disease is the extension of inflammation from the marginal gingiva into the supporting periodontal tissues. The inflammatory invasion of the bone surface and the initial bone loss that follows mark the transition from gingivitis to periodontitis.

Periodontitis is always preceded by gingivitis, but not all gingivitis progresses to periodontitis. Some cases of gingivitis apparently never become periodontitis, and others go through a brief gingivitis phase and rapidly develop into periodontitis. The factors that are responsible for the extension of inflammation to the supporting structures and bring about the conversion of gingivitis to periodontitis are not known at this time.

The transition from gingivitis to periodontitis is associated with changes in the composition of bacterial plaque. In advanced stages of disease, the number of motile organisms and spirochetes increases whereas the number of coccoid rods and straight rods decreases.[36]

The cellular composition of the infiltrated connective tissue also changes with increasing severity of the lesion (see Chapter 16). Fibroblasts and lymphocytes predominate in stage I gingivitis, whereas the number of plasma cells and blast cells increases gradually as the disease progresses. Seymour and associates[66,67] have postulated a stage of "contained" gingivitis in which T lymphocytes are preponderant; they believe that as the lesion becomes a B-lymphocyte lesion, it becomes progressively destructive.

Heijl and co-workers[24] were able to convert a confined, naturally occurring chronic gingivitis into a progressive periodontitis in experimental animals by placing a silk ligature into the sulcus and tying it around the neck of the tooth. This induced ulceration of the sulcular epithelium, a shift in the connective tissue population from predominantly plasma cells to predominantly polymorphonuclear leukocytes, and osteoclastic resorption of the alveolar crest. The recurrence of episodes of acute destruction over time may be one mechanism leading to progressive bone loss in marginal periodontitis.

The extension of inflammation to the supporting structures of a tooth may be modified by the pathogenic potential of plaque or the resistance of the host. The latter includes immunologic activity and other tissue-related mechanisms, such as the degree of fibrosis of the gingiva, probably the width of the attached gingiva, and the reactive fibrogenesis and osteogenesis that occur peripheral to the inflammatory lesion. A fibrin-fibrinolytic system has been mentioned as "walling off" the advancing lesion.[59] The pathway of the spread of inflammation is critical because it affects the pattern of bone destruction in periodontal disease. Considerable controversy exists about the possible changes in the pathway of gingival inflammation caused by trauma from occlusion. The suggested change in the pathway of inflammation, going toward the periodontal ligament rather than to the bone,[13,39] has not been confirmed.[8,68]

Histopathology

Gingival inflammation extends along the collagen fiber bundles and follows the course of the blood vessels through the loosely arranged tissues around them into the alveolar bone" (Fig. 23-1). Although the inflammatory infiltrate is concentrated in the marginal periodontium, the reaction is a much more diffuse one, often reaching the bone and eliciting a response before evidence of crestal resorption or loss of attachment exists.[45] In the upper molar region, inflammation can extend to the maxillary sinus, resulting in thickening of the sinus mucosa.[44]

Interproximally, inflammation spreads to the loose connective tissue around the blood vessels, through the fibers, and then into the bone through vessel channels that perforate the crest of the interdental septum at the center of the crest (Fig. 23-2), toward the side of the crest (Fig. 23-3), or at the angle of the septum, and it may enter the bone through more than one channel. Less frequently, the inflammation spreads from the gingiva directly into the periodontal ligament and from there into the interdental septum (Fig. 23-4).[1]

Continued

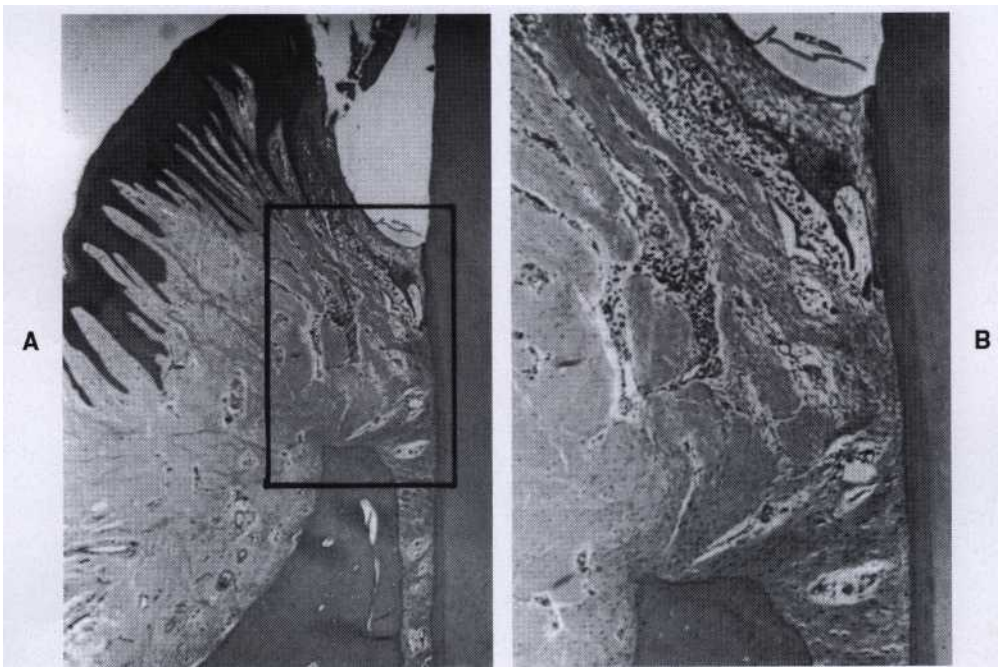

Fig. 23-1 A, Area of inflammation extending from the gingiva into the suprabony area. B, Detailed view of rectangular area in A, showing extension of inflammation along blood vessels in between collagen bundles.

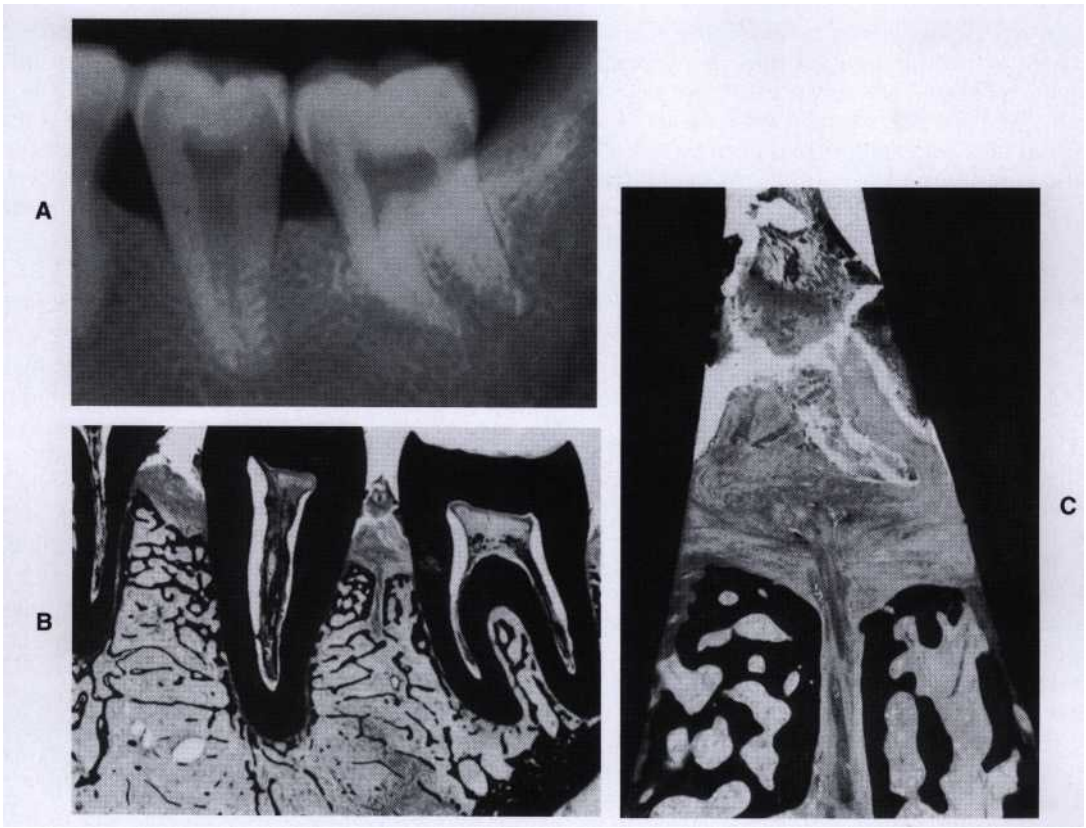

Fig. 23-2 Extension of inflammation into the center of the interdental septum. A, Molar region showing periodontal bone loss. B, Survey section of the second and third molars. G, Inflammation from the gingiva penetrates the transseptal fibers and enters the bone around blood vessel in the center of the septum.

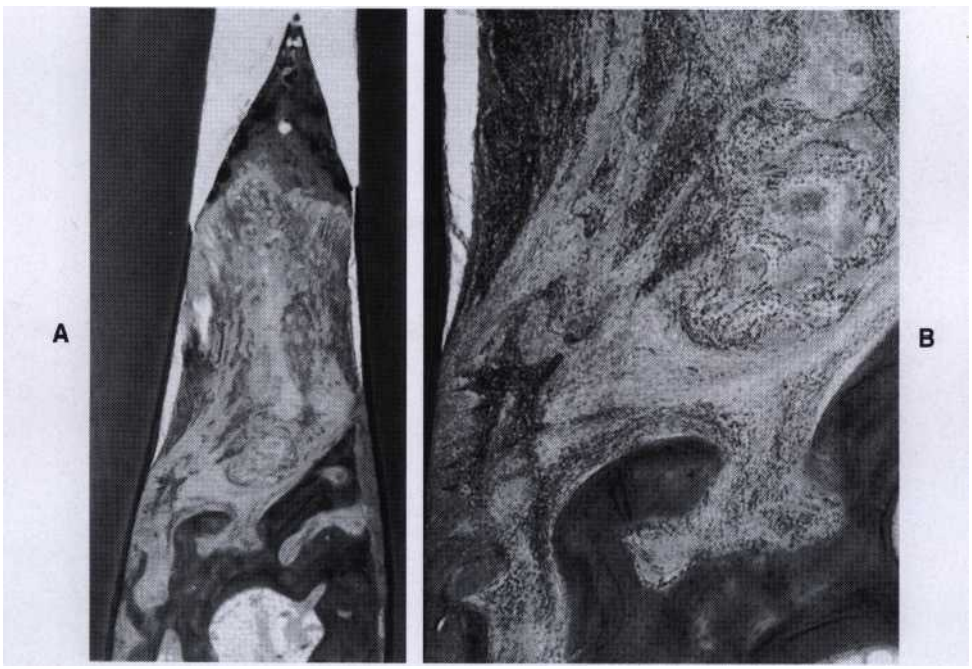

Fig. 23-3 Inflammation enters the interdental septum at the center of the crest and near the crestal angle. A, Interdental periodontal pockets with inflammation extending into the bone. B, Inflammation enters the crest of the interdental bone at two areas. Note the granular necrosis of the collagen fibers in the inflamed area above the bone.

Histopathology—cont'd

Facially and lingually, inflammation from the gingiva spreads along the outer periosteal surface of the bone (see Fig. 23-4) and penetrates into the marrow spaces through vessel channels in the outer cortex.

Along its course from the gingiva to the bone, the inflammation destroys the gingival and transseptal fibers, reducing them to disorganized granular fragments interspersed among the inflammatory cells and edema (Fig. 23-5).[49] However, there is a continuous tendency to recreate transseptal fibers across the crest of the interdental septum farther along the root as the bone destruction progresses. As a result, transseptal fibers are present, even in cases of extreme periodontal bone loss (Fig. 23-6).

The dense transseptal fibers are of clinical importance when surgical procedures are used to eradicate periodontal pockets. They form a firm covering over the bone, which is encountered after the superficial granulation tissue is removed.[54]

After inflammation reaches the bone by extension from the gingiva, it spreads into the marrow spaces and replaces the marrow with a leukocytic and fluid exudate, new blood vessels, and proliferating fibroblasts (Fig. 23-7). Multinuclear osteoclasts and mononuclear phagocytes increase in number, and the bone surfaces appear, lined with Howship's lacunae (Fig. 23-8).

In the marrow spaces, resorption proceeds from within, causing a thinning of the surrounding bony trabeculae and enlargement of the marrow spaces, followed by destruction of the bone and a reduction in bone height. Normally fatty bone marrow is partially or totally replaced by a fibrous type of marrow in the vicinity of the resorption.

Bone destruction in periodontal disease is not a process of bone necrosis.[29] It involves the activity of living cells along viable bone. When tissue necrosis and pus are present in periodontal disease, they occur in the soft tissue walls of periodontal pockets, not along the resorbing margin of the underlying bone.

The amount of inflammatory infiltrate correlates with the degree of bone loss but not with the number of osteoclasts. However, the distance from the apical border of the inflammatory infiltrate to the alveolar bone crest correlates with both the number of osteoclasts on the alveolar crest and the total number of osteoclasts.[58] Similar findings have been reported in experimentally induced periodontitis in animals.[34]

Radius of Action

Garant and Cho11 suggested that locally produced bone resorption factors may have to be present in the proximity of the bone surface to be able to exert their action. Page and Schroeder,[53] on the basis of Waerhaug's measurements made on human autopsy specimens,[14,16] postulated a range of effectiveness of about 1.5 to 2.5 mm within which bacterial plaque can induce loss of bone.

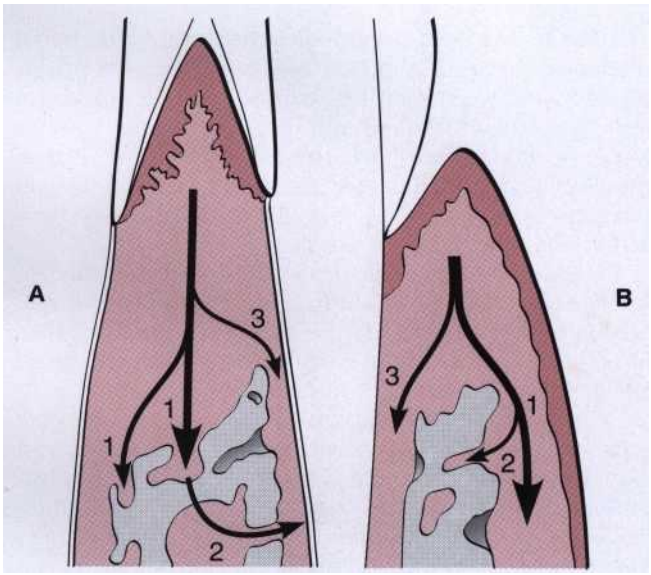

Fig. 23-4 Pathways of inflammation from the gingiva into the supporting periodontal tissues in periodontitis. A, Interproximally, from the gingiva into the bone (1), from the bone into the periodontal ligament (2), and from the gingiva into the periodontal ligament (3). B, Facially and lingually, from the gingiva along the outer periosteum (1), from the periosteum into the bone (2), and from the gingiva into the periodontal ligament (3).

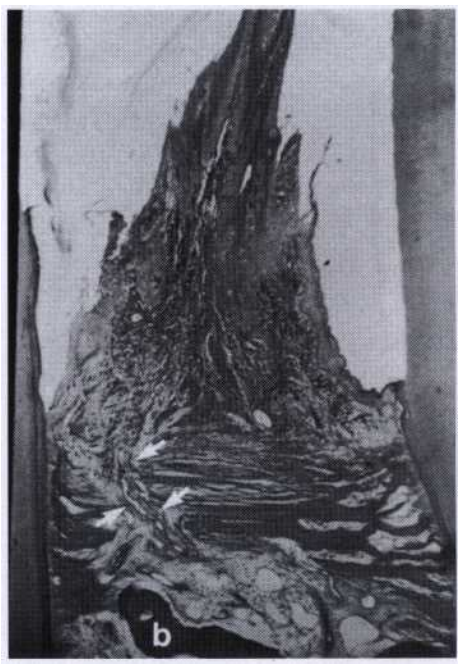

Fig. 23-5 Interruption, destruction, or both of transseptal fibers (arrows) as inflammation extends to the bone (b) around blood vessels.

Fig. 23-6 Reformation of transseptal fibers. Mesiodistal section through interdental septum showing gingival inflammation and bone loss. Recreated transseptal fibers can be seen above the bone margin, partially infiltrated by the inflammatory process.

Beyond 2.5 mm there is no effect; interproximal angular defects can appear only in spaces that are wider than 2.5 mm because narrower spaces would be destroyed entirely. Tall' corroborated this with measurements in human patients.

Large defects far exceeding a distance of 2.5 mm from the tooth surface (as described in aggressive types of periodontitis) may be caused by the presence of bacteria in the tissues.', [10,62]

Rate of Bone Loss

In a study of Sri Lankan tea laborers with no oral hygiene and no dental care, Loe and associates found the rate of bone loss to average about 0.2 mm a year for facial surfaces and about 0.3 mm a year for proximal surfaces when periodontal disease was allowed to progress untreated.37 However, the rate of bone loss may vary, depending on the type of disease present. Lbe and co-workers38 identified three subgroups of patients with periodontal disease based on interproximal loss of attachment* and tooth mortality:

1. Approximately 8% of persons had rapid progression of periodontal disease, characterized by a yearly loss of attachment of 0.1 to 1 mm.
2. Approximately 81% of individuals had moderately progressive periodontal disease, with a yearly loss of attachment of 0.05 to 0.5 mm.
3. The remaining 11% of persons had minimal or no progression of destructive disease (0.05 to 0.09 mm yearly).

***Loss of attachment can be equated with loss of bone, although the former precedes the latter by about 6 to 8 months.21**

Periods of Destruction

Periodontal destruction occurs in an episodic, intermittent fashion, with periods of inactivity or quiescence. The destructive periods result in loss of collagen and alveolar bone with deepening of the periodontal pocket. The reasons for the onset of destructive periods have not been totally elucidated, although the following theories have been offered:

1. Bursts of destructive activity are associated with subgingival ulceration and an acute inflammatory reaction, resulting in rapid loss of alveolar bone. [53,63]
2. Bursts of destructive activity coincide with the conversion of a predominately T-lymphocyte lesion to one with a predominance of B-lymphocyte-plasma cell infiltrate.67
3. Periods of exacerbation are associated with an increase of the loose, unattached, motile, gram-negative, anaerobic pocket flora, and periods of remission coincide with the formation of a dense, unattached, nonmotile, gram-positive flora with a tendency to mineralize .47
4. Tissue invasion by one or several bacterial species is followed by an advanced local host defense that controls the attack .'1

Mechanisms of Bone Destruction

The factors involved in bone destruction in periodontal disease are bacterial and host mediated. Bacterial plaque products induce the differentiation of bone progenitor cells into osteoclasts and stimulate gingival cells to release mediators that have the same effect.[23,65] Plaque products and inflammatory mediators can also act directly on osteoblasts or their progenitors, inhibiting their action and reducing their numbers.

In addition, in rapidly progressing diseases such as localized juvenile periodontitis, bacterial microcolonies or single bacterial cells may be present between collagen fibers and over the bone surface, suggesting a direct effect .6,65

Several host factors released by inflammatory cells are capable of inducing bone resorption in vitro and can play a role in periodontal disease. These include host-produced prostaglandins and their precursors, interleukin 1-a and -ß, and tumor necrosis factor (TNF)-a.

When injected intradermally, prostaglandin E2 induces the vascular changes seen in inflammation, when injected over a bone surface, it induces bone resorption in the absence of inflammatory cells and with few multinucleated osteoclasts. [18,28] In addition, nonsteroidal anti-inflammatory drugs, such as flurbiprofen or ibuprofen, inhibit prostaglandin E2 production, slowing bone loss in naturally occurring periodontal disease in beagle dogs

and humans. This effect occurs without changes in gingival inflammation and rebounds 6 months after cessation of administration of the drug.[27,78] (See also Chapters 6to9.)

Bone Formation in Periodontal Disease

Areas of bone formation are also found immediately adjacent to sites of active bone resorption (Fig. 23-9) and along trabecular surfaces at a distance from the inflammation in an apparent effort to reinforce the remaining bone (buttressing bone formation). This osteogenic response is clearly found in experimentally produced periodontal bone loss in animals.7 In humans, it is less obvious but has been confirmed by histometric[4,5] and histologic studies.[14]

The response of alveolar bone to inflammation includes bone formation and resorption; thus bone loss in periodontal disease is not simply a destructive process but results from the predominance of resorption over formation. New bone formation retards the rate of bone loss, compensating in some degree for the bone destroyed by inflammation.

Autopsy specimens from individuals with untreated disease occasionally show areas where bone resorption has ceased and new bone is being formed on previously eroded bone margins. This confirms the intermittent character of bone resorption in periodontal disease and is consistent with the varied rates of progression observed clinically in untreated periodontal disease.

These periods of remission and exacerbation (or inactivity and activity, respectively) appear to coincide with the quiescence or exacerbation of gingival inflammation, manifested by changes in the extent of bleeding, amount of exudate, and composition of bacterial plaque (see Chapter 22).

The presence of bone formation in response to inflammation, even in active periodontal disease, has a bearing on the outcome of treatment. The basic aim of periodontal therapy is the elimination of inflammation to remove the stimulus for bone resorption and therefore allow the inherent constructive tendencies to predominate.

BONE DESTRUCTION CAUSED BY TRAUMA FROM OCCLUSION

Another cause of periodontal destruction is trauma from occlusion. Trauma from occlusion can produce bone destruction in the absence or presence of inflammation (see also Chapter 24).

In the absence o f inflammation, the charges caused by trauma from occlusion vary from increased compression and tension of the periodontal ligament and increased osteoclasis of alveolar bone to necrosis of the periodontal ligament and bone and resorption of bone and tooth structure. These changes are reversible in that they can be repaired if the offending forces are removed. However, persistent trauma from occlusion results in funnel-shaped widening of the crestal portion of the periodontal ligament, with resorption of the adjacent bone.[35] These changes, which may cause the bony crest to have an angular shape, represent adaptation of the periodontal tissues aimed at "cushioning" increased occlusal forces, but the modified bone shape may weaken tooth support and cause tooth mobility.

When combined with inflammation, trauma from occlusion aggravates the bone destruction caused by the inflammation" and causes bizarre bone patterns.

Fig. 23-7 Early periodontal bone destruction. A, Early bone loss in the canine and premolar areas. B, Interdental septum beneath the periodontal pockets between the canine and first premolar. The inflammation has invaded the marrow space, and lacunar resorption of the surrounding bone surface is evident. Note the inflammation in the periodontal ligament in the right side.

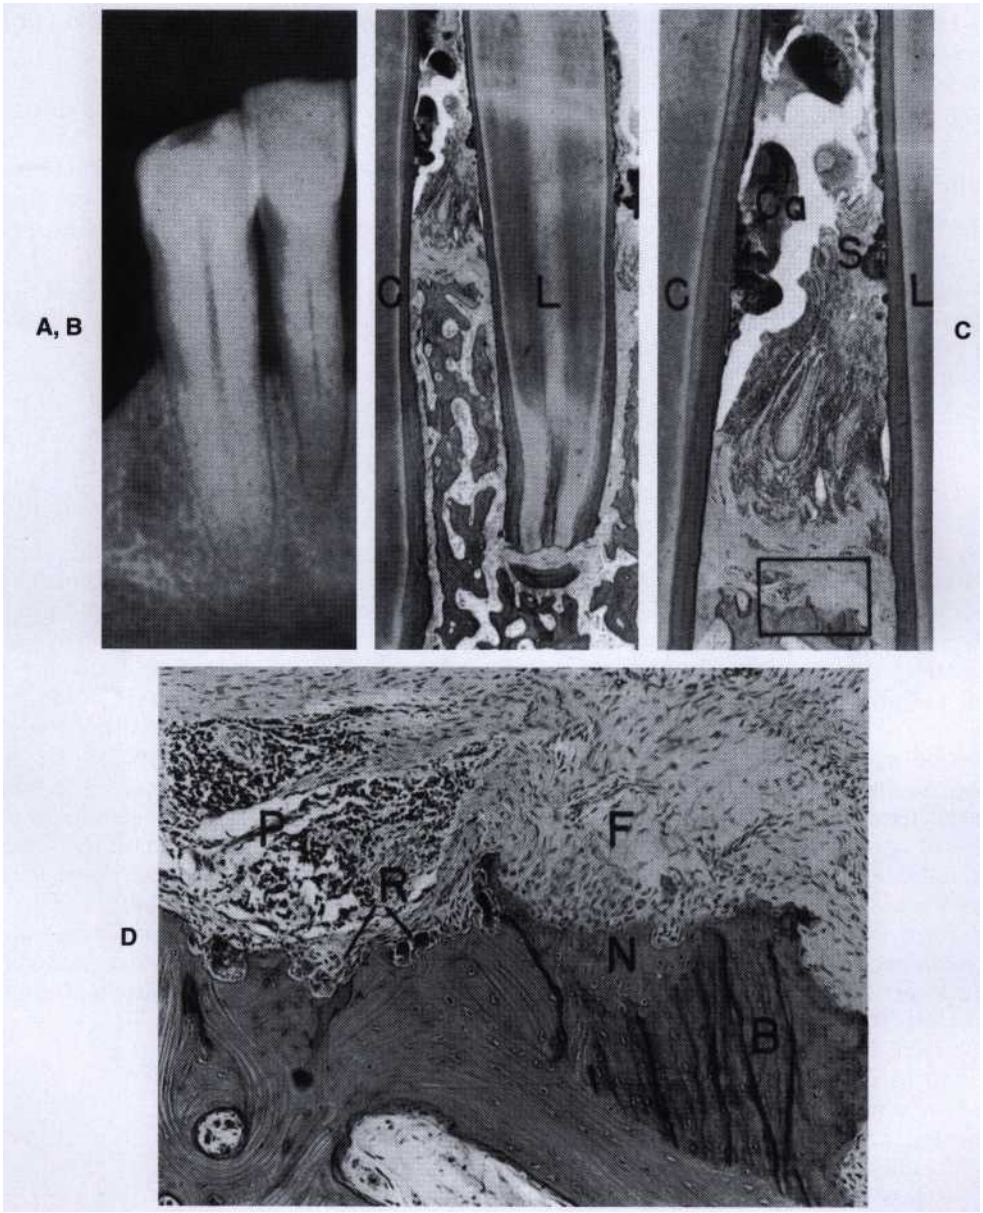

Fig. 23-8 Bone resorption and formation in periodontal disease. A, Lateral incisor and canine with bone loss. B, Survey section of lateral incisor (L) and canine (C). C, Interdental space between lateral incisor (L) and canine (C), showing calculus (Ca) and periodontal pockets with suppuration (S). D, A detailed view of the bone margin within the rectangle showing bone margin beneath the periodontal pockets. Note the osteoclastic resorption (R) beneath the inflammation (P) and newly formed bone (N) with a thin surface layer of osteoid and osteoblasts adjacent to the resorption. The new bone is separated from the lamellated bone (8) by an irregular resorption line. An area of fibrosis is shown at F.

BONE DESTRUCTION CAUSED BY SYSTEMIC DISORDERS

Local and systemic factors regulate the physiologic equilibrium of bone. When a generalized tendency toward bone resorption exists, bone loss initiated by local inflammatory processes may be magnified. This systemic influence on the response of alveolar bone has been termed the *bone factor in periodontal disease.12*

The *bone factor concept,* developed by Irving Glickman" in the early 1950s, envisioned a systemic component in all cases of periodontal disease. In addition to the amount and virulence of plaque bacteria, the nature of the systemic component, not its presence or absence, influences the severity of periodontal destruction. Although the term *bone factor is* not in current use, the concept of a role played by systemic defense mechanisms has been validated, particularly by studies of immune deficiencies in severely destructive types of periodontitis, such as the juvenile forms of the disease.

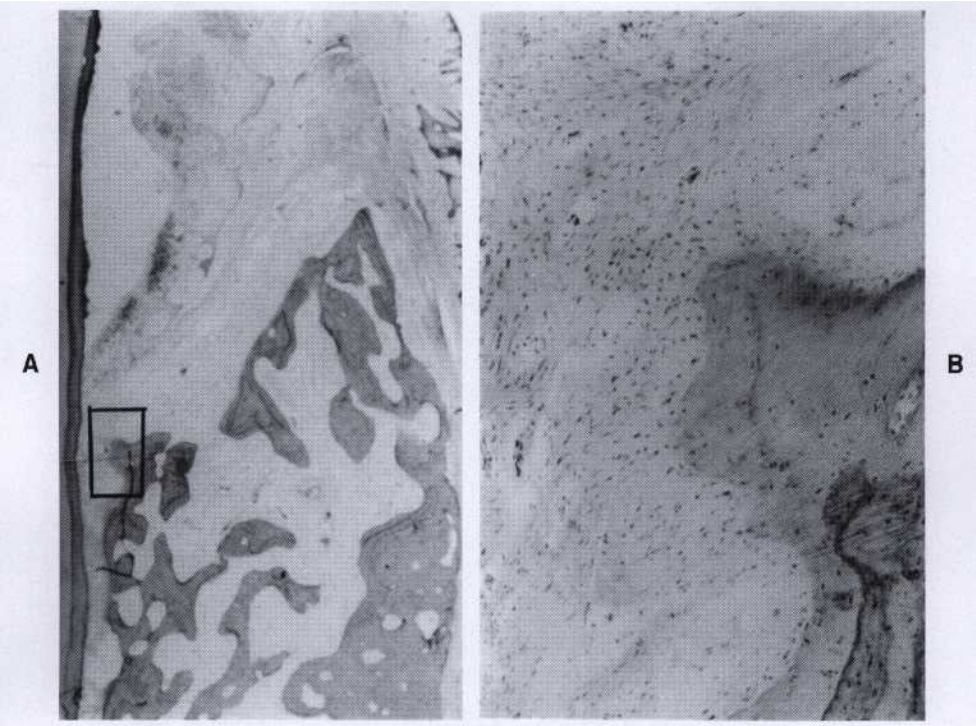

Fig. 23-9 Bone formation in untreated periodontal disease. A, Section showing an infrabony pocket with deep angular bone loss. B, Magnification of the rectangular area in A, showing newly formed bone at bottom of defect.

In recent years, interest has increased in the possible relationship between periodontal bone loss and osteoporosis. Osteoporosis is a physiologic condition of postmenopausal women, resulting in loss of bone mineral content and structural bone changes. Periodontitis and osteoporosis share a number of risk factors (e.g., aging, smoking, diseases, and medications that interfere with healing). Few studies on the relationship between periodontitis and osteoporosis are available, and some show relationships between skeletal density and oral bone density and between crestal height and residual ridge resorption. In 1968, Groen et alto reported relationships between osteopenia and periodontal disease, tooth mobility and tooth loss. Several more recent studies have indicated that such an association may exist, but final proof is lacking." [26,62,73]

Periodontal bone loss may also occur in generalized skeletal disturbances (e.g., hyperparathyroidism, leukemia, or Langerhans' cell histiocytosis) by mechanisms that may be totally unrelated to the usual periodontal problem.

FACTORS DETERMINING BONE MORPHOLOGY IN PERIODONTAL DISEASE

Normal Variation in Alveolar Bone

Considerable normal variation in the morphologic features of alveolar bone exists (see Chapter 2), which affects the osseous contours produced by periodontal disease. The anatomic features that substantially affect the bone destructive pattern in periodontal disease include the following:

- The thickness, width, and crestal angulation of the interdental septa
- The thickness of the facial and lingual alveolar plates
- The presence of fenestrations, dehiscences, or both
- The alignment of the teeth
- Root and root trunk anatomy
- Root position within the alveolar process
- Proximity with another tooth surface

For example, angular osseous defects cannot form in thin facial or lingual alveolar plates, which have little or no cancellous bone between the outer and inner cortical layers. In such instances the entire crest of the plate is destroyed, and the height of the bone is reduced (Fig. 23-10).

Exostoses

Exostoses are outgrowths of bone of varied size and shape. Palatal exostoses have been found in 40% of human skulls.[46] They can occur as small nodules, large nodules, sharp ridges, spike-like projections, or any combination of these (see Fig. 23-20). Exostoses have been described in rare cases as developing after the placement of free gingival grafts .so

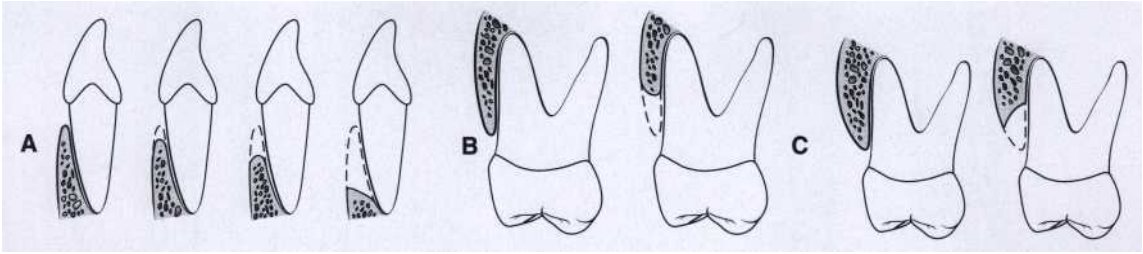

Fig. 23-10 A, A lower incisor with thin labial bone. Bone loss can become vertical only when it reaches thicker bone in apical areas. B, Upper molars with thin facial bone, where only horizontal bone loss can occur. C, Upper molar with a thick facial bone, allowing for vertical bone loss.

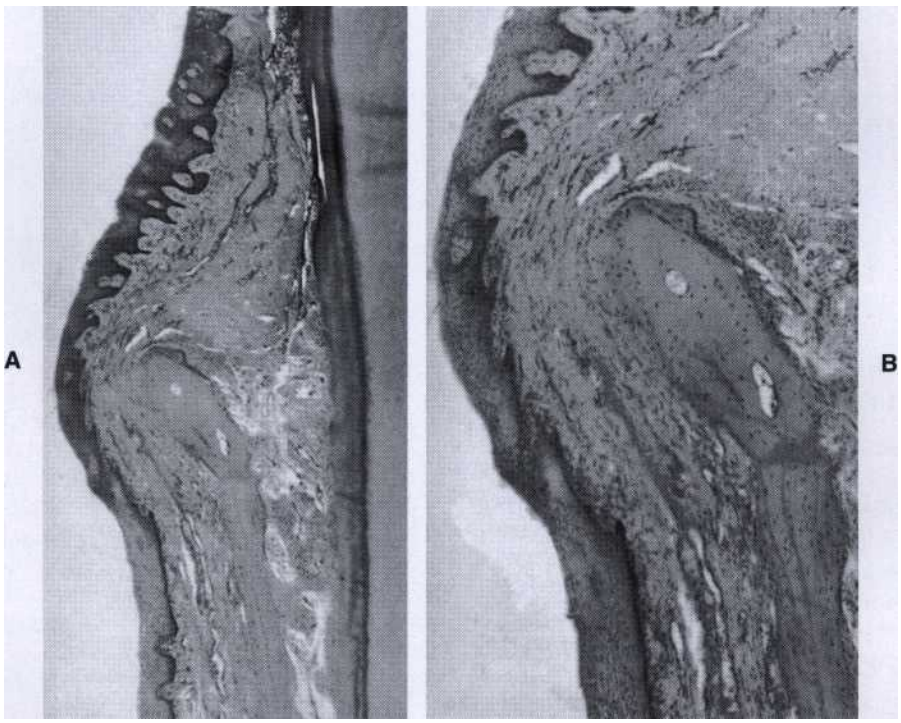

Fig. 23-11 Lipping of facial bone. A, Peripheral buttressing bone formation along the external surface of the facial bony plate and at the crest. Note the deformity in the bone produced by the buttressing bone formation and the bulging of the mucosa. B, Detailed view showing lipping and deformity produced by buttressing bone formation.

Trauma from Occlusion

Trauma from occlusion may be a factor in determining the dimension and shape of bone deformities. It may cause a thickening of the cervical margin of alveolar bone or a change in the morphology of the bone (e.g., angular defects and buttressing bone [see following discussion]) on which inflammatory changes will later be superimposed.

Buttressing Bone Formation (Lipping)

Bone formation sometimes occurs in an attempt to buttress bony trabeculae weakened by resorption. When it occurs within the jaw, it is termed *central buttressing bone formation.* When it occurs on the external surface, it is referred to as *peripheral buttressing bone formation."* The latter may cause bulging of the bone contour, termed *lipping,* which sometimes accompanies the production of osseous craters and angular defects (Fig. *23-11).*

Food Impaction

Interdental bone defects often occur where proximal contact is abnormal or absent. Pressure and irritation from food impaction contribute to the inverted bone architecture. In some instances the poor proximal relationship may be the result of a shift in tooth position because of extensive bone destruction preceding food

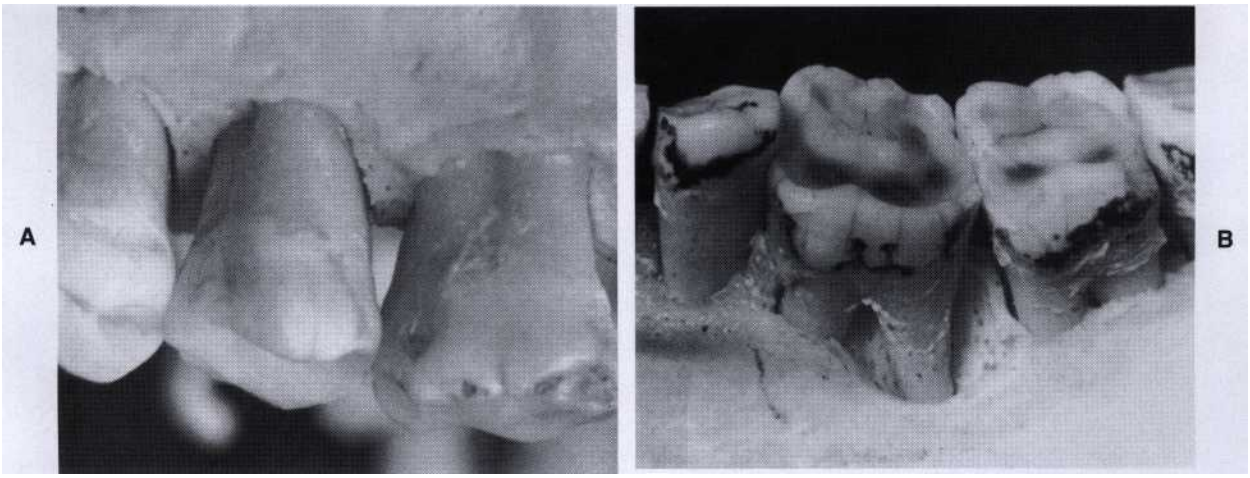

Fig. 23-12 A, Horizontal bone loss. Note the reduction in height of the marginal bone, exposing cancellous bone and reaching the furca of the second molar. B, Vertical (angular) bone loss on the distal root of the first molar.

impaction. In such cases, food impaction is a complicating factor rather than the cause of the bone defect.

juvenile Perioclontitis

A vertical or angular pattern of alveolar bone destruction is found around the first molars in juvenile periodontitis. The cause of the localized bone destruction in this type of periodontal disease is unknown (see Chapter *28).*

BONE DESTRUCTION PATTERNS IN PERIODONTAL DISEASE

Periodontal disease alters the morphologic features of the bone in addition to reducing bone height. An understanding of the nature and pathogenesis of these alterations is essential for effective diagnosis and treatment.

Horizontal Bone Loss

Horizontal bone loss is the most common pattern of bone loss in periodontal disease. The bone is reduced in height, but the bone margin remains roughly perpendicular to the tooth surface. The interdental septa and facial and lingual plates are affected, but not necessarily to an equal degree around the same tooth (Fig. *23-12, A).*

Bone Deformities (Osseous Defects)

Different types of bone deformities can result from periodontal disease. These usually occur in adults and have been reported in human skulls with deciduous dentitions.[30] Their presence may be suggested on radiographs, but careful probing and surgical exposure of the areas is required to determine their exact conformation and dimensions.

Vertical or Angular Defects

Vertical or angular defects are those that occur in an oblique direction, leaving a hollowed-out trough in the bone alongside the root; the base of the defect is located apical to the surrounding bone (see Figs. *23-12, B; 23-13;* and *23-14).* In most instances, angular defects have accompanying infrabony pockets; such pockets always have an underlying angular defect.

Angular defects are classified on the basis of the number of osseous walls." Angular defects may have one, two, or three walls (Figs. *23-15* to *23-17).* The number of walls in the apical portion of the defect may be greater than that in its occlusal portion, in which case the term *combined osseous defect is* used (Fig. *23-18).*

Vertical defects occurring interdentally can generally be seen on the radiograph, although thick, bony plates sometimes may obscure them. Angular defects can also appear on facial and lingual or palatal surfaces, but these defects are not seen on radiographs. Surgical exposure is the only sure way to determine the presence and configuration of vertical osseous defects.

Vertical defects increase with age .[48,52,79] Approximately 60% of persons with interdental angular defects have only a single defect .[48] Vertical defects detected radiographically have been reported to appear most commonly on the distal surfaces [48] and mesial surfaces.[52,79] However, three-wall defects are more frequently found on the mesial surfaces of upper and lower molars .[31]

The three-wall vertical defect was originally called an *infrabony defect.** This defect appears most frequently on the mesial aspects of second and third maxillary and mandibular molars. The one-wall vertical defect is also called a *hemiseptum.*

* **The term** *intrabony* **was later expanded to designate all vertical defects.**

Fig. 23-13 Angular (vertical) defects of different depths.

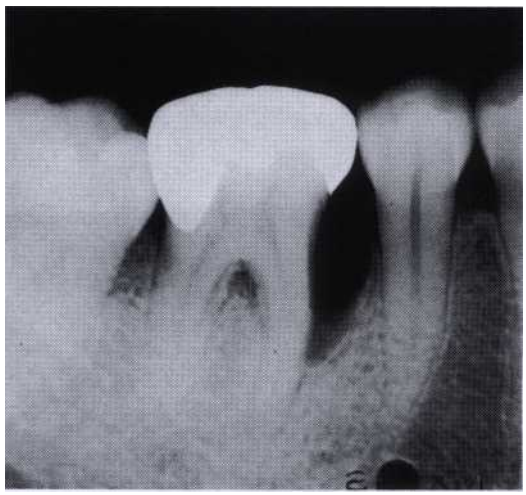

Fig. 23-14 Angular defect on the mesial surface of the first molar. Note also the furcation involvement.

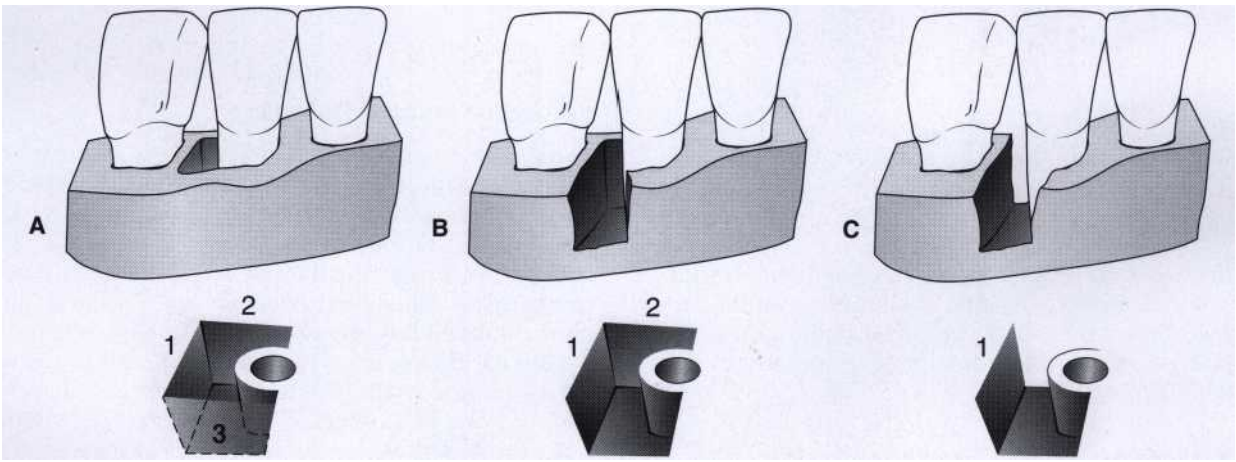

Fig. 23-15 One-, two-, and three-walled vertical defects on right lateral incisor. A, Three bony walls: distal (1), lingual (2), and facial (3). B, Two-wall defect: distal (1) and lingual (2). C, One-wall defect: distal wall only (1).

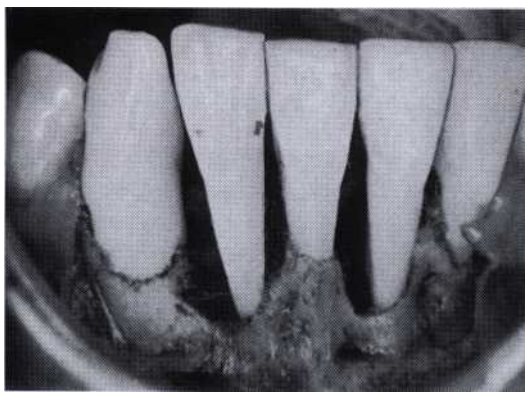

Fig. 23-16 One-wall vertical defect on the mesial surface of the left lateral incisor and 1 z -wall defect (distal wall and half of the labial wall) on the distal surface of the right lateral incisor.

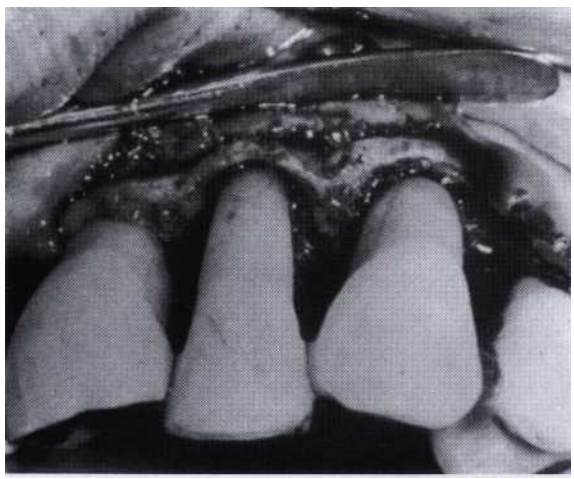

Fig. 23-17 Circumferential vertical defect in relation to the upper lateral incisor and canine.

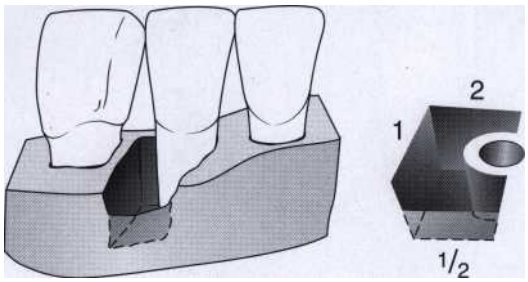

Fig. 23-18 Combined type of osseous defect. Because the facial wall is half the height of the distal (1) and lingual (2) walls, this is an osseous defect with three walls in its apical half and two walls in the occlusal half.

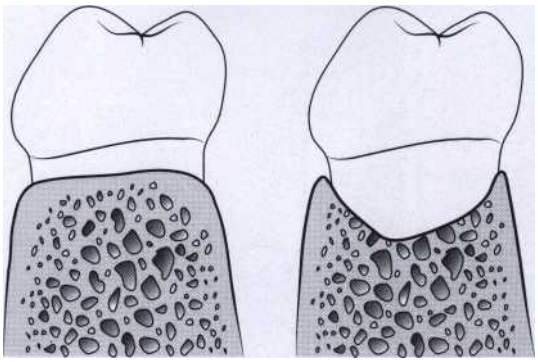

Fig. 23-19 Diagrammatic representation of an osseous crater in a faciolingual section between two lower molars. *Left* **Normal bone contour.** *Right,* **Osseous crater.**

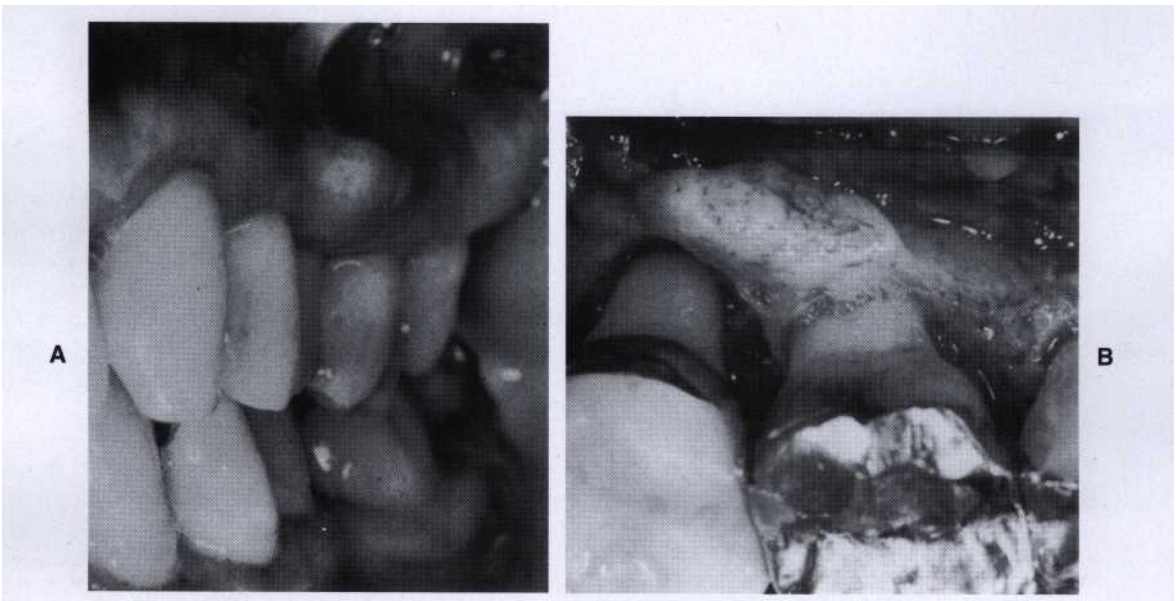

Fig. 23-20 A, Exostosis in the facial aspect. B, Exostosis in the palatal aspect. Note also the circumferential defect in the second molar.

Osseous Craters

Osseous craters are concavities in the crest of the interdental bone confined within the facial and lingual walls (Fig. 23-19). Craters have been found to make up about one third (35.2%) of all defects and about two thirds (62%) of all mandibular defects. They are twice as common in posterior segments as in anterior segments.[42,43]

The heights of the facial and lingual crests of a crater have been found to be identical in 85% of cases, with the remaining 15% being nearly equally divided between higher facial crests and higher lingual crests.[60] The following reasons for the high frequency of interdental craters have been suggested:

- The interdental area collects plaque and is difficult to clean.
- The normal flat or even concave faciolingual shape of the interdental septum in lower molars may favor crater formation.
- Vascular patterns from the gingiva to the center of the crest may provide a pathway for inflammation.[40,41,60]

Bulbous Bone Contours

Bulbous bone contours are bony enlargements caused by exostoses, adaptation to function, or buttressing bone formation (Fig. 23-20). They are found more frequently in the maxilla than in the mandible.

Reversed Architecture

Reversed architecture defects are produced by loss of interdental bone, including the facial plates, lingual plates,

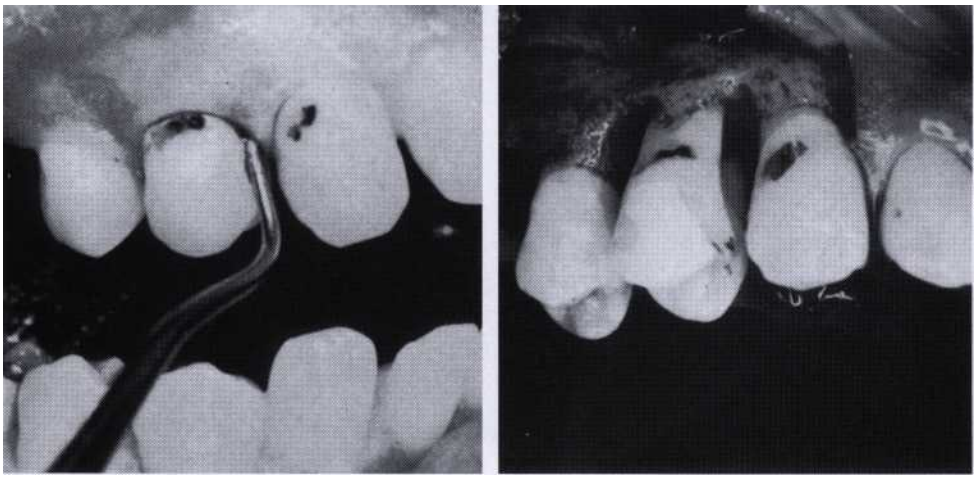

Fig. 23-21 Reversed architecture. *Left,* **Probe in the deep infrabony pocket on the mesial surface of the maxillary premolar.** *Right,* **Elevated flap shows irregular bone margin with notching of interdental bone.**

Fig. 23-22 Labial ledge produced by interproximal resorption.

or both, without concomitant loss of radicular bone, thereby reversing the normal architecture (Fig. 23-21). Such defects are more common in the maxilla .[48]

Ledges

Ledges **are plateau-like bone margins caused by resorption of thickened bony plates (Fig.** 23-22).

Furcation Involvements

The term *furcation involvement* refers to the invasion of the bifurcation and trifurcation of multirooted teeth by periodontal disease. The prevalence of furcation-involved molars is not clear.[9,51] Whereas some reports[32] indicate that the mandibular first molars are the most common sites and the maxillary premolars are the least common, others'[°] have found higher prevalence in upper molars. The number of furcation involvements increases with age.[32,33]

The denuded furcation may be visible clinically or covered by the wall of the pocket. The extent of involvement is determined by exploration with a blunt probe, along with a simultaneous blast of warm air to facilitate visualization (Figs. 23-23 and 23-24).

Furcation involvements have been classified as grades I, II, III, and IV according to the amount of tissue destruction. Grade I is incipient bone loss, grade II is partial bone loss (cul-de-sac), and grade III is total bone loss with through-and-through opening of the furcation. Grade IV is similar to grade III, but with gingival recession exposing the furcation to view.

Microscopically, furcation involvement presents no unique pathologic features. It is simply a phase in the rootward extension of the periodontal pocket. In its early stages, a widening of the periodontal space occurs, with cellular and fluid inflammatory exudation (Fig. 23-25), followed by epithelial proliferation into the furcation area from an adjoining periodontal pocket (Fig. 23-26). Extension of the inflammation into the bone leads to resorption and reduction in bone height (Fig. 23-27). The bone destructive pattern may produce horizontal loss, or angular osseous defects associated with infrabony pockets may exist (Figs. 23-28 and 23-29). Plaque, calculus, and bacterial debris occupy the denuded furcation space.

The destructive pattern in a furcation involvement varies in different cases and with the degree of involvement. Bone loss around each individual root may be horizontal or angular, and very frequently a crater develops in the interradicular area. Probing to determine the presence of these destructive patterns must be done horizontally and vertically around each involved root and in the crater area to establish the depth of the vertical component.

Furcation involvement is a stage of progressive periodontal disease and has its same etiology. The difficulty, and sometimes the impossibility,[2,3] of controlling plaque in furcations are responsible for the presence of extensive lesions in this area.[75]

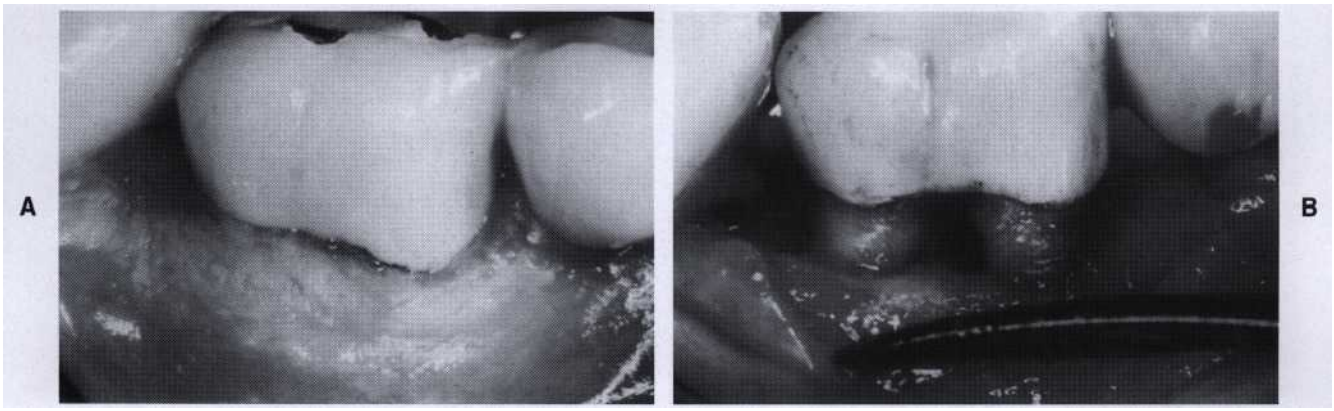

Fig. 23-23 A, Partially stippled gingiva covering the furcation area of the lower first molar. B, Flap elevation reveals furcation involvement.

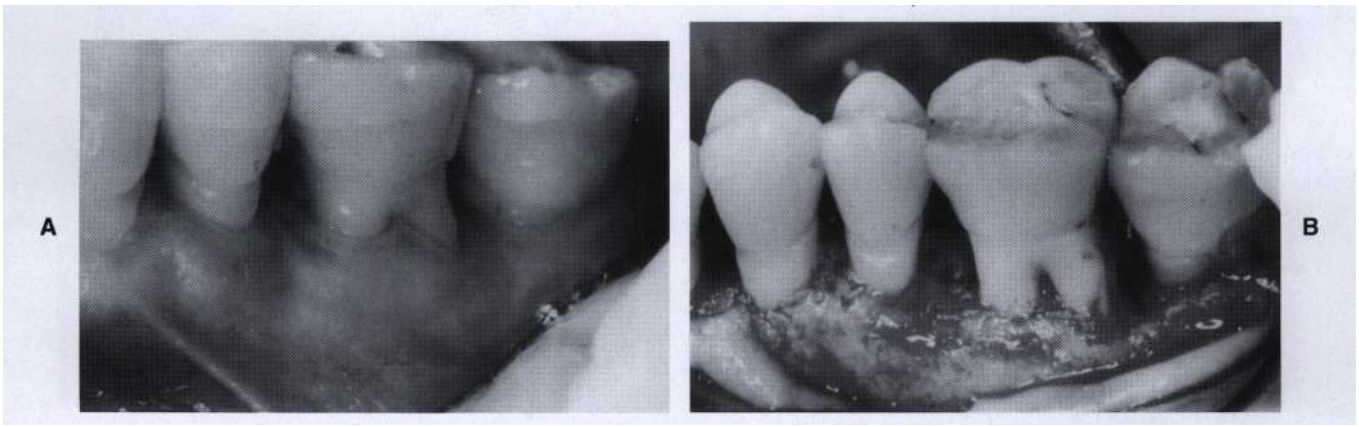

Fig. 23-24 A, Furcation area barely covered by gingival tissue. B, Flap elevation reveals partial furcation involvement.

Fig. 23-25 Furcation area in a mandibular molar. The periodontal space is widened. There is edema, slight leukocytic infiltration of the periodontal ligament (P), and an area of resorption (R) at the margin of the bone (8).

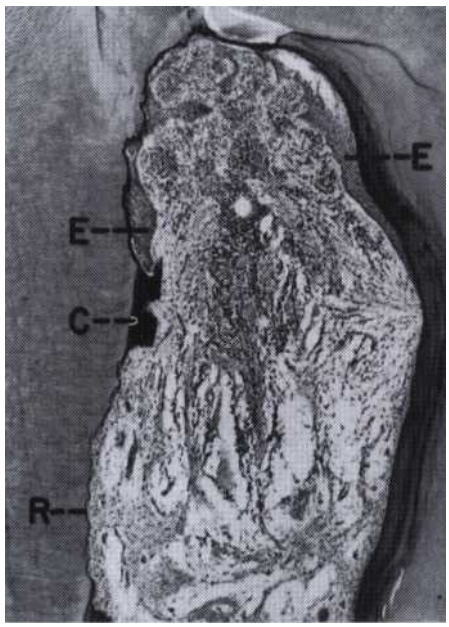

Fig. 23-26 Furcation area showing proliferation of epithelium (E), edema and degeneration of connective tissue, bone loss, and destruction of cementum (C) and dentin with irregularly hollowed-out lacunae along the dentinal surface (R).

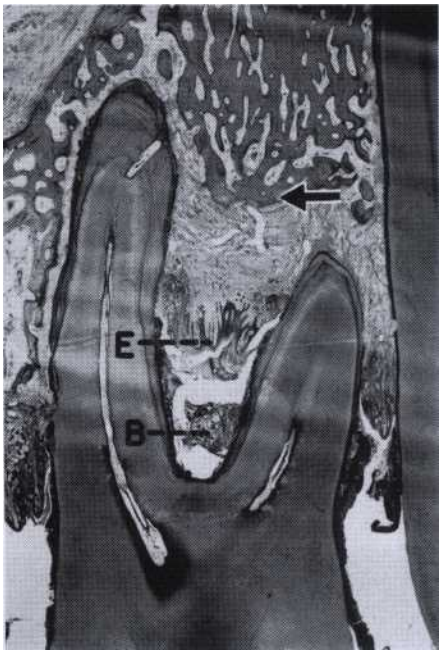

Fig. 23-27 Furcation involvement. Maxillary first molar showing pronounced bone loss, inflammation, and epithelial proliferation (E). Bacterial debris is shown at B. Note the different height of bone between the mesial surface (left) and the furcation area (arrow).

Fig. 23-29 Crater-like osseous defect in trifurcation of a molar.

Fig. 23-28 Different degrees of furcation involvement in a human autopsy specimen. Moderate involvement is found in the third molar; a more advanced lesion in the second molar; and a very severe lesion in the first molar, exposing almost the entire mesial root.

The role of trauma from occlusion in the etiology of furcation lesions is controversial. Some assign a key role to trauma, believing that furcation areas are most sensitive to injury from excessive occlusal forces.'s Others deny the initiating effect of trauma and consider that inflammation and edema caused by plaque in the furcation area tend to extrude the tooth, which then becomes traumatized and sensitive.753

Trauma from occlusion has been suspected as a contributing etiologic factor in cases of furcation involvement with craterlike or angular deformities in the bone and especially when bone destruction is localized to one of the roots.

Other factors that may play a role are the presence of enamel projections into the furcation,42 which occurs in about *13%* of multirooted teeth, and the proximity of the furcation to the cementoenamel junction, which occurs in about 75% of cases of furcation involvement.33

The presence of accessory pulpal canals in the furcation area may extend pulpal inflammation to the furcation21; this possibility should be carefully explored, particularly when mesial and distal bone retain their normal height. Accessory canals connecting the pulp chamber floor to the furcation have been found in *36%* of maxillary first molars, *12%* of maxillary second molars, *32/0* of mandibular first molars, and *24%* of mandibular second molars.72

The diagnosis of furcation involvement is made by clinical examination and careful probing with one of the specially designed probes (see Chapter *30).* Radiographic examination of the area is helpful, but lesions can be obscured by angulation of the beam and the radiopacity of neighboring structures (see Chapter *31).*

For more detailed clinical considerations in the diagnosis and treatment of furcation involvements, see Chapters *30* and *64.*

Pathogenesis

ADAPTIVE CAPACITY OF THE PERIODONTIUM TO OCCLUSAL FORCES

The periodontium tries to accommodate to the forces exerted on the crown. This adaptive capacity varies in different persons and in the same person at different times. The effect of occlusal forces on the periodontium is influenced by the magnitude, direction, duration, and frequency of the forces.

When the **magnitude** of occlusal forces is increased, the periodontium responds with a widening of the periodontal ligament space, an increase in the number and width of periodontal ligament fibers, and an increase in the density of alveolar bone.

Changing the **direction** of occlusal forces causes a reorientation of the stresses and strains within the periodontium[24] (Fig. 24-1). The principal fibers of the periodontal ligament are arranged so that they best accommodate occlusal forces along the long axis of the tooth. Lateral (horizontal) forces and torque (rotational) forces are more likely to injure the periodontium.

The response of alveolar bone is also affected by the **duration** and **frequency** of occlusal forces. Constant pressure on the bone is more injurious than intermittent forces. The more frequent the application of an intermittent force, the more injurious the force to the periodontium.

TRAUMA FROM OCCLUSION

An inherent "margin of safety" common to all tissues permits some variation in occlusion without adversely affecting the periodontium. However, *when occlusal forces exceed the adaptive capacity of the tissues, tissue injury results.*[13,35,53,54] The resultant injury is termed *trauma from occlusion.**

Thus *trauma from occlusion refers to the tissue injury, not the occlusal force.* An occlusion that produces such injury is called a *traumatic occlusion.*[2] Excessive occlusal forces may also disrupt the function of the masticatory musculature and cause painful spasms, injure the temporomandibular joints, or produce excessive tooth wear, but the term *trauma from occlusion is* generally used in connection with injury in the periodontium.

* **The term is used throughout this text to designate periodontal tissue injury produced by occlusal forces. It is also known as traumatism and occlusal trauma.**

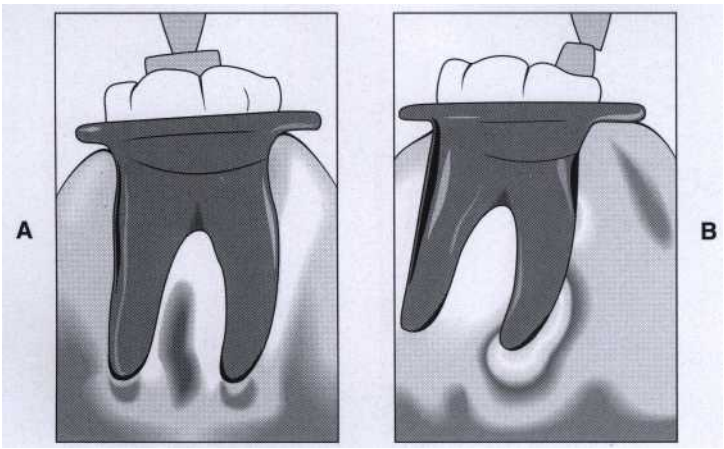

Fig. 24-1 Stress patterns around the roots changed by shifting the direction of occlusal forces (experimental model using photoelastic analysis). A, Buccal view of an ivorine molar subjected to an axial force. The shaded fringes indicate that the internal stresses are at the root apices. B, Buccal view of ivorine molar subjected to a mesial tilting force. The shaded fringes indicate that the internal stresses are along the mesial surface and at the apex of the mesial root. (From Glickman I, Roeber F, Brion M, et al: Photoelastic analysis of internal stresses in the periodontium created by occlusal forces. J Periodontol 1970; 41:30.)

Acute and Chronic Trauma

Trauma from occlusion may be acute or chronic. *Acute trauma from occlusion* results from an abrupt occlusal impact, such as that produced by biting on a hard object (e.g., an olive pit). In addition, restorations or prosthetic appliances that interfere with or alter the direction of occlusal forces on the teeth may induce acute trauma. The results are tooth pain, sensitivity to percussion, and increased tooth mobility. If the force is dissipated by a shift in the position of the tooth or by wearing away or correction of the restoration, the injury heals and the symptoms subside. Otherwise, periodontal injury may worsen and develop into necrosis accompanied by periodontal abscess formation or persist as a symptom-free chronic condition. Acute trauma can also produce cementum tears (see Chapter 2).

Chronic trauma from occlusion is more common than the acute form and is of greater clinical significance. It most often develops from gradual changes in occlusion produced by tooth wear, drifting movement, and extrusion of teeth, combined with parafunctional habits such as bruxism and clenching, rather than as a sequela of acute periodontal trauma (see Chapters 25 and 51). The features of chronic trauma from occlusion and their significance are discussed in the following text.

The criterion that determines whether an occlusion is traumatic is whether it produces periodontal injury, not how the teeth occlude. Any occlusion that produces periodontal injury is traumatic. Malocclusion is not necessary to produce trauma; periodontal injury may occur when the occlusion appears normal. The dentition may be anatomically and aesthetically acceptable but functionally injurious. Similarly, not all malocclusions are necessarily injurious to the periodontium. Traumatic occlusal relationships are referred to by such terms as *occlusal disharmony, functional imbalance,* and *occlusal dystrophy.* These terms refer to the occlusion's effect on the periodontium, not to the position of the teeth. Because *trauma from occlusion* refers to the tissue injury rather than the occlusion, an increased occlusal force is not traumatic if the periodontium can accommodate it.

Primary and Secondary Trauma from Occlusion

Trauma from occlusion may be caused by alterations in occlusal forces, reduced capacity of the periodontium to withstand occlusal forces, or both. When trauma from occlusion is the result of alterations in occlusal forces, it is called *primary trauma from occlusion.* When it results from reduced ability of the tissues to resist the occlusal forces, it is known as *secondary trauma from occlusion.*

Primary trauma from occlusion occurs if trauma from occlusion is considered the primary etiologic factor in periodontal destruction and if the only local alteration to which a tooth is subjected is from occlusion. Examples include periodontal injury produced around teeth with a previously healthy periodontium following 1) the insertion of a "high filling," 2) the insertion of a prosthetic replacement that creates excessive forces on abutment and antagonistic teeth, *3)* the drifting movement or extrusion of teeth into spaces created by unreplaced missing teeth, or 4) the orthodontic movement of teeth into functionally unacceptable positions. Most studies on experimental animals of the effect of trauma from occlusion have examined the primary type of trauma. Changes produced by primary trauma do not alter the level of connective tissue attachment and do not initiate pocket formation. This is probably because the supracrestal gingival fibers are not affected and therefore prevent apical migration of the functional epithelium."

Secondary trauma from occlusion occurs when the adaptive capacity of the tissues to withstand occlusal forces is impaired by bone loss resulting from marginal inflammation. This reduces the periodontal attachment area and alters the leverage on the remaining tissues. The periodontium becomes more vulnerable to injury, and previously well-tolerated occlusal forces become traumatic.

Fig. 24-2 depicts three different situations on which excessive occlusal forces can be superimposed:

1. Normal periodontium with normal height of bone
2. Normal periodontium with reduced height of bone
3. Marginal periodontitis with reduced height of bone

The first case is an example of primary trauma from occlusion, whereas the last two represent secondary trauma from occlusion. The effects of trauma from occlusion in these different situations are analyzed in the following discussion.

It has been found in experimental animals that systemic disorders can reduce tissue resistance and that previously tolerable forces may become excessive.[30,61,72] This could theoretically represent another mechanism by which tissue resistance to increased forces is lowered, resulting in secondary trauma from occlusion.

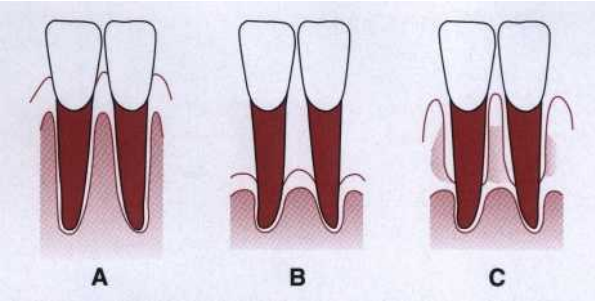

Fig. 24-2 Traumatic forces can occur on A, normal periodontium with normal height of bone; B, normal periodontium with reduced height of bone; or C, marginal periodontitis with reduced height of bone.

TISSUE RESPONSE TO INCREASED OCCLUSAL FORCES

Stages of Tissue Response

Tissue response occurs in three stages[9-16] injury, repair, and adaptive remodeling of the periodontium.

Stage I: Injury. Tissue injury is produced by excessive occlusal forces. The body then attempts to repair the injury and restore the periodontium. This can occur if the forces are diminished or if the tooth drifts away from them. However, if the offending force is chronic, the periodontium is remodeled to cushion its impact. The ligament is widened at the expense of the bone, resulting in angular bone defects without periodontal pockets, and the tooth becomes loose.

Under the forces of occlusion, a tooth rotates around a fulcrum or axis of rotation, which in single-rooted teeth is located in the junction between the middle third and the apical third of the clinical root (see Fig. 2-12). This creates areas of pressure and tension on opposite sides of the fulcrum. Different lesions are produced by different degrees of pressure and tension. If jiggling forces are exerted, these different lesions may coexist in the same area.

Slightly excessive pressure stimulates resorption of the alveolar bone, with a resultant widening of the periodontal ligament space. Slightly excessive tension causes elongation of the periodontal ligament fibers and apposition of alveolar bone. In areas of increased pressure, the blood vessels are numerous and reduced in size; in areas of increased tension, they are enlarged.[79]

Greater pressure produces a gradation of changes in the periodontal ligament, starting with compression of the fibers, which produces areas of hyalinization.[64-66] Subsequent injury to the fibroblasts and other connective tissue cells leads to necrosis of areas of the ligament.[62,66] Vascular changes are also produced: within 30 minutes, retardation and stasis of blood flow occur; at 2 to 3 hours, blood vessels appear to be packed with erythrocytes, which start to fragment; and between 1 and 7 days, disintegration of the blood vessel walls and release of the contents into the surrounding tissue occur.[63] In addition, increased resorption of alveolar bone and resorption of the tooth surface occur[39,44] (Figs. 24-3 and 24-4).

Severe tension causes widening of the periodontal ligament, thrombosis, hemorrhage, tearing of the periodontal ligament, and resorption of alveolar bone.

Pressure severe enough to force the root against bone causes necrosis of the periodontal ligament and bone. The bone is resorbed from viable periodontal ligament adjacent to necrotic areas and from marrow spaces, a process called *undermining resorption*.[34,53]

The areas of the periodontium most susceptible to injury from excessive occlusal forces are the furcations.[31]

Injury to the periodontium produces a temporary depression in mitotic activity and the rate of proliferation and differentiation of fibroblasts,[11] in collagen formation, and in bone formation.[39,71,73] These return to normal levels after dissipation of the forces.

Stage II: Repair. Repair is constantly occurring in the normal periodontium, and trauma from occlusion stimulates increased reparative activity.

The damaged tissues are removed, and new connective tissue cells and fibers, bone, and cementum are formed in an attempt to restore the injured periodontium (Fig. 24-5). Forces remain traumatic only as long as the damage produced exceeds the reparative capacity of the tissues.

When bone is resorbed by excessive occlusal forces, the body attempts to reinforce the thinned bony trabeculae with new bone (Fig. 24-6). This attempt to compensate for lost bone is called *buttressing bone formation* and is an important feature of the reparative process associated with trauma from occlusion.[28] It also occurs when bone is destroyed by inflammation or osteolytic tumors.

Buttressing bone formation occurs within the jaw (central buttressing) and on the bone surface (peripheral buttressing). In central buttressing, the endosteal cells deposit new bone, which restores the bony trabeculae and reduces the size of the marrow spaces (see Fig. 24-6). Peripheral buttressing occurs on the facial and lingual surfaces of the alveolar plate. Depending on its severity, peripheral buttressing may produce a shelf-like thickening of the alveolar margin, referred to as lipping (Fig. 24-7; see also Fig. 24-3), or a pronounced bulge in the contour of the facial and lingual bone[16,26] (see Chapter 23).

Cartilage-like material sometimes develops in the periodontal ligament space as an aftermath of the trauma.[21] Formation of crystals from erythrocytes has also been shown.[67]

Stage III: Adaptive Remodeling of the Periodontium. If the repair process cannot keep pace with the destruction caused by the occlusion, the periodontium is remodeled in an effort to create a structural

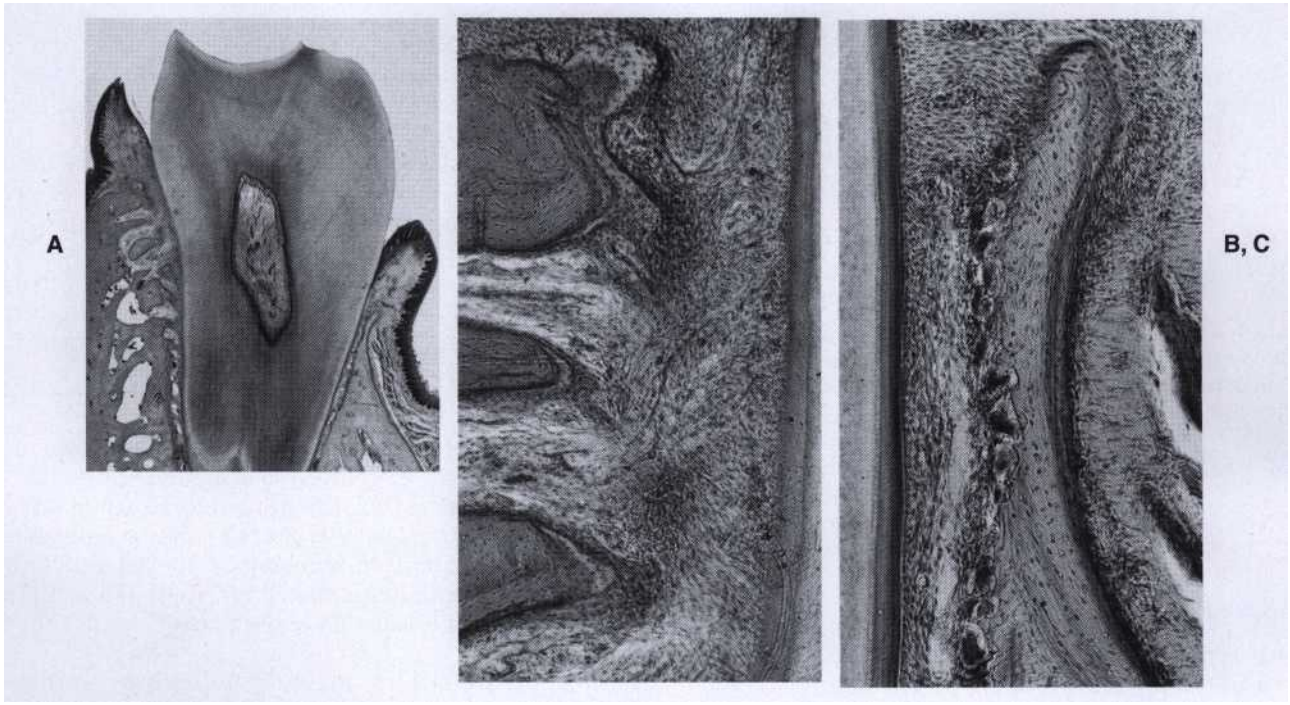

Fig. 24-3 Periodontal accommodation to lateral forces. A, Mandibular premolar. B, Lingual surface, showing new bone formation in response to tension on the periodontal ligament. Note the pale-staining osteoid bordered by osteoblasts and the incremental lines indicative of previous additions to the bone. C, Facial surface shows compression of the periodontal ligament and osteoclastic resorption of the bony plate. Note the new bone formed on the external surface. This is peripheral buttressing bone, which reinforces the resorbing facial plate. Note also that the buttressing bone has produced a bulge in the bony contour.

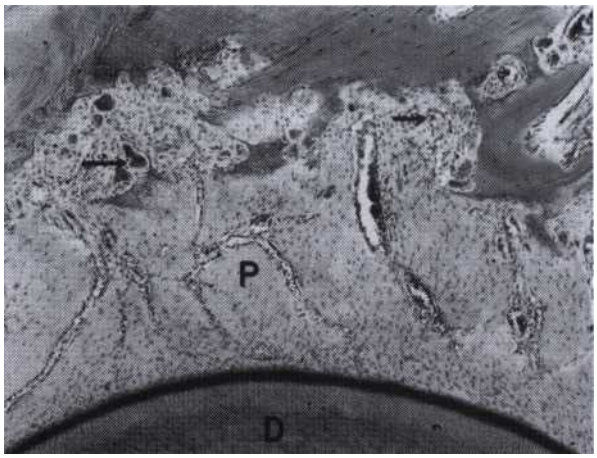

Fig. 24-4 Trauma from occlusion at the root apex. Note bone resorption with prominent osteoclasts (arrows). The periodontal ligament (P) is widened as the result of bone resorption, and the blood vessels are engorged. The root is shown at D.

relationship in which the forces are no longer injurious to the tissues. *This results in a thickened periodontal ligament, which is funnel shaped at the crest, and angular defects in the bone, with no pocket formation. The involved teeth become loose." Increased vascularization has also been reported.15*

The three stages in the evolution of traumatic lesions have been differentiated histometrically by means of the relative amounts of periodontal bone surface undergoing resorption or formation"," (Fig. 24-8). The injury phase shows an increase in areas of resorption and a decrease in bone formation, whereas the repair phase demonstrates decreased resorption and increased bone formation. After adaptive remodeling of the periodontium, resorption and formation return to normal.

EFFECTS OF INSUFFICIENT OCCLUSAL FORCE

Insufficient occlusal force may also be injurious to the supporting periodontal tissues.[11,46] Insufficient stimulation causes thinning of the periodontal ligament, atrophy of the fibers, osteoporosis of the alveolar bone, and reduction in bone height. Hypofunction can result from an open-bite relationship, an absence of functional antagonists, or unilateral chewing habits that neglect one side of the mouth.

REVERSIBILITY OF TRAUMATIC LESIONS

Trauma from occlusion is reversible. When trauma is artificially induced in experimental animals, the teeth move away or intrude into the jaw. When the impact of the artificially created force is relieved, the tissues undergo

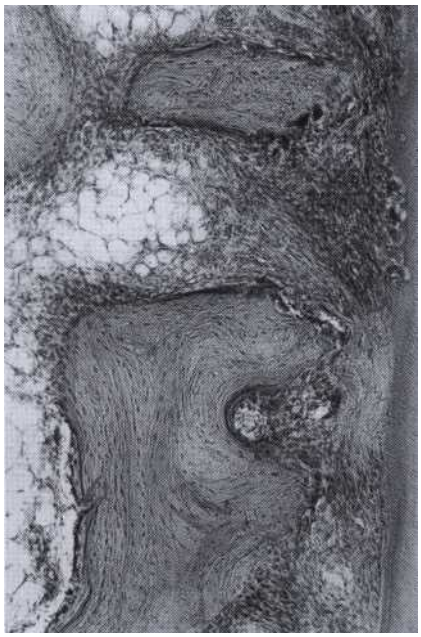

Fig. 24-5 Trauma from occlusion. Injury is more severe than that shown in Fig. 24-4. The cementum (right) is undergoing resorption, the periodontal ligament is compressed and necrotic, and the bone is undergoing resorption. Note the osteoblasts and new bone (central buttressing bone formation) on the trabecular margins adjacent to the marrow.

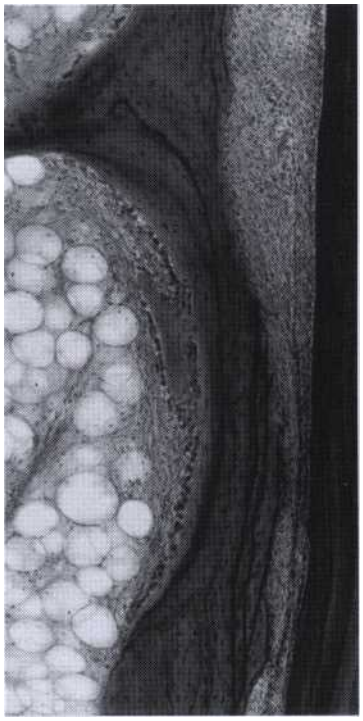

Fig. 24-6 Central buttressing bone. Note the new bone formation on the marrow side of alveolar bone that is undergoing resorption on the side of the periodontal ligament.

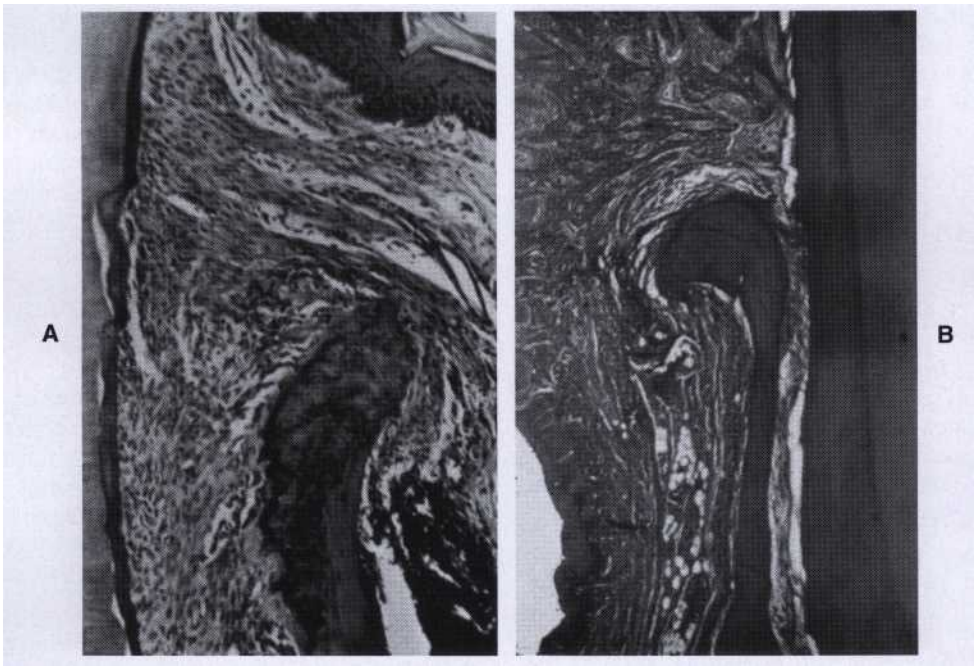

Fig. 24-7 A, Widening of the periodontal ligament space in cervical area and a change in the shape of marginal alveolar bone as a result of chronic prolonged trauma from occlusion in rats. B, A comparable change in shape of marginal bone found in a human autopsy case.

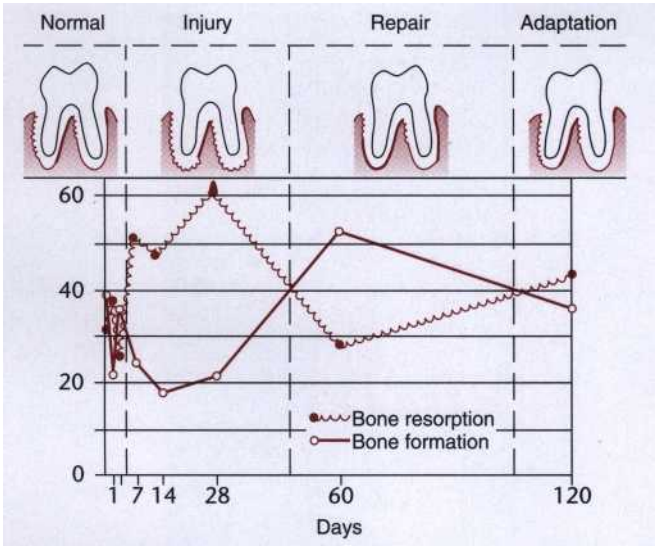

Fig. 24-8 Evolution of traumatic lesions as depicted experimentally in rats by variations in relative amounts of areas of bone formation and bone resorption in periodontal bone surfaces. Horizontal axis: days after initiation of traumatic interference. Vertical axis: percentage of bone surface undergoing resorption or formation. The stages in the evolution of the lesions are represented in the top drawings, which show the average amount of bone activity for each group. See references 9, 16, and 39.

repair. Although trauma from occlusion is reversible under such conditions, it does not always correct itself, nor is it therefore always temporary and of limited clinical significance. The injurious force must be relieved for repair to occur.[31,58] If conditions in humans do not permit the teeth to escape from or adapt to excessive occlusal force, periodontal damage persists and worsens.

The presence of inflammation in the periodontium as a result of plaque accumulation may impair the reversibility of traumatic lesions.[40,58]

EFFECTS OF EXCESSIVE OCCLUSAL FORCES ON DENTAL PULP

The effects of excessive occlusal forces on the dental pulp have not been established. Some clinicians report the disappearance of pulpal symptoms after correction of excessive occlusal forces. Pulpal reactions have been noted in animals subjected to increased occlusal forces",[,]" but did not occur when the forces were minimal and occurred over short periods.[45]

INFLUENCE OF TRAUMA FROM OCCLUSION ON PROGRESSION OF MARGINAL PERIODONTITIS

The clinical impressions of early investigators and clinicians assigned an important role to trauma from occlusion in the etiology of periodontal lesions. Numerous studies have since been performed attempting to determine the mechanisms by which trauma from occlusion may affect periodontal disease.

Initial studies involved the placement of high crowns or restorations on the teeth of dogs or monkeys, resulting in a continuous or intermittent force in one direction.',[,]" These investigations provided an orthodontic type of force and gave clear descriptions of changes occurring in pressure zones and tension zones. These procedures usually resulted in tooth displacement and consolidation in a new, nontraumatized position.

Trauma from occlusion in humans, however, occurs as a result of forces that act alternatively in opposing directions. These were analyzed in experimental animals with jiggling forces, usually produced by means of a high crown combined with an orthodontic appliance that would bring the traumatized tooth back to its original position when the force was dissipated by separating the teeth. In another method, the teeth were separated by wooden or elastic material wedged interproximally to displace a tooth toward the opposite proximal side. After 48 hours the wedge was removed, and the procedure was repeated on the opposite side.

These studies resulted in a combination of changes produced by pressure and tension on both sides of the tooth, with an increase in the width of the ligament and increased tooth mobility. None of these methods caused gingival inflammation or pocket formation, and the results essentially represented different degrees of functional adaptation to increased forces.",[79]

To more closely mimic the problem in humans, studies were then conducted on the effect produced by jiggling trauma and simultaneous plaque-induced gingival inflammation.

The accumulation of bacterial plaque that initiates gingivitis and results in periodontal pocket formation affects the marginal gingiva, but trauma from occlusion occurs in the supporting tissues and does not affect the gingiva (Fig. 24-9). The marginal gingiva is unaffected by trauma from occlusion because its blood supply is sufficient to maintain it, even when the vessels of the periodontal ligament are obliterated by excessive occlusal forces.[33] It has been repeatedly proven that *trauma from occlusion does not cause pockets or glngivitiS,*[2,32,39,60,77,78,80*] nor does it increase gingival fluid flow.[37,43,51] Furthermore, experimental trauma in dogs does not influence bacterial repopulation of pockets after scaling and root planing.[41] However, mobile teeth in humans harbor significantly higher proportions of *Campylobacter rectus* and *Peptostreptococcus micros* than nonmobile teeth.

As long as inflammation is confined to the gingiva, the inflammatory process is not affected by occlusal forces.[42] When inflammation extends from the gingiva into the supporting periodontal tissues (i.e., when gingivitis becomes periodontitis), plaque-induced inflammation enters the zone influenced by occlusion, which Glickman has called the *zone o f co-destruction.*[23,25,27]

* **Of historical interest are references 5 and 74, which describe periodontal pocket formation in animals as a result of trauma from occlusion.**

Two groups have studied this topic extensively with conflicting results, probably owing to the different methods used. The Eastman Dental Center group in Rochester, NY, used squirrel monkeys, produced trauma by repetitive interdental wedging, and added mild to moderate gingival inflammation; experimental times were up to 10 weeks. They reported that the presence of trauma did not increase the loss of attachment induced by periodontitis.[52,55,56,59] The University of Gothenburg group in Sweden used beagle dogs, produced trauma by placing cap splints and orthodontic appliances, and induced severe gingival inflammation; experimental times were up to 1 year. This group found that occlusal stresses increase the periodontal destruction induced by periodontitis.[18,19,49]

When trauma from occlusion is eliminated, a substantial reversal of bone loss occurs, except in the presence of periodontitis. This indicates that inflammation inhibits the potential for bone regeneration.[40,48,57,58] *Thus it is important to eliminate the marginal inflammatory component in cases of trauma from occlusion because the presence of inflammation affects bone regeneration after the removal of the traumatizing contacts.*[4] It also has been shown in experimental animals that trauma from occlusion does not induce progressive destruction of the periodontal tissues in regions kept healthy after the elimination of preexistent periodontitis.[18]

Trauma from occlusion also tends to change the shape of the alveolar crest. The change in shape consists of a widening of the marginal periodontal ligament space, a narrowing of the interproximal alveolar bone, and a shelf-like thickening of the alveolar margin.[16,49,52] Therefore although trauma from occlusion does not alter the inflammatory process, it changes the architecture of the area around the inflamed site.[16,49] *Thus in the absence of inflammation, the response to trauma from occlusion is limited to adaptation to the increased forces. However, in the presence of inflammation, the changes in the shape of the alveolar crest may be conducive to angular bone loss, and existing pockets may become intrabony.*

Other theories that have been proposed to explain the interaction of trauma and inflammation include the following:

1. Trauma from occlusion may alter the pathway of extension of gingival inflammation to the underlying tissues. This may be favored by the reduced collagen density and increased number of leukocytes, osteoclasts, and blood vessels in the coronal portion of increasingly mobile teeth.' Inflammation then may proceed to the periodontal ligament rather than to the bone. Resulting bone loss would be angular, and pockets could become intrabony.[1,23,25,27,29,50]
2. Trauma-induced areas of root resorption uncovered by apical migration of the inflamed gingival attachment may offer a favorable environment for the formation and attachment of plaque and calculus and therefore may be responsible for the development of deeper lesions.[69]
3. Supragingival plaque can become subgingival if the tooth is tilted orthodontically or migrates into an edentulous area, resulting in the transformation of a suprabony pocket into an intrabony pocket.[17,20]
4. Increased mobility of traumatically loosened teeth may have a pumping effect on plaque metabolites, increasing their diffusion.[76]

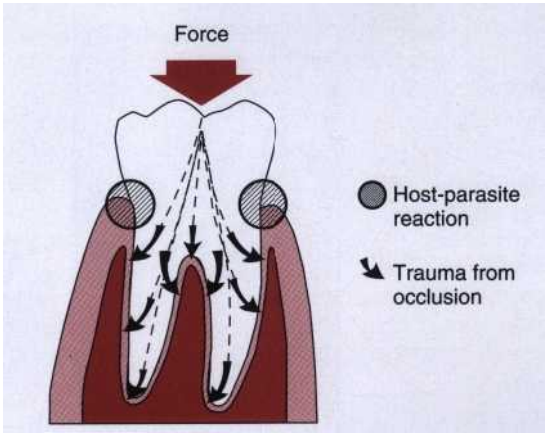

Fig. 24-9 The reaction between dental plaque and the host takes place in the gingival sulcus region. Trauma from occlusion appears in the tissues supporting the tooth.

Clinical and Radiographic Signs of Trauma from Occlusion Alone

The most common clinical sign of trauma to the periodontium is increased tooth mobility. In the injury stage of trauma from occlusion, destruction of periodontal fibers occurs, which increases the mobility of the tooth. In the final stage, the accommodation of the periodontium to increased forces entails a widening of the periodontal ligament, which also leads to increased tooth mobility. Although this tooth mobility is greater than the so-called normal mobility, it cannot be considered pathologic because it is an adaptation and not a disease process. When it becomes progressively worse, it can be considered pathologic.

Other causes of increased tooth mobility include advanced bone loss, inflammation of the periodontal ligament that is of periodontal or periapical origin, and some systemic causes (e.g., pregnancy). The destruction of surrounding alveolar bone, such as occurs in osteomyelitis or jaw tumors, may also increase tooth mobility (see Chapter 30).

Radiographic signs of trauma from occlusion may include the following:

1. Increased width of the periodontal space, often with thickening of the lamina dura along the lateral aspect of the root, in the apical region, and in bifurcation areas. These changes do not *necessarily* indicate destructive changes because they may result from thickening and strengthening of the periodontal ligament and alveolar bone, constituting a favorable response to increased occlusal forces (Fig. 24-10).
2. A "vertical" rather than "horizontal" destruction of the interdental septum.

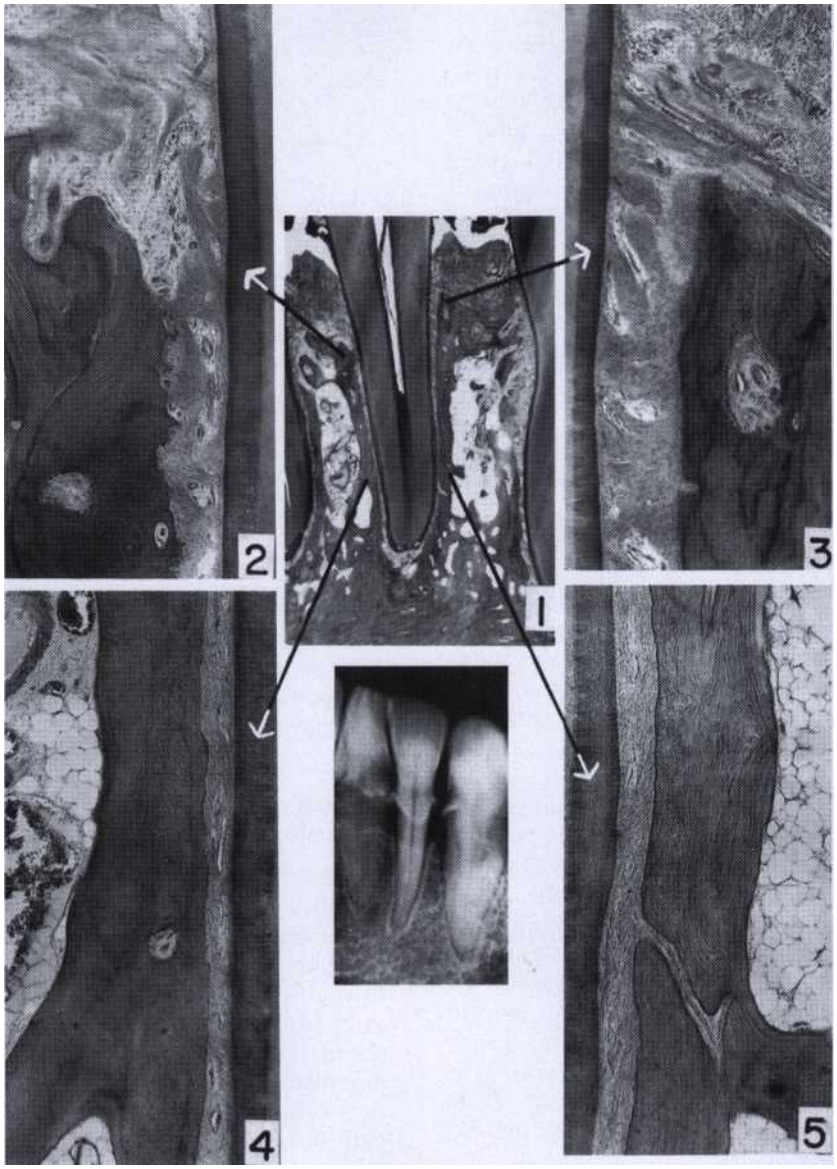

Fig. 24-10 Widened periodontal space produced by two types of tissue response to increased occlusal forces. Radiograph shows thickening of periodontal space and lamina dura around the lateral incisor. 1, Survey microscopic section of the lateral incisor. 2, Mesial surface widening of the periodontal space has resulted from resorption of alveolar bone associated with pressure. 3, Distal surface widening of the periodontal space has resulted from thickening of the periodontal ligament, which is a favorable response to increased tension. 4 and 5, Thinned periodontal ligament at axis of rotation, one third the distance from the apex.

3. Radiolucence and condensation of the alveolar bone.
4. Root resorption (see Chapter 22).

In summary, trauma from occlusion does not initiate gingivitis or periodontal pockets, but it may constitute an additional risk factor for the progression and severity of the disease. An understanding of the effect of trauma from occlusion on the periodontium is useful in the clinical management of periodontal problems.

PATHOLOGIC TOOTH MIGRATION

Pathologic migration refers to tooth displacement that results when the balance among the factors that maintain physiologic tooth position is disturbed by periodontal disease. Pathologic migration is relatively common and may be an early sign of disease, or it may occur in association with gingival inflammation and pocket formation as the disease progresses.

Pathologic migration occurs most frequently in the anterior region, but posterior teeth may also be affected. The teeth may move in any direction, and the migration is usually accompanied by mobility and rotation. Pathologic migration in the occlusal or incisal direction is termed *extrusion*. All degrees of pathologic migration are encountered, and one or more teeth may be affected (Fig. 24-11). It is important to detect it in its early stages and prevent more serious involvement by eliminating the causative factors. Even in the early stage, some degree of bone loss occurs.

Pathogenesis

Two major factors play a role in maintaining the normal position of the teeth: the health and normal height of the periodontium and the forces exerted on the teeth. The latter includes the forces of occlusion and pressure from the lips, cheeks, and tongue. The following factors are important in relation to the forces of occlusion: tooth morphologic features and cuspal inclination; the presence of a full complement of teeth; a physiologic tendency toward mesial migration, the nature and location of contact point relationships; proximal, incisal, and occlusal attrition, and the axial inclination of the teeth. Alterations in any of these factors start an interrelated sequence of changes in the environment of a single tooth or group of teeth that results in pathologic migration. Thus pathologic migration occurs under conditions that weaken the periodontal support, increase or modify the forces exerted on the teeth, or both.

Weakened Periodontal Support. The inflammatory destruction of the periodontium in periodontitis creates an imbalance between the forces maintaining the tooth in position and the occlusal and muscular forces on which it is ordinarily called to bear. The tooth with weakened support is unable to maintain its normal position in the arch and moves away from the opposing force unless it is restrained by proximal contact. The force that moves the weakly supported tooth may be created by factors such as occlusal contacts or pressure from the tongue.

It is important to understand that the abnormality in pathologic migration rests with the weakened periodontium. The force itself need not be abnormal. Forces that are acceptable to an intact periodontium become injurious when periodontal support is reduced. An example of this is the tooth with abnormal proximal contacts. Abnormally located proximal contacts convert the normal anterior component of force to a wedging force that moves the tooth occlusally or incisally. The wedging

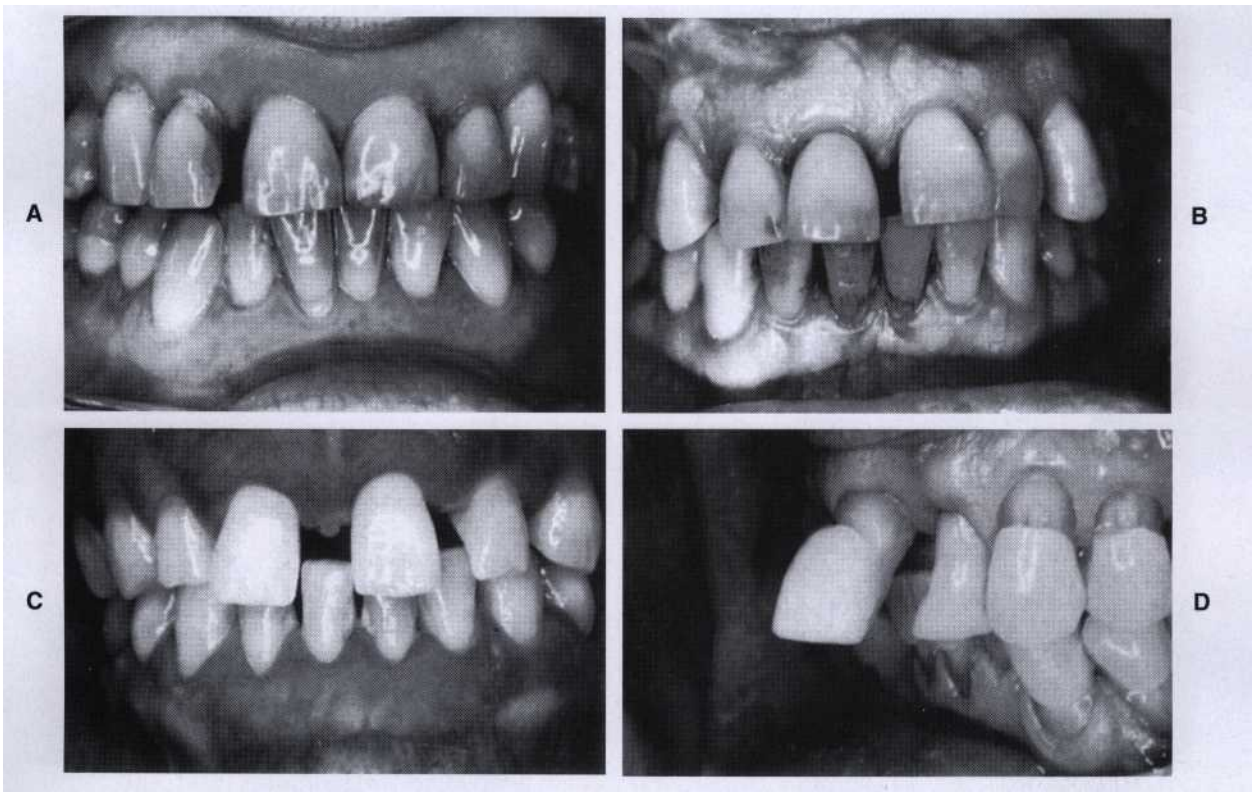

Fig. 24-11 Stages in pathologic migration. A, Migration of the right maxillary lateral incisor. B, Labial migration of maxillary central incisors and left canine, and mesial migration of the right lateral incisor. C, Migration and extrusion of maxillary and mandibular incisors. D, Severe migration of the maxillary central incisor.

force, which can be withstood by the intact periodontium, causes the tooth to extrude when the periodontal support is weakened by disease. As its *position changes, the tooth is subjected to abnormal occlusal forces, which aggravate the periodontal destruction and the tooth migration.*

Pathologic migration may continue after a tooth no longer contacts its antagonist. Pressures from the tongue, the food bolus during mastication, and proliferating granulation tissue provide the force.

Pathologic migration is also an early sign of localized aggressive periodontitis. Weakened by loss of periodontal support, the maxillary and mandibular anterior incisors drift labially and extrude, creating diastemata between the teeth (see Chapter 28).

Changes in the Forces Exerted on the Teeth.

Changes in the magnitude, direction, or frequency of the forces exerted on the teeth can induce pathologic migration of a tooth or group of teeth. These forces do not have to be abnormal to cause migration if the periodontium is sufficiently weakened. Changes in the forces may occur as a result of unreplaced missing teeth, failure to replace first molars, or other causes.

UNREPLACED MISSING TEETH. Drifting of teeth into the spaces created by unreplaced missing teeth often occurs. Drifting differs from pathologic migration in that it does not result from destruction of the periodontal tissues. However, it usually creates conditions that lead to periodontal disease, and thus the initial tooth movement is aggravated by loss of periodontal support (Fig. 24-12).

Drifting generally occurs in a mesial direction, combined with tilting or extrusion beyond the occlusal plane. The premolars frequently drift distally (Fig. 24-13). Although drifting is a common sequela when missing teeth are not replaced, it does not always occur (Fig. 24-14).

FAILURE TO REPLACE FIRST MOLARS. The pattern of changes that may follow failure to replace missing first molars is characteristic. In extreme cases it consists of the following:

1. The second and third molars tilt, resulting in a decrease in vertical dimension (Fig. 24-15).
2. The premolars move distally, and the mandibular incisors tilt or drift lingually. While drifting distally, the mandibular premolars lose their intercuspating relationship with the maxillary teeth and may tilt distally.
3. Anterior overbite is increased. The mandibular incisors strike the maxillary incisors near the gingiva or traumatize the gingiva.
4. The maxillary incisors are pushed labially and laterally (Fig. 24-16).
5. The anterior teeth extrude because the incisal apposition has largely disappeared.
6. Diastemata are created by the separation of the anterior teeth (see Fig. 24-15).

Fig. 24-12 Calculus and bone loss on the mesial surface of a canine that has drifted distally.

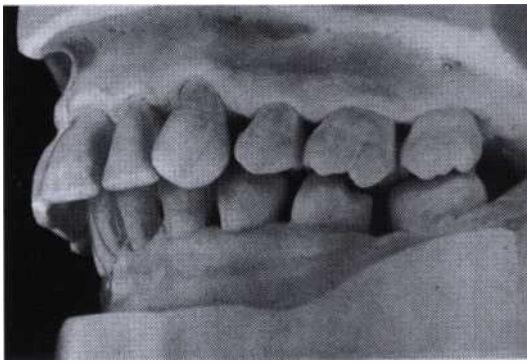

Fig. 24-13 Maxillary first molar tilted and extruded into the space created by a missing mandibular tooth.

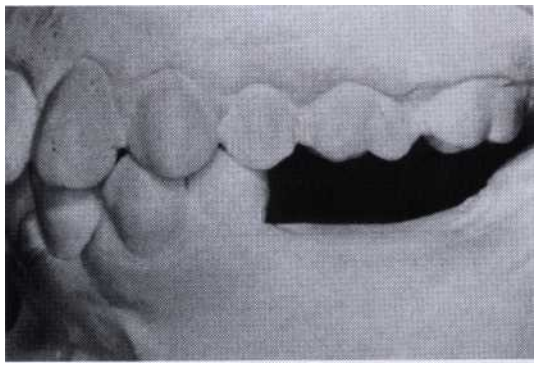

Fig. 24-14 No drifting or extrusion despite 4 years' absence of mandibular teeth.

The disturbed proximal contact relationships lead to food impaction, gingival inflammation, and pocket formation, followed by bone loss and tooth mobility. Occlusal disharmonies created by the altered tooth positions traumatize the supporting tissues of the periodontium and aggravate the destruction caused by the inflammation. Reduction in periodontal support leads to further migration of the teeth and mutilation of the occlusion.

OTHER CAUSES. *Trauma from occlusion* may cause a shift in tooth position either by itself or in combination with inflammatory periodontal disease. The direction of movement depends on the occlusal force.

Pressure from the tongue may cause drifting of the teeth in the absence of periodontal disease or may contribute to pathologic migration of teeth with reduced periodontal support (Fig. 24-17).

In tooth support weakened by periodontal destruction, *pressure from the granulation tissue of periodontal pockets* has been mentioned as contributing to pathologic migration.38 The teeth may return to their original positions after the pockets are eliminated, but if more destruction has occurred on one side of a tooth than the other, the healing tissues tend to pull in the direction of the lesser destruction.

DIAGNOSTIC DECISION MAKING

The masticatory system consists of the temporomandibular joints (TMJs), masticatory muscles, teeth in occlusion, and neurologic and vascular supplies supporting all these structures.

Research suggests that masticatory system disorders include many varied conditions with multiple possible contributing factors rather than different manifestations of a single disease or syndrome .2.73.11' The ability to understand the anatomy and function of the masticatory system and correctly interpret relevant diagnostic information is a prerequisite to fulfilling comprehensive standards of care. Our diagnostic process must be broad based and inclusive enough to determine the most appropriate cause of masticatory dysfunction. 119

*** I would like to acknowledge the incredible efforts of Dr. David K. Warfield in helping me compile the numerous references reviewed during the development of this chapter. His encouragement, along with that of Drs. Peter Dawson and Henry Gremillion, was very meaningful and often timely.** Drs. **Dawson, Gremillion, Parker Mahan, and Okeson provided invaluable foundations through their publications, texts, and lectures. Although there are many others from whom I have learned much, these four exceptional dentists certainly deserve my public appreciation. I would especially like to acknowledge my precious wife, Martha-Anne, whose patience and support was priceless, as always.**

THE TEMPOROMANDIBULAR JOINT

Harmonious function of the TMJs is a product of the coordination of the muscles of mastication by intricate mechanisms of neurologic control. Understanding the dynamics and the relationship of the TMJ to the associated muscles and nerves provides the working knowledge required for effective assessment and diagnosis.

The TMJ is one of the most complex joints in the human body. It is capable of providing both hinging (rotation) and gliding (translation) movements and sustaining incredible forces of mastication. The TMJ is formed by the head of the condyle of the mandible as it fits into the articular fossa of the temporal bone (Fig. 25-1). The body of the mandible effectively connects both condyles so that neither condyle functions independently of the other. Interposed between the head of the condyle and the articular surface of the temporal bone is the articular disc, consisting of dense connective tissue, resulting in a compound joint with two joint cavities (see Figs. 25-1 and 25-2). The articulating surfaces of the osseous structures are essentially convex in a healthy situation, so the biconcave configuration of the articular disc compensates for the opposing convexities (see Fig. 25-1). The articular surfaces of the condyles and temporal bones consist of fibrous connective tissue, rendering them resistant to breakdown and capable of repair. Deep to the superficial

connective tissue layer, articular cartilage provides the cellular and structural basis for response to the functional loading and movement of the TMJs.[73,119,161] The discal ligaments and attachments to the capsule along with the disc itself become the means of separating the joint into superior and inferior joint spaces (see Figs. 25-1 and 25-2). Synovial lubrication of the articular surfaces is a function of synovial fluid production by endothelial cells along the borders of each joint cavity and at the anterior extent of the retrodiscal tissues.*

MUSCLES AND NERVES OF THE MASTICATORY SYSTEM

The muscles and nerves of the masticatory system are extensively reviewed elsewhere and are only briefly discussed here for the purpose of understanding the mechanisms involved. Appropriate references are provided for further reading.

The muscles of mastication consist principally of two groups: the elevator muscles and depressor muscles. The muscles responsible for elevating the mandible are the masseter, internal pterygoid, and much of the temporal muscle. The posteriorly oriented fibers of the temporal muscle also retrude the mandible. The superficial muscle bundle of the masseter muscle may also assist in protruding the mandible, while the deeper bundle serves to stabilize the condylar head against the articular eminence. Juxtaposed with the masseter muscle, the medial pterygoid forms a muscular support for the mandible at its angle. Although the primary function of this muscle is elevation of the mandible, it is also active during protrusion.[73,119] The lateral pterygoid muscle is now known to function as two distinct muscles, the inferior and superior lateral pterygoid muscles, having independent and nearly opposite functions.[6,14] The inferior lateral pterygoid muscle depresses and protrudes the mandible. The superior lateral pterygoid muscle does not contract during depression of the mandible but rather contracts along with the elevator muscles, bracing the condyle anteromedially.[99,107,117,119,139]

Physiologic mandibular posture and movement are products of harmonious muscular contraction among masticatory and supportive muscles. The neurologic input to produce synergy of complementary and antagonistic muscles is extremely complex. Motor and sensory innervation of the TMJs and the rest of the masticatory system are provided by structures of the trigeminal nerve. Mechanoreceptors in the skin, muscle, and ligamentous structures, especially the periodontal ligament, discern pressure differences at sensitive degrees of discrimination. Painful stimuli are perceived by nociceptors and result in both pain perception and reflex responses. The innervation of both the capsular ligaments and discal ligaments provide essential proprioceptive input with regard to joint position. Efferent or motor neurons cause muscle contraction in response to central cortical stimulation and in response to afferent stimuli in reflex activity.[38,119,164]

***See references 38, 73, 119, 159, 161, and 164.**

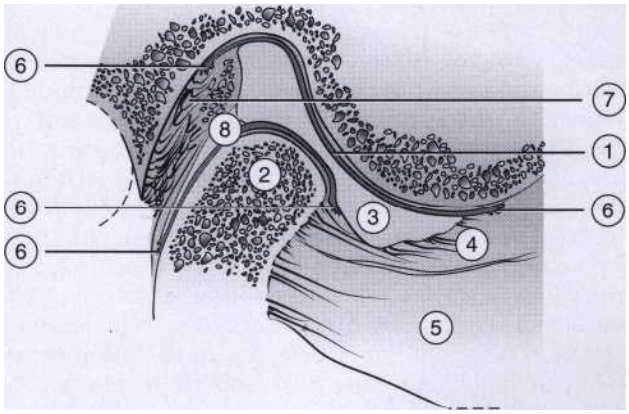

Fig. 25-1 Lateral view of cross-section through the temporomandibular joint. 1, Posterior slope of the articular eminence of the temporal bone; 2, head of the condyle; 3, disc (note biconcave shape); 4, superior lateral pterygoid muscle (note attachment to both the head of the condyle and disc); 5, inferior lateral pterygoid muscle; 6, synovial tissue; 7, retrodiscal tissue; 8, discal ligament attachment to the posterior surface of the head of the condyle. (Modified from Dawson PE: Evaluation, Diagnosis, and Treatment of Occlusal Problems, ed 2. St Louis, Mosby, 1989.)

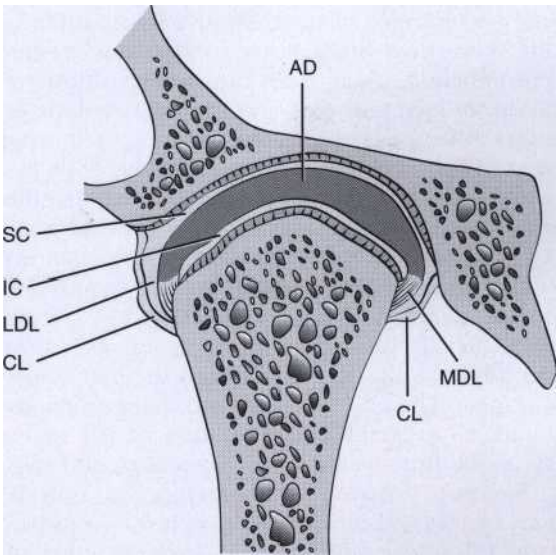

Fig. 25-2 Temporomandibular joint (anterior view), showing collateral ligaments. The following are identified: *AD,* articular disc; *CL,* capsular ligament; IC, inferior joint cavity; *LDL,* lateral discal ligament; *MDL,* medial discal ligament; SC, superior joint cavity. (From Okeson JP: Management of Temporomandibular Joint Disorders and Occlusion, ed 4. St Louis, Mosby, 1998.)

Sensory input from the periodontal ligament (PDL) offers the potential to be an important component of the complex neurologic management of the masticatory system. Currently, little evidence of the existence of proprioceptive sensory organs within the neuroanatomy of the PDL is available, although it was once considered likely. Pain perception causes the nociceptive reflex to rapidly open the mouth through contraction of depressor muscles and suppression of elevator muscles, consistent with

other protective reflexes within the musculoskeletal system.[119] Protective reflexes may be suppressed in individuals experiencing chronic occlusal parafunction (clenching or grinding of their teeth).[23,46] Pressure perception is a function of the numerous mechanoreceptors within the PDL of teeth in contact. Discrimination within the dentition based on specific teeth in contact, direction of force, and intensity of force and their influence on muscle activity have been demonstrated in human study populations and animal studies.[22,35,90,98,142] Both research and clinical observations suggest that elevator muscle contraction is suppressed when anterior teeth promote disclusion or separation of posterior teeth during excursive mandibular movements.[160] Implicit in the experience of loss of attachment due to periodontitis is the loss of some mechanoreceptors. Patients with significant bone loss, significant inflammatory disruption of the integrity of the PDL, or chronic occlusal parafunction may experience compromised regulation of muscle activity.*

CENTRIC RELATION

The mandible is suspended from the cranial base by ligaments and muscles. Understanding mandibular movement begins from an initial reference point for each condyle, commonly referred to as *centric relation.* In this clinically determined relationship of the mandible to the maxilla, occurring when both condyle-disc assemblies are positioned in their most superior position in the maxillary (or glenoid) fossa and against the slope of the articular eminence of the temporal bone. Verification of centric relation is obtained by loading the TMJs bilaterally with the teeth apart, using the bimanual mandibular manipulation technique advocated by Dawson and others.[38,39,152] When both condyles are in this relationship, rotation or hinging action occurs around an axis defined by the medial poles of each condyle (Fig. 25-3). The term *centric relation is* limited to the rotation axis through both condyles while they are seated in their respective glenoid fossa. The only occlusal consideration relative to centric relation occurs when rotation of the mandible brings about initial contact of opposing occlusal surfaces. The term *retruded contact position,* as used in the chapters of this text dealing with occlusion, can be used to define this relationship. Should the contraction of elevator muscles occur at the point of initial occlusal contact, resulting in the distraction of one or both condyle-disc assemblies from their seated relationship, then centric relation is no longer occurring.[38,39]

For TMJs to maintain orthopedic stability, the condyles must remain fully seated in their respective fossa when the teeth occlude in maximal intercuspation. Orthopedic instability occurs when the occlusal relationships are such that contraction of elevator muscles is required to achieve stable occlusion in maximal intercuspal position, resulting in the unseating of one or both condyles from their respective fossa (Fig. 25-4). The strain on the discal ligaments caused by a loaded joint being displaced from the fossa can lead to internal derangement of that joint, as is described later. Postural and parafunctional stress can also be a source of orthopedic instability of a TMJ. An individual's susceptibility to masticatory system disorders determines whether that person adapts with minimal consequence or suffers dysfunction or degeneration.[24,38,119,152]

*See references 2, 23, 46, 70, 73, 111, 119, and 137.

BIOMECHANICS OF THE MASTICATORY SYSTEM

Biomechanics of mandibular movement are a function of neurologic input from cortical and stomatognathic sources acting to initiate or restrict muscular contraction. Muscular action either stabilizes the condyle against the articular eminence or directs its rotational and/or translational movement relative to each respective temporal bone. The position and functional movement of one condyle is always dependent on the status or activity of the other. Because the maxillary teeth have a fixed relationship to the cranial base, just as mandibular teeth have a fixed relationship to the condyle, contact of their respective occlusal surfaces may directly influence condylar position or movement.",'[19]

The mandible can move within a range of motion that is limited by skeletal, muscular, and ligamentous structures. Pure rotation of up to approximately 25 mm can occur before translation of the condyle is required to continue toward maximal opening of the jaw. Movement of the condyle is relative to the disc, so rotation effectively occurs within the inferior joint space (Fig. 25-5, A). Strict translation protrudes the mandible while the condyle-disc assembly moves anterior and inferior toward the articular eminence of the temporal bone. The disc moves relative to the temporal bone, and movement occurs within the upper joint space (see Fig. 25-5, B). In combination translation/rotation movement of the condyle, the axis of rotation for each condyle changes as the condyle translates down the articular eminence to a position inferior to its respective fossa (see Fig. 25-5, C). Harmonious muscle function and ligament attachments keep the condyle-disc assembly properly related so that the articular disc remains loaded in its concave, avascular central portion between the condyle and the articular surface of the temporal bone. The elasticity and vascularity of the retrodiscal tissues permit anterior movement of the disc during translation of each respective condyle. Rotation and translation of the condyle can occur in the absence of any tooth-to-tooth contact because the condyle-disc assembly can be supported by the muscles of mastication against the articular eminence during rotation, translation, and combination movements. When the teeth are in contact, their ability to influence both the position and the direction of movement of condyle-disc assemblies is defined by the intensity of muscle activity and the steepness of the inclines of those teeth.[38,67,77,93,119]

DYSFUNCTION AND DETERIORATION

Ideally, function never exceeds the integrity or adaptive limits of the structural elements of the masticatory system. In clinical experience, the tolerance of the components of the masticatory system can be exceeded by both acute trauma and chronic trauma.

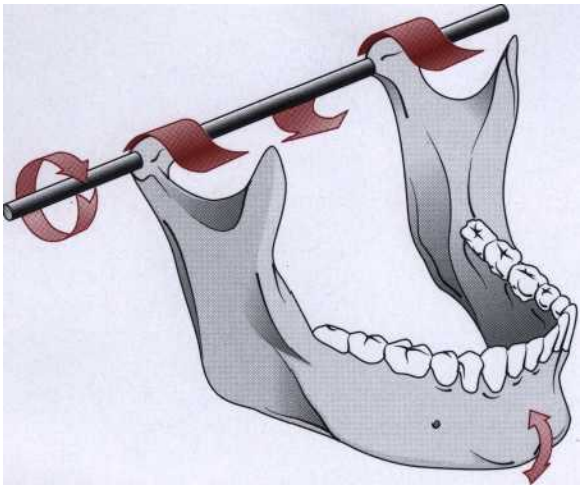

Fig. 25-3 In centric relation, the condyles can rotate on a fixed axis. As long as the rotational axis stays fixed at the most superior position against the eminentiae, the mandible can open or close and still be in centric relation. If the condyle axis moves forward, it is no longer in centric relation. (From Dawson PE: Evaluation, Diagnosis, and Treatment of Occlusal Problems, ed 2. St Louis, Mosby, 1989.)

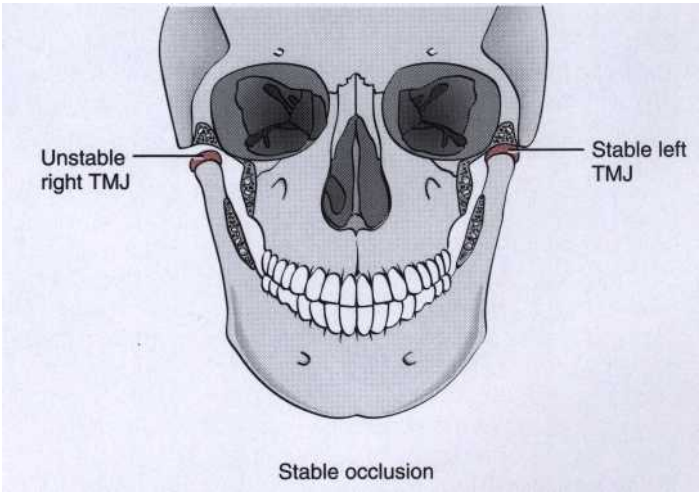

Fig. 25-4 An example of orthopedic instability. Note that with the teeth in their stable position (maximal intercuspation), the left temporomandibular joint is in a stable relationship with the fossa. The right temporomandibular joint, however, is not in a stable position in the fossa. When the elevator muscles contract, the right condyle moves superiorly, seeking a more stable relationship with the disc and fossa (the musculoskeletally stable position). This type of loading can lead to an intracapusular disorder. (From Okeson JP: Management of Temporomandibular Joint Disorders and Occlusion, ed 4. St Louis, Mosby, 1998.)

Acute trauma to the head and neck region can range from a distinct event, such as an accident or a blow to the face, to a sustained overuse experience, such as a long dental appointment. Acute trauma can serve as an initiating event leading toward a chronic condition, so accurate documentation and careful monitoring may prove extremely valuable should symptoms or dysfunction persist.[12,19,41]

Chronic trauma is defined as any experience that repeatedly exceeds the tolerances of the affected masticatory system structure. Postural stresses and parafunctional occlusal habits, with or without occlusal discrepancies, may produce musculoskeletal disharmony and orthopedic instability of the TMJ. Occlusal relationships that disrupt the condyle during physiologic movement of rotation or translation require muscular and TMJ compensation. The extent to which the repeated loading of the teeth and/or the condyles during function and parafunction exceeds the tolerance of an individual determine whether structural or muscular compromise occurs.[119] In the absence of prospective research, it is somewhat difficult to associate defined occlusal patterns with specific muscle or joint disorders; however, retrospective studies and clinical experience still offer valuable perspectives. When correlation of TMJ dysfunction could be made with specific occlusal relationships, the trend was to recognize that when inclines of posterior teeth dominated occlusal function, masticatory system harmony was disrupted.* Other researchers have found that various occlusal interferences and relationships are common among individuals with and without masticatory system disorders. They could not distinguish a particular occlusal feature as a specific etiologic or predisposing factor to the development of masticatory system disorders, although some found that several factors occurring together encouraged dysfunction.[33,66,127,129,151] There seems to be less correlation between static references, such as class of malocclusion, and masticatory system disorders than when functional or extrafunctional occlusal force exceed the tolerance of the TMJ and masticatory musculature.[119,141]

The general terms for occlusal parafunction to be used in this text include *bruxism,* or grinding of the teeth, and *clenching,* where a person holds the teeth firmly together with significant force. Bruxism is commonly confirmed by observing excessive tooth wear. Clenching type of parafunction can be distinguished from grinding the teeth and seems to be more commonly associated with masticatory system disorders than does bruxism.* Discrimination between occlusal function or parafunction-related masticatory system disorders and those with other etiology requires exacting standards of occlusal evaluation. Should there be sufficient evidence to suspect that the occlusal relationships in function or parafunction may have exceeded the tolerances of that individual's masticatory system, then responsible intervention or monitoring can be initiated.[39,57,122,127]

Disruption of the relationship or alignment of the condyle, disc, and articular surface of the temporal bone is commonly called an *intracapsular disorder* or *internal derangement* of the TMJ. The articular disc can be displaced as a result of an acute blow to the jaw, the effect of chronic trauma, and/or the result of uncoordinated

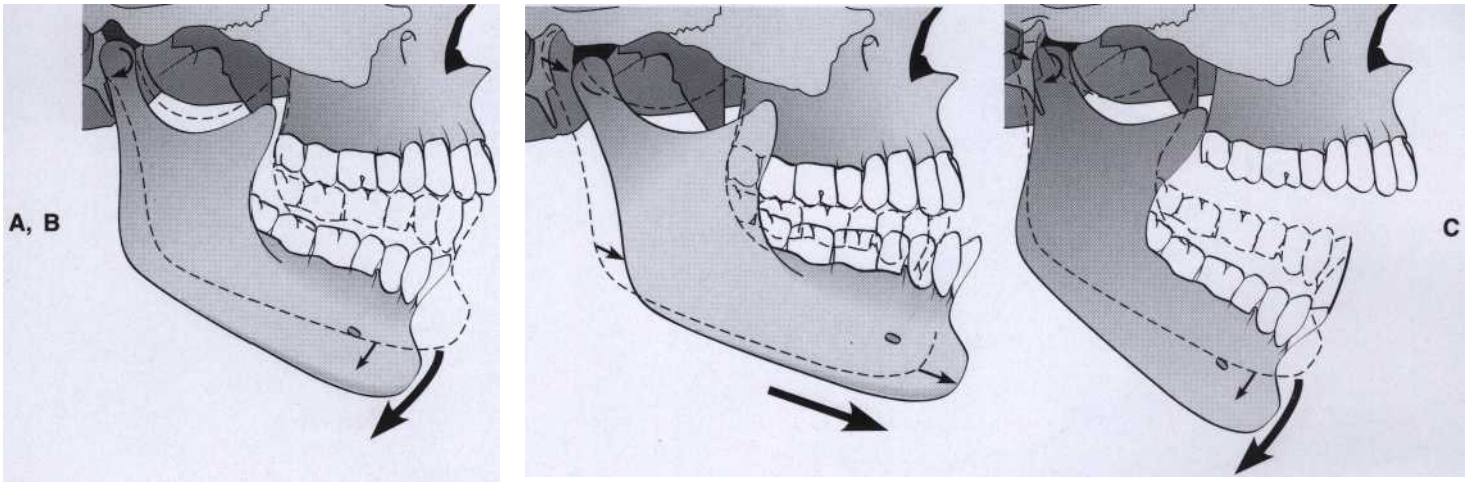

Fig. 25-5 A, Rotational movement of the mandible with the condyles in centric relation. This pure rotational opening can occur until the anterior teeth are about 20 to 25 mm apart. B, Translational movement of the condyle-disc assembly during protrusion of the mandible. C, Second stage of rotational movement during opening. Note the dual activity relative to the disc. 1, Rotation of the condylar head, relative to the disc, occurs in the inferior space. 2, Movement of the disc anteriorly and inferiorly along the articular surface of the temporal bone. The disc moves anteriorly and inferiorly with the head of the condyle, which continues to rotate against the disc. Translation occurs in the superior joint space and rotation in the inferior joint space. (From Okeson JP: Management of Temporomandibular joint Disorders and Occlusion, ed 4. St Louis, Mosby, 1998.)

contraction of the lateral pterygoid muscle. When the disc cannot return to its normal relationship to the condyle on full closure of the mouth, it is considered to be *displaced* or *dislocated.* Progressive disc displacement most commonly occurs in an anterior and medial direction due to the insertion of muscle fibers into the anteromedial aspect of the disc and the reported variability in resistance of the attachment of the lateral aspect of the disc.[11,143] Stretching of the retrodiscal tissues and collateral ligaments permits the disc to be displaced and function to be limited because of pain due to compressive forces on retrodiscal tissues. At some stage of opening, the remaining elasticity of the retrodiscal tissues and tension of the capsular ligaments can pull the disc onto the head of the condyle, often with a discernible sound. Closing then results in the disc again becoming dislocated anteriorly, with a commonly occurring joint sound often referred to as a *reciprocal click* (Fig. 25-6).*

When the disc remains anterior to the head of the condyle during rotation and the limited range of translation possible, the condition is called *closed lock* or *disc displacement (dislocation) without reduction* (Fig. 25-7). The entire disc need not be locked anterior to the head of the condyle for this condition to limit function, cause pain, or both. The lateral aspect of the disc would be more likely than the medial aspect to be displaced anteriorly if a *partial anterior disc displacement without reduction* were to occur. A history of joint sounds is commonly reported, although this state of the condyle-disc assembly may not result in currently discernible sounds.[38,119]

***See references 9, 38, 39, 119, 130, and 154.**

The vascular portion of the retrodiscal tissues being loaded (between the condyle and the articular surface of the eminentia) accounts for most current or history of pain originating within the TMJ. Adaptation of the retrodiscal tissues to completely nonvascular fibrous tissue or perforation of the disc may account for cessation of those painful symptoms.[123]

The presence of abnormal anatomic features of the condyle and fossa results in deviation in shape of the affected articular surface to which the disc then must adapt its normal anatomy, resulting in a deviation in form and function. If this type of functional limitation or irregularity is observed at a consistently occurring point in jaw opening and/or closing, it is often within the compensation mechanisms of the patient and should be distinguished from the disc derangements described previously.'"

When the intensity and duration of the functional and dysfunctional loading of the TMJs result in injury, molecular agents appear to be active in the degeneration of joints. Free radicals, various catabolic enzymes, neuropeptides, estrogen, cytokines, and prostaglandins are implicated in inflammatory reactions that have an impact on the articular surfaces, synovial fluid, or both.* Loss of the ability of the synovial fluid to lubricate articular surfaces can result in adherence of the disc. Limitation of rotation occurs with adherence between the disc and the condyle, whereas fixation of the disc against the fossa permits rotation but does not allow the disc to move forward during translation.'"

***See references 50, 60, 81, 84, 86, 108, 109, 115, 133, and 145.**

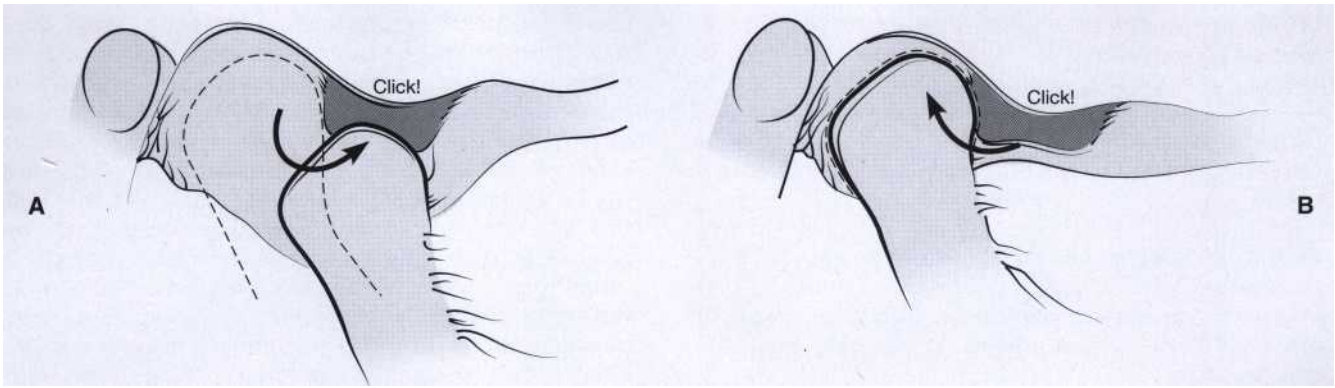

Fig. 25-6 Reciprocal click. A, Reciprocal click occurs when the condyle moves onto the disc from a position behind the posterior band of the disc and then clicks off the disc (B) when the condyle moves back. This occurs as the condyle translates forward and back in the opening and closing movements. (From Dawson PE: Evaluation, Diagnosis, and Treatment of Occlusal Problems, ed 2. St Louis, Mosby, 1989.)

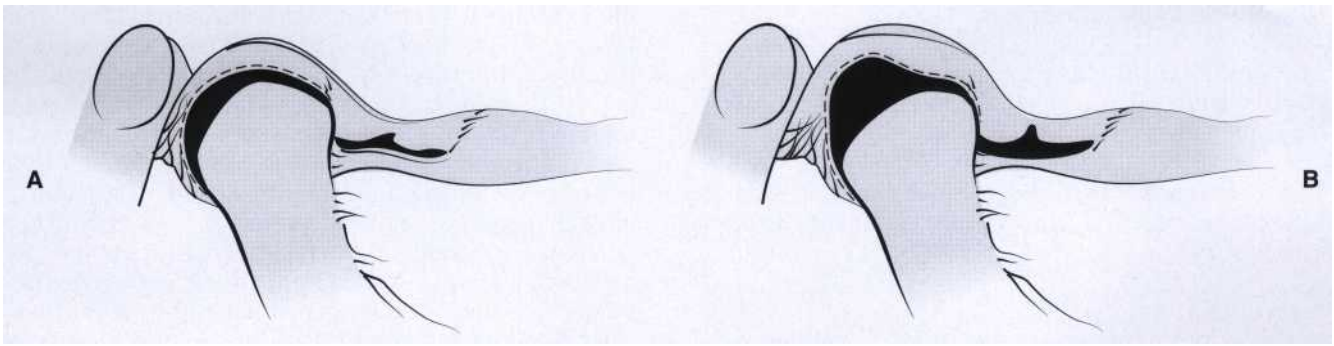

Fig. 25-7 Anterior disc displacement without reduction. A, Condyle positioned in the fossa on retrodiscal tissues with the disc remaining anterior to head of condyle. B, During translation, the disc is further misshaped, restricting full opening of the mandible.

Hypermobility (subluxation) of the TMJ can permit the condyle to translate beyond the eminentia with both the disc and the condyle beyond its prominence. The combination of anatomic features, which predispose individuals to subluxation, often allows for self-reduction of the condyles. When condyles translate beyond the eminentia but the discs are trapped posteriorly, the combined steepness of the disc and the eminentia prevents reduction of each condyle so that the mandible is locked open.[119]

OROFACIAL PAIN

Discomfort associated with masticatory system disorders falls under the larger umbrella of orofacial pain. Pain associated with TMJ dysfunction is most frequently muscular in origin.[38] Working knowledge of even the uncommon sources of pain perceived in the region of the masticatory system is essential to providing comprehensive diagnosis and treatment. Sources of dental or periodontal pain should be identified by clinical, radiographic, and/or historical information. Nondental sources of pain include TMJ structures, muscles, cervical structures, neuropathies, vascular inflammation, all types of headache, sleep disorders, systemic disorders, and psychoimmune neurologic sources."$ A survey of 45,700 American households revealed that 22% of respondents had experienced some type of orofacial pain in the previous 6 months, establishing a meaningful probability that the periodontal patient's list of symptoms includes pain.[94] The current list of possible sources of orofacial pain, prepared by the American Academy of Orofacial Pain, is depicted in Box 25-1.[118]

Headache pain is perceived primarily within the trigeminal nerve pathways, although other cranial and cervical nerves may offer painful sensory input.[73,118] Pain originating in masticatory system structures, which are also innervated by the trigeminal nerve, requires diagnostic differentiation from headache pain.[141] Headache can present in a myriad of forms and can influence perception of pain and diagnosis of origin of pain.[73,118] Pain of dental and periodontal origin must be clearly defined and differentiated from heart attack, sinus pain or myofascial pain.[118,119] Pain originating in pulpal or periodontal nocioceptors would be differentiated within a comprehensive clinical and radiographic

BOX 25-1

Differential Diagnosis of Orofacial Pain

Intracranial Pain Disorders[65,73,118,124]
Neoplasm, aneurysm, abscess, hemorrhage, hematoma, edema

Primary Headaches Disorders (Neurovascular Disorders)[87,119]
Migraine, migraine variants, cluster headache, paroxysmal hemicrania, cranial arteritis, carotidynia, tension-type headache[80,118,119,140]

Neurogenic Pain Disorders
Paroxysmal neuralgias: Trigeminal, glossopharyngeal, nervus intermedius and superior laryngeal neuralgias[156]
Continuous pain disorders: Deafferentation pain syndromes (peripheral neuritis, postherpetic neuritis, posttraumatic and postsurgical neuralgia, neuralgia–inducing cavitation osteonecrosis[16,17])
Sympathetically maintained pain

Intraoral Pain Disorders
Dental pulp, periodontium, mucogingival tissues, tongue[13,105]

Temporomandibular Disorders
Masticatory muscle, temporomandibular joint, associated structures

Associated Structures[118,119]
Ears, eyes, nose, paranasal sinuses, throat, lymph nodes, salivary glands, neck

Axis II, Mental Disorders
Somatoform disorders
Pain syndromes of psychogenic origin

evaluation. Orofacial pain originating in the TMJs and/or the muscles of mastication can occur as a product of neoplasm, macrotrauma, repeated microtrauma, systemic disease, or anatomic predisposition. Within the joint structures, inflammation and/or compression of vascularized components are the direct source of pain. Synovitis or capsulitis, with or without osteoarthritis, and the polyarthritides are characterized by local pain, which increases with function while limiting range of motion of the affected TMJ. In addition to the potential for pain, symptoms of arthritis can include limited mandibular opening, disruption of other jaw mechanics, and joint sounds characteristic of degenerative change to and/or direct contact between articular surfaces.* Orofacial pain originating in the muscles of mastication may be perceived in that region or may be referred to other structures such as individual teeth. Similarly, pain referral to the region of certain muscles requires definition of origin. Because local provocation at the origin of pain should produce symptoms at the site of perception of pain, movement of the jaw would be expected to elicit pain in painful muscles of mastication. Cranial nerves experience referral on the same side, whereas skeletal nerve referral can occur to the opposite side; both sources generally refer pain centrally or superiorly.[73,119,146] The muscles of mastication can be subject to a variety of disorders and dysfunction, many of which can be painful. The American Academy of Orofacial Pain designates myofascial pain, myositis, myospasm, local myalgia, and myofibrotic contracture as major categories of these conditions. Muscle palpation that reveals a taut band of muscle or fascia and that results in pain, which is also frequently referred, is virtually diagnostic for myofascial pain. Myostitis of masticatory muscles arises from direct trauma or infection in close proximity to muscle. Associated pain increases with mandibular movement, thereby limiting range of motion. Muscle spasm is the sustained involuntary contraction resulting in pain and dramatic shortening of the affected muscle. Myospasm of masticatory muscles greatly limits mandibular movement and can change occlusion suddenly due to its rapid onset. Local myalgia, pain specific to individual muscles, may result from ischemia or fatigue and may present as delayed-onset muscle soreness and/or protective co-contraction. Occlusal parafunction, extended dental appointments, metabolic imbalances, and sympathetic nervous system influences have been associated with this painful muscular reaction. An extended period of limited range of mandibular movement can result in fibrosis of the muscle and related attachments, creating a painless condition called myofibrotic *contracture*.[118]

Otolaryngologic symptoms associated with masticatory system disorders have been reported and include degrees of deafness, tinnitus, and vertigo.* Trauma and postural stress in the cervical spine can be responsible for both the perception and origin of pain within the masticatory system.[12,19,73,119]

Determination of a specific origin or source of pain can be made more difficult by both pain referral and modulation of painful experiences by the central nervous system. Sensitization of peripheral nocioceptors by higher neural centers and inflammation at the site of origin of pain can alter pain perception. Persistent inflammation therefore may be a contributing factor to chronic pain.[74,101,144] Systemic conditions that may contribute to or predispose an individual to compromised pain regulation include sleep disorders, fibromyalgia, chronic depression, chronic fatigue syndrome, hypothyroidism, insufficient thyroid receptor activity, prolactin feedback disorder, epinephrine sensitivity related to mitral valve prolapse, premenstrual syndrome, androgen excess in women, and posttraumatic stress disorder. Although some of these situations exhibit gender bias due to hor-

monal factors, the influence of stress on pain experiences and the effect of variable coping skills are reported for both genders.*

COMPREHENSIVE EVALUATION

Patient History and Interview

The written history and personal interview should be designed to invite open-ended response and reflection by the patient on past experiences and current condition. Standard dental or medical history forms may require modification to include questions regarding any history of limited or painful jaw movement, noise in either joint, and masticatory muscle symptoms (Box 25-2). These issues should be documented with regard to timing, duration, frequency, and relationship to any history of trauma.[118]

Clinical Examination

The clinical examination continues the interview process through codiscovery of the patient's masticatory system status. The dentist leads the patient to understand the meaning of signs and symptoms of dysfunction or deterioration, seeking opportunities to expand responses to questions asked of the patient. The physical examination actually begins during the interview when asymmetries in facial form, head posture, and mandibular movement patterns can be observed. Clinical evaluation of the various structures of the masticatory system, although individual to each practitioner, should include the following:[9,38,119]

1. Observation and measurement of full range motion of the mandible
2. Auscultation and light palpation of each TMJ in its full range of motion
3. Load testing of each TMJ
4. Palpitation of each muscle of mastication and related head and neck muscles
5. Evaluation of all the soft tissues of the face, oral cavity, and oropharynx
6. Periodontal and dental examinations
7. Complete occlusal analysis, including accurately mounted diagnostic models

Evaluation of the TMJ begins with range-of-motion analysis. Observation of departure from a straight path of opening and closing the mandible suggests an intracapsular disorder or masticatory muscle incoordination.[38,119] An average maximal opening of 50 mm is common; findings of less than 40 mm of opening suggest limited opening due to a masticatory system disorder. The range of right and left lateral excursions is usually about 9 mm, and protrusion of mandible is commonly 7 mm. Limitation in range of motion may be normal for some patients, but for most, these observations are of diagnostic value.[9,44,64,119,147] Auscultation of the joint by listening with a stethoscope or Doppler instrument, which amplifies joint sound for both the patient and the dentist, can reveal noises diagnostic for numerous conditions. The intensity and nature of any sounds, clicks, pops, and/or crepitus (grinding, grating, or rubbing sounds) should be recorded accurately. Any sound detected as part of the initial evaluation should be tracked consistently to detect any change. Diagnostic interpretation and management based on specific sounds correlated with status of the TMJ can be found in other references.[7,9,38,119,157]

Firm palpation of the TMJ with the mouth closed can be uncomfortable to the patient with inflammation in joint structures or superficial muscles. Palpation while opening may become more uncomfortable if retrodiscal tissues are also inflamed. Load testing of the TMJ is essentially a means to palpate the head of the condyle, surface of the glenoid fossa, and tissue interposed between

BOX 25-2

Examples of Questions or Subjects to Be Included in Patient History

Are you now experiencing or have you ever experienced any of the following?

1. Pain in either jaw joint or pain when opening or closing your mouth[8]
2. Acute or direct trauma to the face, jaw, head, or neck such as during an accident
3. Any locking or restricted movement of either jaw joint[44,147]
4. Inability to bite or close teeth together completely without discomfort of one or both jaw joints
5. Earache without infection, especially if it is recurring
6. Ringing or rushing sounds in either ear
7. Any type of neuralgia, especially with trigger points
8. Tooth pain without diagnosed dental problem or following tooth removal[103,104,162]
9. Fibromyalgia[37,126,131]
10. Sleep apnea or any sleep disturbance
11. Any sounds (clicks, pops, etc.) in either jaw joint, especially when opening or while eating
12. Chronic or frequently recurring headaches, especially migraine or cluster type of headache[4]
13. Shingles or any painful infection of face or neck
14. Having to "adjust" the jaw or manipulate jaw joint with your hand to be able to open or close your mouth
15. An occupation or activity that requires regular stressful posture such as cradling a telephone between head and shoulder, working at a computer, playing a musical instrument, or scuba diving[150,166]
16. Awareness of frequently keeping your teeth together, maintaining a clenched jaw, or holding your jaw in an assumed position such as holding a pipe
17. Lyme disease[61]
18. Neck muscles that are commonly tired or sore
19. Sleep position or posture that maintains pressure on your lower jaw

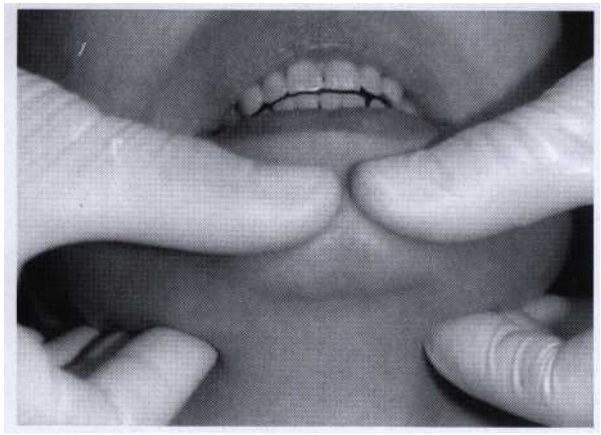

Fig. 25-8 Bimanual manipulation load testing in centric relation with the teeth apart.

them, except in the case of bone-to-bone contact. With bimanual mandibular manipulation, the dentist loads the joints equally and may detect resistance or tension on either side. The patient is in a supine position in the dental chair to minimize postural influence on muscle activity. The patient's head is braced by the support of the chair and by being cradled against the dentist's arm and/or abdomen. The dentist's middle fingers locate the notch in the mandible just anterior to the angle, and the thumbs are placed near the midline in the mental region of the mandible (Fig. *25-8).* Initially, the dentist provides very gentle guidance to the hinging action of the mandible, with a slight lifting force applied by the fingers and slight depressing force applied with the thumbs. Should the patient remain comfortable, then increasing force can be applied at both points, ultimately with enough pressure to load test the joints (see Fig. *25-8).* With the avascular fibrous discs interposed, the condyles are in centric relation and the loading of both joints is comfortable. Discomfort may occur with muscle incoordination or bracing or with an anterior displaced disc and attempted loading of vascular retrodiscal tissues of either TMJ. When performed properly, the patient can bite firmly as part of guided loading of the TMJs and report the nature or absence of pain or tension. 9,38,59,119

Muscle palpation is also a learned technique that requires both experience and expertise to derive the most reliable information. Too little pressure is not diagnostic of modest muscle pain or spasm, while too much pressure can hurt even when normal musculature is palpated." Externally, the muscles palpated include the anterior, middle, and posterior temporalis; superficial masseter; anterior and posterior digastric; sternocleidomastoid; trapezeius; posterior cervical muscles; and insertion of the medial pterygoid muscle. Intraorally, the deep masseter is tested with moderate squeezing pressure and the medial pterygoid muscle is palpated directly in the general region of the insertion point for mandibular block local anesthesia. The lateral pterygoid is difficult to palpate due to the dominance of the medial pterygoid in the same region. Its palpation superior and distal to the palpation point for the medial pterygoid can be attempted distal to the maxillary tuberosity. Offering manual resistance to the patient's efforts to protrude the mandible is also a test of the lateral pterygoid muscle. Neither method of evaluation of the possible soreness of the lateral pterygoid muscle is completely reliable, although some insight into muscle status is obtained.*

During any of the muscle palpation portion of the clinical examination, it may be possible for the dentist to detect a particularly taut and uncomfortable band of muscle fibers. This condition represents regional myofascial pain or trigger point myalgia, which can be responsible for referral of pain to the teeth and other orofacial regions. Diagnostic injection of local anesthesia can be very effective in identifying trigger point pain and pain referral patterns but is beyond the scope of this text. 119,116

The occlusal analysis is a logical extension of the evaluation of the teeth and periodontium. Tooth mobility is assessed in both static and dynamic modes. Pressure applied to a tooth with a firm object allows detection of movement with both visual and tactile evaluation possible. Asking the patient to move in excursions of the mandible while maintaining firm contact of opposing teeth also permits visual and tactile assessment. Sources of tooth mobility include inadequate periodontal support, inflammation of the periodontium, and excessive occlusal loading of the teeth with adequate periodontium, resulting in adaptive mobility. The physical evaluation of the teeth and any restorations can reflect history of trauma or wear. Visual observation, registration with marking paper or wax, and electronic assessment of tooth contacts as the patient moves in all excursions may reveal disharmonies sufficient to cause orthopedic instability of either TMJ. If the teeth are found to be relatively firm, then the relationship of the maxillary and mandibular teeth may influence the direction of condylar movement as soon as tooth-to-tooth contact is made. While maintaining centric relation, the physical examination continues by positioning the condyles in a fully seated relationship without tooth-to-tooth contact using bimanual manipulation or a leaf gauge technique. The mandible is manually guided to close until the first tooth-to-tooth contact is made. If that position is also maximal intercuspation, then optimal seating of the condyles is maintained. If the initial tooth-to-tooth contact is not maximal intercuspation, then the condyles will be directed from a fully seated position to an inferior position relative to their respective fossae, resulting in an orthopedic instability. The direction and extent of the accommodation of the mandible should be carefully measured and recorded at the initial evaluation and consistently evaluated at subsequent appointments so that any trend may be discovered.**

To increase the reliability of this evaluation, a muscle deprogramming effort may be employed. The simplest approach is to use cotton rolls placed between the anterior teeth for *5* to *15* minutes to allow possible muscle relaxation through avoidance of proprioceptive or

* **See references 3, 9, 38, 47, 49, 73, 119, and 148.**

** **See references 9, 29, 30, 38-40, 48, 69, 71, 78, 79, 85, 95, 96, 119, 120, 132, 134, 141, and 155.**

pressure neurologic input. A prefabricated or directly fabricated acrylic or composite bite stop for anterior teeth will offer the same advantage.9.10,119 A more complex means of confirming the seating of the condyles in centric relation is achieved with a maxillary or mandibular muscle relaxation occlusal appliance. These appliances provide full coverage for the respective arch and occlusal contact for at least one cusp or incisal edge of the opposing teeth so that teeth are protected from spontaneous shifting. The occlusal design provides immediate disclusion of all the posterior teeth in every protrusive or lateral excursion. This allows for the progressive deprogramming of muscles through the advantage of reduced muscle contractions and limited noxious neurologic input. 39,88,160

Models of the dentition must be accurately mounted to be diagnostic. The facebow transfer relates the maxillary cast to the axis of rotation of the articulator as the maxillary teeth relate to the cranial case. With careful bimanual manipulation or the use of an anterior bite stop, a transfer wafer is generated with the condyles fully seated in their glenoid fossa. The maxillary and mandibular teeth of each diagnostic model then relate to one another in centric relation as determined by condylar position, and they may reveal an occlusal discrepancy in centric relation, which would require compensation by the patient.[9,38]

Imaging

When the clinical evaluation and the history of the patient indicate the possibility of structural masticatory system disorders or the possible presence of pathology, especially neoplasm, then appropriate imaging of the TMJ is warranted. The current state of the art technique for imaging of soft tissue, especially the articular disc, is magnetic resonance (MR) imaging. The current highest standard for imaging for hard tissue, such as the condyle or the temporal bone, is computed tomography (CT). Both techniques are usually reserved for more difficult or strategic diagnosis, such as when joint surgery is being considered. Their interpretation usually requires specialized training for the clinician or access to a radiologist. Though arthrography is still being used for certain diagnostic situations, such as suspected perforation of the articular disc, CT and MR imaging are experiencing greater utilization.', 18,75,89,125 Although plain film tomography is occasionally a feature of some of the newer radiographic equipment, the technique most readily available to a majority of practitioners is panoramic radiography. The image produced depicts only general relationships and gross anatomy, so the information provided should be regarded for screening purposes only. When pathology or marked deformation is suggested by a panoramic radiograph, further diagnostic imaging and procedures may be warranted. 18,73

DIAGNOSTIC DECISION MAKING

Complete evaluation of every patient's periodontal status must include the diagnostic components required to reveal any form of masticatory system disorder. The existence of factors responsible for historical, current, or potential impairment of masticatory system function can be integrated into a comprehensive treatment plan. Patients who require substantial periodontal therapy or have suffered the effects of advanced periodontal disease may be at increased risk to develop masticatory system disorders, so diagnostic processes must remain consistently thorough and inclusive for all patients .23,137 For the patient presenting with symptomatic masticatory system disorder, the diagnostic strategy would logically begin with the inclusion of all potential sources of pain or dysfunction followed by the systematic exclusion of possible causative or contributing factors, beginning with the least likely. When no symptoms are reported, the history and clinical examination would need to be just as thorough due to the tendency for a number of patients to tolerate modest dysfunction or mild transient discomfort. The diagnostic strategy for the patient presenting minimal or no signs and symptoms of masticatory system disorders would be to attempt to confirm a stable condition while identifying risk factors. Careful and complete documentation of the indication of past or current trauma and disharmony would provide the basis for trend analysis and anticipation of possible future problems.*

Consistent professional maintenance care has been clearly demonstrated to be a key ingredient in successful management of a patient's periodontal condition."', 106 Complementing any treatment sequence, these appointments afford dentists the opportunity at every stage of comprehensive care to provide continuing evaluation of the status of the entire masticatory system and to provide timely and appropriate intervention when needed.

Chronic Periodontitis

Richard]. Nagy and M. John Novak

CHAPTER OUTLINE

CLINICAL FEATURES
- **General Characteristics**
- **Disease Distribution**
- **Disease Severity**
- **Symptoms**
- **Disease Progression**
- **Prevalence**

RISK FACTORS FOR DISEASE
- **Prior History of Periodontitis**
- **Local Factors**
- **Systemic Factors**
- **Environmental and Behavioral Factors**
- **Genetic Factors**

Chronic periodontitis, formerly known as "adult periodontitis" or "chronic adult periodontitis," is the most prevalent form of periodontitis. It is generally considered to be a slowly progressing disease. However, in the presence of systemic or environmental factors that may modify the host response to plaque accumulation, such as diabetes, smoking, or stress, disease progression may become more aggressive. Although chronic periodontitis is most frequently observed in adults, it can occur in children and adolescents in response to chronic plaque and calculus accumulation. This observation underlies the recent name change from "adult" periodontitis, which suggests that chronic, plaque-induced periodontitis is only observed in adults, to a more universal description of "chronic" periodontitis that can occur at any age (reviewed in Chapter 4).

Chronic periodontitis has recently been defined as "an infectious disease resulting in inflammation within the supporting tissues of the teeth, progressive attachment loss, and bone loss."' This definition outlines the major clinical and etiologic characteristics of the disease: microbial plaque formation, periodontal inflammation, and loss of attachment and alveolar bone. Periodontal pocket formation is usually a sequela of the disease process unless gingival recession accompanies attachment loss, in which case pocket depths may remain shallow even in the presence of ongoing attachment and bone loss.

CLINICAL FEATURES

General Characteristics

Characteristic clinical findings in patients with chronic periodontitis include supragingival and subgingival plaque accumulation that is frequently associated with calculus formation, gingival inflammation, pocket formation, loss of periodontal attachment and loss of alveolar bone (Fig. 26-1). The gingiva ordinarily is slightly to moderately swollen and exhibits alterations in color ranging from pale red to magenta. Loss of gingival stippling and changes in the surface topography may include blunted or rolled gingival margins and flattened or cratered papillae. In many patients, the changes in color, contour, and consistency that are frequently associated with gingival inflammation may not be visible on inspection, and inflammation may be detected only as bleeding of the gingiva in response to examination of the periodontal pocket with a periodontal probe. Gingival bleeding, either spontaneous or in response to probing, is frequent, and inflammation-related exudates of crevicular fluid and suppuration from the pocket also

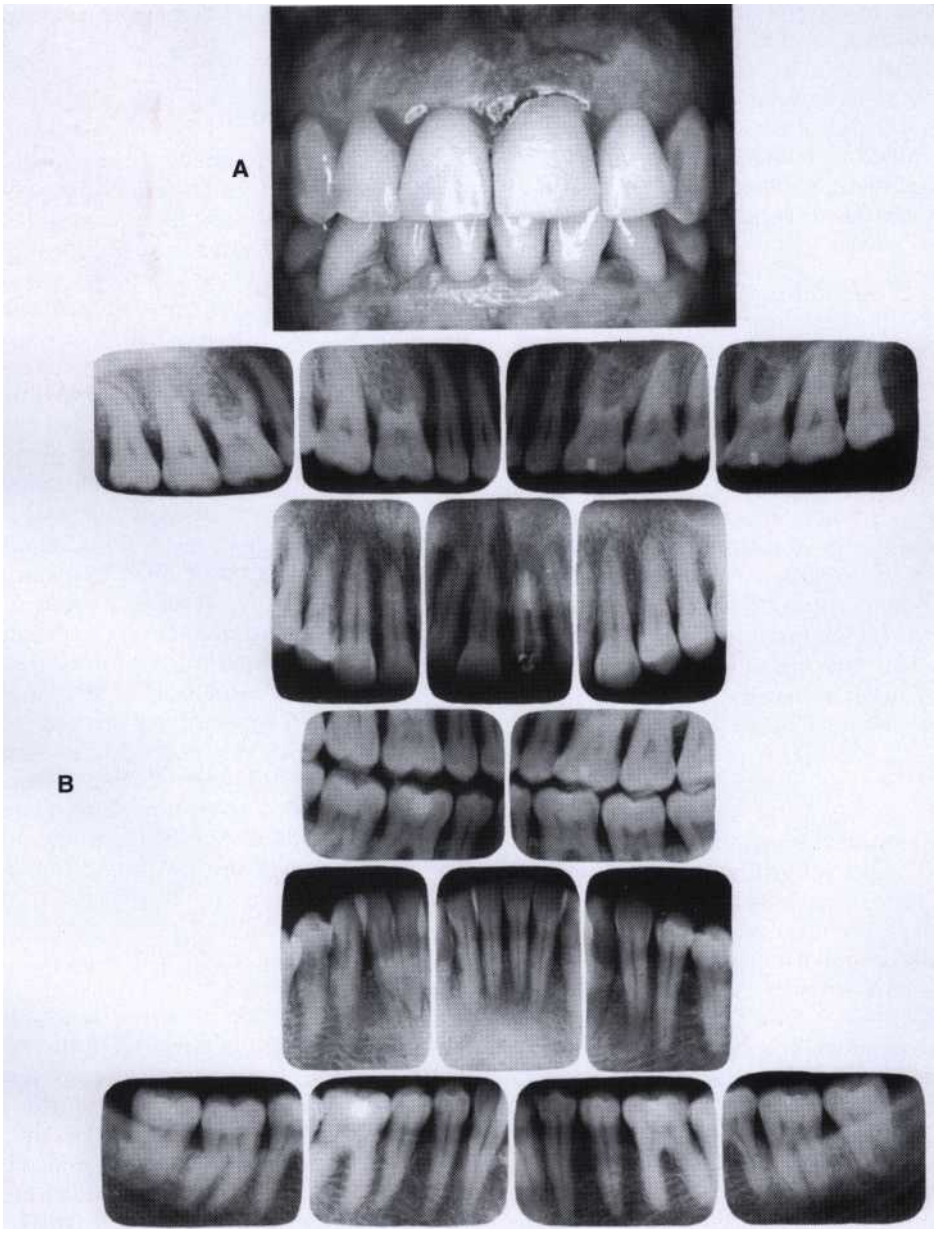

Fig. 26-1 Chronic periodontitis in a 47-year-old female. A, Clinical view showing generalized gingival inflammation and periodontal pocket formation. B, Radiographs showing generalized horizontal bone loss that varies in severity in different areas.

may be found. In some cases, probably as a result of long standing, low-grade inflammation, thickened, fibrotic marginal tissues may obscure the underlying inflammatory changes. Pocket depths are variable, and both horizontal and vertical bone loss can be found. Tooth mobility often appears in advanced cases when bone loss has been considerable.

Chronic periodontitis can be clinically diagnosed by the detection of chronic inflammatory changes in the marginal gingiva, presence of periodontal pockets, and loss of clinical attachment. It is diagnosed radiographically by evidence of bone loss. These findings may be similar to those seen in aggressive disease. A differential diagnosis is based on the age of the patient, rate of disease progression over time, familial nature of aggressive disease, and relative absence of local factors in aggressive disease compared with the presence of abundant plaque and calculus in chronic periodontitis.

Disease Distribution

Chronic periodontitis is considered a site-specific disease. The clinical signs of chronic periodontitis-namely inflammation, pocket formation, attachment loss, and bone loss-are considered to be due to the direct, site-specific effects of subgingival plaque accumulation. As a result of this local effect, pocketing, attachment, and bone loss may occur on one surface of a tooth while

other surfaces maintain normal attachment levels. For example, a proximal surface with chronic plaque accumulation may have loss of attachment, whereas the plaque-free facial surface of the same tooth may be free of disease. In addition to being site specific, chronic periodontitis may be described as being *localized* when few sites demonstrate attachment and bone loss or *generalized* when many sites around the mouth are affected (see Chapter 4).

Localized periodontitis: Periodontitis is considered localized when <30% of the sites assessed in the mouth demonstrate attachment loss and bone loss.

Generalized periodontitis: Periodontitis is considered generalized when >30% of the sites assessed in the mouth demonstrate attachment loss and bone loss.

The pattern of bone loss observed in chronic periodontitis may be vertical, when attachment and bone loss on one tooth surface is greater than that occurring on an adjacent surface, or horizontal, when attachment and bone loss proceeds at a uniform rate on the majority of tooth surfaces. Vertical bone loss is usually associated with angular bony defects and intrabony pocket formation. Horizontal bone loss is usually associated with suprabony pockets (see Chapters 24 and 25).

Disease Severity

The severity of destruction of the periodontium that occurs as a result of chronic periodontitis is generally considered a function of time. With increasing age, attachment loss and bone loss becomes more prevalent and more severe due to an accumulation of destruction (see Chapter 5). Disease severity may be described as being *slight (mild), moderate,* or *severe* (see Chapter 4). These terms may be used to describe the disease severity of the entire mouth, a part of the mouth such as a quadrant or sextant, or the disease status of an individual tooth.

Slight (mild) periodontitis: Periodontal destruction is generally considered slight when no more than 1 to 2 mm of clinical attachment loss has occurred.

Moderate periodontitis: Periodontal destruction is generally considered moderate when 3 to 4 mm of clinical attachment loss has occurred.

Severe periodontitis: Periodontal destruction is considered severe when 5 mm or more of clinical attachment loss has occurred.

Symptoms

Because chronic periodontitis is usually painless, patients may be less likely to seek treatment and accept treatment recommendations. In addition, a negative response to questions such as "Are you in pain?" is not sufficient to eliminate suspicion of periodontitis. Occasionally, pain may be present in the absence of caries due to exposed roots that are sensitive to heat, cold, or both. Areas of localized dull pain, sometimes radiating deep into the jaw, have been associated with periodontitis. The presence of areas of food impaction may add to the patient's discomfort. Gingival tenderness or "itchiness" can also be found.

Disease Progression

Patients appear to have the same susceptibility to plaque-induced chronic periodontitis throughout their lives. The rate of disease progression is usually slow but may be modified by systemic and/or environmental and behavioral factors. Onset of chronic periodontitis can occur at any time, and the first signs may be detected during adolescence in the presence of chronic plaque and calculus accumulation. However, because of its slow rate of progression, chronic periodontitis usually becomes clinically significant in the mid-30s or later.

Chronic periodontitis does not progress at an equal rate in all affected sites throughout the mouth. Some involved areas may remain static for long periods of time,' whereas others may progress more rapidly. More rapidly progressive lesions occur most frequently in interproximal areas' and are usually associated with areas of greater plaque accumulation and inaccessibility to plaque control measures (e.g., funation areas, overhanging margins, sites of malposed teeth, or areas of food impaction). Several models have been proposed to describe the rate of disease progression.' In these models, progression is measured by determining the amount of attachment loss during a given time. The *continuous model,* the *random* or *episodic burst model,* and the *asynchronous multiple burst model* of disease progression are described in Chapter 9.

Prevalence

Chronic periodontitis increases in prevalence and severity with age, generally affecting both sexes equally. Periodontitis is an age-associated, not age-related, disease. In other words, it is not the age of the individual that causes the increase in disease prevalence, but rather the length of time that the periodontal tissues are challenged by chronic plaque accumulation. The incidence and prevalence of chronic periodontitis are discussed in detail in **Chapter 5.**

RISK FACTORS FOR DISEASE

Prior History of Periodontitis

Although not a true risk factor for disease but rather a disease predictor, a prior history of periodontitis puts patients at greater risk for developing further loss of attachment and bone, given a challenge from bacterial plaque accumulation.' This means that a patient who presents with pocketing and attachment and bone loss will continue to lose periodontal support if not successfully treated. In addition, a chronic periodontitis patient that has been successfully treated will develop continuing disease if plaque is allowed to accumulate. This stresses the need for continuous monitoring and maintenance of periodontitis patients to prevent a reoccurrence of the disease. The risk factors that contribute to patient susceptibility are discussed in the following sections.

Local Factors

Plaque accumulation on tooth and gingival surfaces at the dentogingival junction is considered the primary initiating agent in the etiology of chronic periodontitis. Attachment and bone loss are associated with an increase in the proportion of gram-negative organisms in the subgingival plaque biofilm, with specific increases in organisms known to be exceptionally pathogenic and virulent. *Bacteroides gingivalis, Bacteroides forsythus,* and *Treponema denticola,* otherwise known as the "red complex," are frequently associated with ongoing attachment and bone loss in chronic periodontitis. These microorganims and their virulence factors are described in detail in Chapters 6 and 8. The identification and characterization of these and other pathogenic microorganisms and their association with attachment and bone loss has led to the specific plaque hypothesis for the development of chronic periodontitis. This hypothesis implies that although a general increase occurs in the proportion of gram-negative microorganisms in the subgingival plaque in periodontitis, it is the presence of increased proportions of members of the red complex and perhaps other microorganisms that precipitates attachment and bone loss. The mechanisms by which this occurs have not been clearly delineated, but these bacteria may impart a local effect on the cells of the inflammatory response and the cells and tissues of the host, resulting in a local, site-specific disease process. The interactions between pathogenic bacteria and the host and their potential effects on disease progression are discussed in detail in Chapter 8.

Because plaque accumulation is the primary initiating agent in periodontal destruction, anything that facilitates plaque accumulation or prevents plaque removal by oral hygiene procedures can be detrimental to the patient. *Plaque retentive factors* are important in the development and progression of chronic periodontitis because they retain plaque microorganisms in close proximity to the periodontal tissues, providing an ecologic niche for plaque growth and maturation. Calculus is considered the most important plaque retentive factor because of its ability to retain and harbor plaque bacteria on its rough surface. As a result, calculus removal is essential for the maintenance of a healthy periodontium. Other factors that are known to retain plaque or prevent its removal are subgingival and/or overhanging margins of restorations; carious lesions that extend subgingivally; furcations exposed by loss of attachment and bone; crowded and malaligned teeth; and root grooves and concavities. These potential risk factors for periodontitis are discussed further in Chapter 32, and their impact on the prognosis of periodontal treatment is discussed in Chapter 33.

Systemic Factors

The rate of progression of plaque-induced chronic periodontitis is generally considered to be slow. However, when chronic periodontitis occurs in a patient who also suffers from a systemic disease that influences the effectiveness of the host response, the rate of periodontal destruction may be significantly increased. Diabetes is a systemic condition that can increase the severity and extent of periodontal disease in an affected patient. Type 11 or non-insulin-dependent diabetes mellitus (NIDDM) is the most prevalent form of diabetes and accounts for 90% of diabetics.' In addition, Type II diabetes is most likely to develop in an adult population at the same time as chronic periodontitis. The synergistic effect of plaque accumulation and modulation of an effective host response through the effects of diabetes can lead to severe and extensive periodontal destruction that may be difficult to manage with standard clinical techniques without controlling the systemic condition. An increase in Type II diabetes in teenagers and young adults has been observed and may be associated with an increase in juvenile obesity. In addition, Type I or insulin-dependent diabetes (IDDM) is observed in children, teenagers, and young adults and may lead to increased periodontal destruction when it is uncontrolled. It is likely that chronic periodontitis, aggravated by the complications of Type I and/or Type II diabetes may increase in prevalence in the near future and will provide therapeutic challenges to the clinician.

Environmental and Behavioral Factors

Smoking has been shown to increase the severity and extent of periodontal disease. When combined with plaque-induced chronic periodontitis, an increase in the rate of periodontal destruction may be observed in nonsmoking patients who have chronic periodontitis. As a result, smokers with chronic periodontitis have more attachment and bone loss, more funation involvements, and deeper pockets. In addition, they appear to form more supragingival and less subgingival calculus and demonstrate less bleeding on probing than nonsmokers. The reasons for this effect are receiving considerable attention at present. Initial evidence points to changes in the subgingival microflora between smokers and nonsmokers in addition to the effects of smoking on the host response. The clinical, microbiologic, and immunologic effects of smoking also appear to have an influence on the response to therapy and the frequency of recurrent disease. The effects of smoking are reviewed further in Chapter 14.

Emotional stress has previously been associated with necrotizing ulcerative disease, perhaps because of the effects of stress on immune function. Increasing evidence suggests that emotional stress also may influence the extent and severity of chronic periodontitis, probably through the same mechanisms.

Genetic Factors

Periodontitis is considered to be a multifactorial disease in which the normal balance between microbial plaque and host response is disrupted. This disruption, as described previously, can occur through changes in the plaque composition, changes in the host response, or environmental and behavioral influences that can affect both plaque response and host response. In addition, periodontal destruction is frequently seen among family members and across different generations within a family, suggesting the possibility of a genetic basis to the susceptibility to periodontal disease. Recent studies have demonstrated a familial aggregation of localized and

generalized aggressive periodontitis (reviewed in Chapters 10 and 27). In addition, studies of monozygotic twins suggest a genetic component to chronic periodontitis, but the influences of bacterial transmission among family members and environmental effects make it difficult to interpret a complex interaction. These studies are discussed in detail in Chapter 10.

Although no clear genetic determinants have been described for patients with chronic periodontitis, a genetic predisposition to more aggressive periodontal breakdown in response to plaque and calculus accumulation may exist. Recent data indicate that a genetic variation or polymorphism in the genes encoding interleukin 1-a and interleukin 1-ß is associated with an increased susceptibility to a more aggressive form of chronic periodontitis in subjects of Northern European origin.' In addition, smokers demonstrating the composite IL-1 genotype are at even greater risk for severe disease. A recent study suggested that patients with the IL-1 genotype increased the risk for tooth loss by 2.7 times; those who were heavy smokers and IL-1 genotype negative increased the risk for tooth loss by 2.9 times. The combined effect of the IL-1 genotype and smoking increased the risk of tooth loss by 7.7 times.[6] With increased characterization of genetic polymorphisms that may exist in other target genes, a complex genotype is likely to be identified for many different clinical forms of periodontitis.

Chediak-Higashi Syndrome
Hypophosphatasia
Leukocyte Adhesion Deficiency

Unusual and severe forms of periodontitis can be more frequently seen in certain severe combined and acquired immunodeficiency diseases and in some patients who were treated yet continue to show periodontal deterioration. This chapter reviews the following aggressive periodontal diseases: necrotizing ulcerative periodontitis (NUP), the refractory forms of periodontitis, and periodontitis as a manifestation of systemic diseases.

NECROTIZING ULCERATIVE PERIODONTITIS

NUP is an extension of necrotizing ulcerative gingivitis (NUG) into the periodontal structures, leading to attachment and bone loss. NUP may include combinations of the following signs and symptoms: necrosis and ulceration of the coronal portion of the interdental papillae and/or gingival margin; painful, bright-red marginal gingiva that bleeds on even slight manipulation; mouth malodor (halitosis); and systemic manifestations including fever, malaise, and lymphadenopathy. In addition, increased levels of stress, heavy smoking, and poor nutrition have been shown to be contributing factors to NUP.

Two types of NUP have been described according to their relationship with acquired immunodeficiency syndrome (AIDS).

NON-AIDS TYPE NECROTIZING ULCERATIVE PERIODONTITIS

Clinical Features

This type of periodontitis occurs after repeated long-term episodes of NUG. NUG is characterized by areas of ulceration and necrosis of the gingival margin that become covered by a whitish-yellowish soft material known as a *pseudomembrane.* The ulcerated margin is surrounded by an erythematous halo. The lesions are painful and bleed often, giving rise to localized lymphadenopathy and even fever and malaise. Microscopically, NUG lesions are the result of nonspecific necrotizing inflammation presenting a predominantly polymorphonuclear neutrophil (PMN) infiltrate in the ulcerated areas with an abundant chronic component (lymphocytes and plasma cells) in the peripheral and deeper areas.[38]

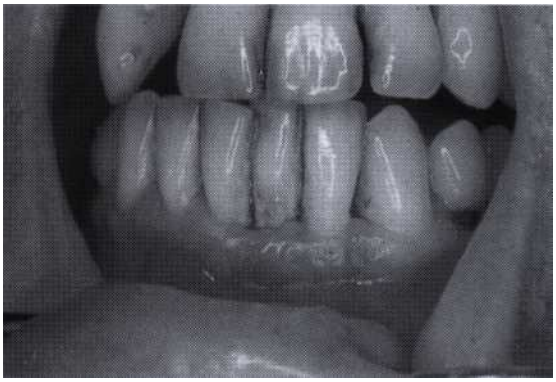

Fig. 27-1 Necrotizing ulcerative periodontitis in a 42-year-old, HIV-negative, white male.

The inflammatory infiltrate in lesions of NUG, especially in long-standing cases, can extend to the underlying bone, resulting in deep, crater-like osseous lesions, most often located in interdental areas. These cases are diagnosed as NUP

Lesions resembling this description and progressing to become *gangrenous stomatitis,* or *noma,* have been described in children with severe malnutrition in underdeveloped countries. Jimenez and Baer" described NUG in children and adolescents aged 2 to 14 with malnutrition in Colombia; in advanced stages, NUG extended from the gingiva to other areas of the oral cavity, becoming gangrenous stomatitis or noma and causing exposure, necrosis, and sequestration of the alveolar bone. Experimentally, noma-like lesions have been produced in rats by administering cortisone and causing mechanical injury to the gingiva[34] and in hamsters by total body irradiation.[25]

NUP is characterized by deep interdental osseous craters (Fig. 27-1; Color Fig. 27-1, A-C), but deep "conventional" pockets are not found because the ulcerative and necrotizing character of the gingival lesion destroys the marginal epithelium, resulting in recession. Lesions of NUP can lead to advanced bone loss, tooth mobility, and tooth loss.

Etiology

The etiologic agents of NUP have not been studied, but they can be assumed to be similar to those present in NUG, which has been extensively investigated. However, this similarity has not been established. The mechanisms by which cases of NUG may become NUP ave also not been investigated. Cutler et all have descr bed impaired bactericidal activity of PMNs in two children with NUP.

AIDS-ASSOCIATED NECROTIZING ULCERATIVE PERIODONTITIS

Clinical Features

Typical changes of inflammatory periodontal diseases can arise in the course of infection by the human immunodeficiency virus (HIV). The prevalence of these illnesses may be up to 5%.[9] The HIV-associated periodontal diseases include linear gingival erythema (LGE), NUG, and NUP.[30] The necrotizing forms appear particularly in severe or advanced immunosuppression. Gingival and periodontal lesions are frequently found in patients with AIDS. These gingival and periodontal lesions in HIV-positive patients appear to be similar to those seen in NUP in HIV-negative patients but frequently result in complications that are extremely rare in non-AIDS patients. These complications consist of large areas of soft tissue necrosis with exposure of bone and sequestration of bone fragments, which sometimes extend to the vestibular area and/or the palate and become necrotizing stomatitis.

Progression

Bone loss associated with HIV-positive NUP may be extremely rapid. Winkler and colleagues[40] mention cases in which 10 mm of bone were lost in 3 months.

Etiology

AIDS favors the occurrence of opportunistic infections leading to NUG, atypical gingivitis (an aggressive form of chronic periodontitis), and NUP Murray and co-workers" have reported that cases of NUP in AIDS patients demonstrate greater numbers of the opportunistic fungus *Candida albicans* and higher prevalence of *Actinobacillus actinomycetemcomitans, Prevotella intermedia, Porphyromonas gingivalis, Fusobacterium nucleatum,* and *Campylobacter spp.* They also observed that the destructive periodontal lesions seen in AIDS patients differ substantially from NUG lesions; particularly noteworthy is the low or variable level of spirochetes, which is inconsistent with the NUG flora. The flora found in NUP in AIDS patients is more in line with that of chronic periodontitis.

For a more detailed description of these diseases, see Chapters 15 and 19; treatment is discussed in Chapters 39 and 45.

REFRACTORY PERIODONTITIS

Refractory periodontitis has been defined by the American Academy of Periodontology as "those patients who are unresponsive to any treatment provided, whatever the thoroughness or frequency." Refractory periodontitis should be distinguished from recurrent disease, in which a complete remission occurs after therapy, followed by recurrence of the disease as a result of reformation of plaque, and calculus. To classify cases as refractory (unresponsive), the clinician must clearly differentiate them from incompletely treated cases. In such patients the irritants may not have been completely removed, and the disease may temporarily have become less severe but never completely resolved.

Because of the lack of clear guidelines and parameters for the diagnosis and classification of patients as having refractory periodontitis, two different opinions have been expressed in the literature:

1. Refractory periodontitis is a distinct entity, different from other types of periodontitis.[6-10] Refractory peri-

odontitis results from different bacterial agents, specific alterations of the host response, or a combination of these factors. According to this view, multiple categories or subtypes of refractory patients may exist. Until more information is known, these patients should be grouped together into the default designation of refractory periodontitis.

2. Refractory periodontitis is not a distinct entity, **and all cases of refractory periodontitis can fall** into some of the other categories of periodontitis.[1] Refractory cases are most often seen during the management of aggressive forms of periodontitis, periodontitis as a manifestation of a systemic disease that cannot be resolved, and chronic periodontitis exacerbated by smoking or uncontrolled systemic conditions such as diabetes and AIDS

The incorporation of refractory periodontitis into the classification of periodontal diseases may have been a reflection of our ignorance with respect to the factors that result in unresponsiveness to therapy. As a result, the term *refractory periodontitis* has been removed as a single disease entity (see Chapter 4), even though it is appreciated that any of the forms of periodontitis may be unresponsive to conventional therapy due to inadequate or inappropriate therapy or to factors as yet undefined.

Clinical Features

Pretreatment clinical findings and severity are not diagnostic of refractory periodontitis. After the initial treatment, Magnusson et al reported no difference in the amount of plaque in sites that were gaining or losing attachment, but losing sites had persistent bleeding on probing and suppuration.[a3]

Deterioration in cases of refractory periodontitis occurs either by new involvement of additional teeth or by increased bone and attachment loss in previously treated areas.

Etiology

Refractory periodontitis may be due to an abnormal host response, an unusually pathogenic and virulent microflora, failure to eliminate plaque-retentive factors, or a combination of any of these factors. Plaque accumulation and smoking have been consistently associated with the lack of clinical responsiveness.

A high proportion of A. actinomy etemcomitans[11] and P. *intermedia* has been reported in refractory periodontitis cases.[32] Rodenburg et al noted that the total number of bacteria in the pockets of refractory patients was lower than that in untreated patients, but A. actinomycetemcomitans comprised a larger proportion of the subgingival microflora than in untreated patients.[32] This has been explained (1) by the assumption that A. actinomycetemcomitans is more difficult to eradicate from the subgingival area than are other bacteria because of its invasive capability and (2) by reinfection from other sites of the mouth.[31]

Slots and Rams[35] have noted the following microorganisms and their incidence in refractory chronic periodontitis: *F.* nucleatum (75% of patients/sites), P. intermedia (40%), A. actinomycetemcomitans (30%), Peptostreptococcus micros (30%), Staphylococcus sp. (30%), *Bacteroides* forsythus (25%), Campylobacter rectus (25%), P. gingivalis (15%), *Candida* sp. (15%), and Enterobacteriaceae or *Pseudomonadacea* spp. (10%).

Haffajee et all' identified three major microbial complexes in patients with refractory periodontitis: (1) *B.* forsythus, E nucleatum, and C. rectus; (2) Streptococcus in*termedius, B.* gingivalis, and *Peptostreptococcus* micros; and (3) S. *intermedius* and *F.* nucleatum.

Walker et all' have indicated that at least two patterns or rates of attachment loss may be associated with refractory periodontitis; each pattern may be indicative of a different flora. The pattern associated with a relatively rapid loss of attachment was characterized by a gram-negative flora that contained spirochetes, P. *intermedia,* and *Fusobacterium* species. A slow, continuous rate was associated with a predominantly gram-negative flora containing a high proportion of S. *intermedius* or *S. inter*medius-like organisms. However, Colombo et all reported that elevated levels of Streptococcus constellatus was more related to refractory disease in test subjects compared to control subjects with similar levels of the known putative periodontopathogens found in each group. This shows the wide variation in microbial species known to be related to refractory disease. Thus refractory periodontal disease may not be related to the **persistence of microbial species** alone.

MacFarlane et al[22] have described impaired PMN phagocytosis in cases of refractory periodontitis and reduction of PMN chemotaxis. They also found a high percentage of smokers in the group of refractory cases. Hernichel-Gorbach et ales have evaluated the host responses of patients with generalized refractory periodontitis and reported that a majority of these patients may have some alteration in the mononuclear cell-cytokine system.

Frequency

Cases of refractory periodontitis may be similar to cases identified by Hirschfeld and Wasserman[16] as "extreme downhill," which constituted 4.2% of the 600 patients studied and followed for 22 years. In McFall's study of 100 patients followed for 19 years, 8% were identified as "extreme downhill."[26]

PERIODONTITIS AS A MANIFESTATION OF SYSTEMIC DISEASES

Many systemic conditions associated with or predisposing to periodontal attachment loss have defective numbers of neutrophils or defective neutrophil function as a common finding. This underscores the importance of the neutrophil in the protection of the periodontium against infection. Severe periodontitis has been observed in individuals with primary neutrophil disorders including agranulocytosis, neutropenia, Chediak-Higashi syndrome, and lazy leukocyte syndrome. In addition, more frequent and severe periodontitis has been observed in

Fig. 27-2 Dentition of a 17-year-old boy with Papillon-Lefevre syndrome. The missing teeth were exfoliated.

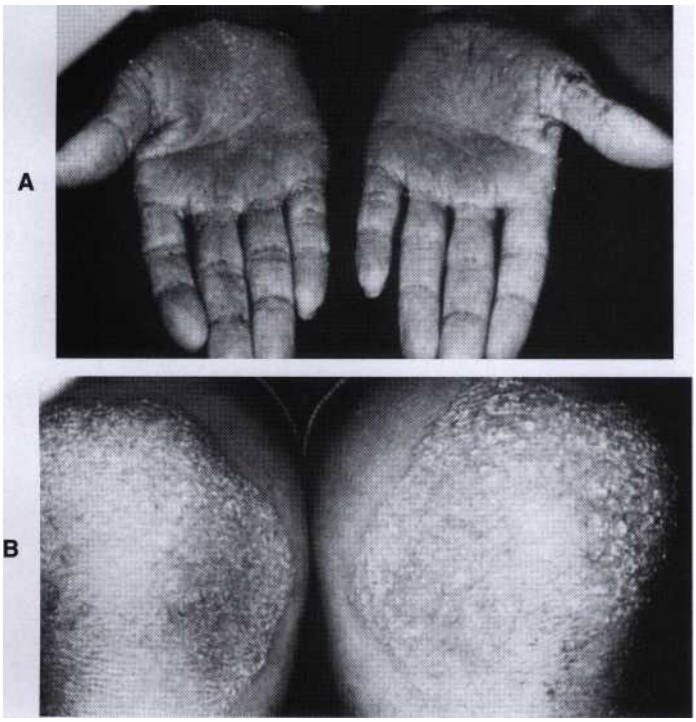

Fig. 27-3 Palms (A) and knees (B) of the patient in Fig. 27-1. Note the hyperkeratotic scaly lesions.

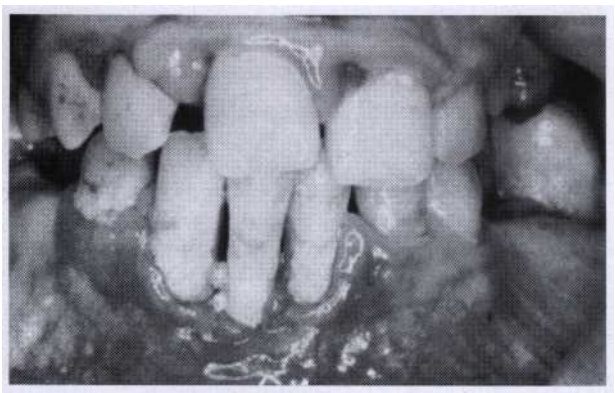

Fig. 27-4 A 14-year-old patient with Down syndrome and severe periodontal destruction.

individuals who exhibit secondary neutrophil impairment as seen in Down syndrome, Papillon-Lefevre syndrome, and inflammatory bowel disease. The remainder of this chapter discusses some of these entities.

Papillon-Lefevre Syndrome

Papillon-Lefevre syndrome is characterized by hyperkeratotic skin lesions, severe destruction of the periodontium, **and in some cases, calcification of the dura.**[4,12] The cutaneous and periodontal changes usually appear together before the age of 4 years. The skin lesions consist of hyperkeratosis and ichthyosis of localized areas on palms, soles, knees, and elbows (Figs. 27-2 and 27-3).

Periodontal involvement consists of early inflammatory changes that lead to bone loss and exfoliation of teeth. Primary teeth are lost by 5 or 6 years of age. The permanent dentition then erupts normally, but within a few years the permanent teeth are lost owing to destructive periodontal disease. By the age of 15 years, patients are usually edentulous except for the third molars. These also are lost a few years after they erupt. Tooth extraction sites heal uneventfully.[13] The microscopic changes reported include marked chronic inflammation of the lateral wall of the pocket with a predominantly plasma cell infiltrate, considerable osteoclastic activity and apparent lack of osteoblastic activity, and an extremely thin cementum.23 Bacterial flora studies of plaque in a case of Papillon-Lefevre syndrome revealed a similarity to bacterial flora in chronic periodontitis.[21] Spirochete-rich zones in the apical portion of the pockets, as well as spirochete adherence to the cementum and microcolony formation of Mycoplasma spp., have been reported in Papillon-Lefevre syndrome .z0 Gram-negative cocci and rods appear at the apical border of plaque.[37] No significant alterations have been found in peripheral blood lymphocytes and polymorphonuclear neutrophils (PMNs).[33]

Papillon-Lefevre syndrome is inherited and appears to follow an autosomal recessive pattern. Parents are not affected, and both must carry the autosomal genes for the syndrome to appear in the offspring. It may occur in siblings; males and females are equally affected. The estimated frequency is 1 to 4 cases per 1 million individuals. Rare cases of adult onset of this syndrome, albeit with mild periodontal lesions, have also been described .[3]

Down Syndrome

Down syndrome (mongolism, trisomy 21) is a congenital disease caused by a chromosomal abnormality and characterized by mental deficiency and growth retardation. The prevalence of periodontal disease in Down syndrome is high (occurring in almost 100% of patients younger than 30 years). Although plaque, calculus, and local irritants (e.g., diastemata, crowding of teeth, high frenum attachments, and malocclusion) are present and oral hygiene is poor, the severity of periodontal destruction exceeds that explainable by local factors alone.5,7,36

Periodontal disease in Down syndrome is characterized by formation of deep periodontal pockets associated with substantial plaque accumulation and moderate gingivitis (Fig. 27-4). These findings are usually generalized,

although they tend to be more severe in the lower anterior region; marked recession is also sometimes seen in this region, apparently associated with high frenum attachment. The disease progresses rapidly. Acute necrotizing lesions are a frequent finding.

Two factors have been proposed to explain the high prevalence and increased severity of periodontal destruction associated with Down syndrome: a reduced resistance to infections because of poor circulation, especially in areas of terminal vascularization such as the gingival tissue,[9,10] and a defect in T-cell maturation and polymorphonuclear leukocyte chemotaxis.[17] Increased numbers of P. *interrnedia* have been reported in the mouths of children with Down syndrome.[19]

Neutropenia

Destructive generalized periodontal lesions have been described in children with neutropenia. For further information, see Chapter 14.

Chediak-Higashi Syndrome

Chediak-Higashi syndrome is rare and is characterized by recurrent bacterial infections including rapidly destructive periodontitis. It is discussed in Chapters 10 and 14.

Hypophosphatasia

Hypophosphatasia is a rare familial skeletal disease characterized by rickets, poor cranial bone formation, craneostenosis, and premature loss of primary teeth, particularly the incisors. Patients have a low level of serum alkaline phosphatase, and phosphoethanolamine is present in serum and urine.

Teeth are lost with no clinical evidence of gingival inflammation and show reduced cementum formation.' In patients with minimal bone abnormalities, premature loss of deciduous teeth may be the only symptom of hypophosphatasia. In adolescents, this disease resembles localized *juvenile periodontitis.*[41]

Leukocyte Adhesion Deficiency

Cases of leukocyte adhesion deficiency (LAD) are rare and begin during or immediately after eruption of the primary teeth. Extremely acute inflammation and proliferation of the gingival tissues with rapid destruction of bone are found. Profound defects in peripheral blood neutrophils and monocytes and an absence of neutrophils in the gingival tissues have been noted in patients with LAD[28,29]; these patients also have frequent respiratory tract infections and sometimes otitis media. All primary teeth are affected, but the permanent dentition may not be affected.[29]

- **Immunologic Factors**
- **Genetic Factors**
- **Environmental Factors**

Aggressive periodontitis generally affects systemically healthy individuals less than 30 years old, although patients may be older. Aggressive periodontitis may be universally distinguished from chronic periodontitis by the age of onset, the rapid rate of disease progression, the nature and composition of the associated subgingival microflora, alterations in the host's immune response, and a familial aggregation of diseased individuals.[18] In addition, a strong racial influence is observed in the United States; the disease is more prevalent among African-Americans." Aggressive periodontitis describes three of the diseases formerly classified as early onset periodontitis. Localized aggressive periodontitis was formerly classified as localized juvenile periodontitis (LJP). Generalized aggressive periodontitis encompasses the diseases previously classified as generalized juvenile periodontitis (GJP) and rapidly progressive periodontitis (RPP) (see Chapter 4).

LOCALIZED AGGRESSIVE PERIODONTITIS

Historical Background

In 1923, Gottlieb" reported a patient with a fatal case of epidemic influenza and a disease that he called *diffuse atrophy of the alveolar bone.* This disease was characterized by a loss of collagen fibers in the periodontal ligament and their replacement by loose connective tissue and extensive bone resorption, resulting in a widened periodontal ligament space. The gingiva apparently was not involved. In 1928, Gottlieb" attributed this condition to the inhibition of continuous cementum formation, which he considered essential for maintenance of the periodontal ligament fibers. He then termed the disease *deep cementopathia.* Gottlieb hypothesized that deep cementopathia was a "disease of eruption" and that cementum initiated a foreign body response. As a result, it was postulated that the host attempted to exfoliate the tooth, resulting in the observed bone resorption and pocket formation.[14]

In 1938, Wannenmacher[49] described incisor-first molar involvement and called the disease *parodontitis marginalis progressiva.* Several explanations evolved for the etiology and pathogenesis of this type of disease. Many individuals considered this to be a degenerative, noninflammatory disease process[12,34,45] and therefore gave it the name *periodontosis.* Other investigators denied the existence of a degenerative type of periodontal disease and attributed the changes observed to trauma from occlusion.[6] Ultimately, in 1966 the World Workshop in Periodontics[38] concluded that the concept of periodontosis as a degenerative entity was unsubstantiated and that

the term should be eliminated from periodontal nomenclature. The committee did recognize that a clinical entity different from adult periodontitis might occur among adolescents and young adults.

The term *juvenile periodontitis* was introduced by Chaput and colleagues in 1967 and by Butler' in 1969. In 1971, Baer' defined it as "a disease of the periodontium occurring in an otherwise healthy adolescent which is characterized by a rapid loss of alveolar bone about more than one tooth of the permanent dentition. The amount of destruction manifested is not commensurate with the amount of local irritants." In 1989 the World Workshop in Clinical Periodontics[8] categorized this disease as localized juvenile periodontitis (LJP), a subset of the broad classification of early onset periodontitis (EOP). Under this classification system, age of onset and distribution of lesions were of primary importance when making a diagnosis of LJP Most recently, disease with the characteristics of LJP has been renamed *localized aggressive periodontitis.*

Clinical Characteristics

Localized aggressive periodontitis usually has an age of onset around puberty.[22] Clinically, it is characterized as having "localized first molar/incisor presentation with interproximal attachment loss on at least two permanent teeth, one of which is a first molar, and involving no more than two teeth other than first molars and incisors" (Color Fig. 28-1, A-D). The localized distribution of lesions in localized aggressive periodontitis is characteristic but as yet unexplained. The following possible reasons for the limitation of periodontal destruction to certain teeth have been suggested:

1. After initial colonization of the first permanent teeth to erupt (the first molars and incisors), *Actinobacillus actinomycetemcomitans* evades the host defenses by different mechanisms, including production of polymorphonuclear leukocyte chemotaxis-inhibiting factors, endotoxin, collagenases, leukotoxin, and other factors that allow the bacteria to colonize the pocket and initiate the destruction of the periodontal tissues. After this initial attack, adequate immune defenses are stimulated to produce opsonic antibodies to enhance the clearance and phagocytosis of invading bacteria and neutralize leukotoxic activity. In this manner, colonization of other sites may be prevented.[51] A strong antibody response to infecting agents is one characteristic of localized aggressive periodontitis.[22]
2. Bacteria antagonistic to *A. actinomycetemcomitans* may colonize the periodontal tissues and inhibit *A. actinomycetemcomitans* from further colonization of periodontal sites in the mouth. This would localize *A. actinomycetemcomitans* infection and tissue destruction."
3. *A. actinomycetemcomitans* may lose its leukotoxin-producing ability for unknown reasons." If this happens, the progression of the disease may become arrested or retarded and colonization of new periodontal sites averted.
4. The possibility that a defect in cementum formation may be responsible for the localization of the lesions has been suggested .[25,35] Root surfaces of teeth extracted from patients with localized aggressive periodontitis have been found to have hypoplastic or aplastic cementum. This was true not only of root surfaces exposed to periodontal pockets but also of roots still surrounded by their periodontium.

A striking feature of localized aggressive periodontitis is the lack of clinical inflammation despite the presence of deep periodontal pockets (see Color Fig. 28-1, E and F). Furthermore, in many cases the amount of plaque on the affected teeth is minimal, which seems inconsistent with the amount of periodontal destruction present .[22] The plaque that is present forms a thin biofilm on the teeth and rarely mineralizes to form calculus." Although the quantity of plaque may be limited, it often contains elevated levels of *A. actinomycetemcomitans,* and in some patients, *Porphyromonas gingivalis.* The potential significance of the qualitative composition of the microbial flora in localized aggressive periodontitis is discussed later in this chapter (Risk Factors for Aggressive Periodontitis: Microbiologic Factors).

As the name suggests, localized aggressive periodontitis progresses rapidly. Evidence suggests that the rate of bone loss is about three to four times faster than in chronic periodontitis.[2] Other clinical features of localized aggressive periodontitis may include distolabial migration of the maxillary incisors with concomitant diastema formation (see Color Fig. 28-1, B), increasing mobility of the first molars, sensitivity of denuded root surfaces to thermal and tactile stimuli, and deep, dull, radiating pain during mastication, probably because of irritation of the supporting structures by mobile teeth and impacted food. Periodontal abscesses may form at this stage, and regional lymph node enlargement may occur.[30]

It should be noted that not all cases of localized aggressive periodontitis progress to the degree described previously. In some patients, the progression of attachment loss and bone loss may be self-arresting.[22]

Radiographic Findings

Vertical loss of alveolar bone around the first molars and incisors, beginning around puberty in otherwise healthy teenagers, is a classic diagnostic sign of localized aggressive periodontitis. Radiographic findings may include an "arc-shaped loss of alveolar bone extending from the distal surface of the second premolar to the mesial surface of the second molar"" (see Color Fig. 28-1, D).

Prevalence and Distribution by Age and Sex

The prevalence of localized aggressive periodontitis in geographically diverse adolescent populations is estimated to be below 1%. Most reports suggest a low prevalence, about 0.2%.[27] Two independent radiographic studies of 16-year-old adolescents, one in Finland" and the other in Switzerland,[21] followed the strict diagnostic criteria delineated by Baer[2] and reported a prevalence rate of 0.1%. A clinical and radiographic study of 7266 English adolescents *15* to 19 years old also showed a prevalence rate of 0.1%.'0 In the U.S., a national survey of adolescents age 14 to 17 reported that *0.53%* had localized aggressive periodontitis.[27] Blacks were at much higher risk for localized aggressive periodontitis, and

black males were 2.9 times more likely to have the disease than black females. In contrast, white females were more likely to have localized aggressive periodontitis than white males. Several other studies have found the highest prevalence of localized aggressive periodontitis among black males,[5,32,40] followed in descending order by black females, white females, and white males.[32]

Localized aggressive periodontitis affects both males and females and is seen most frequently in the period between puberty and 20 years of age. Some studies have suggested a predilection for female patients, particularly in the youngest age groups,[20] whereas others report no male-female differences in incidence when studies are designed to correct for ascertainment bias." (For **additional epidemiologic data on localized aggressive periodontitis, see Chapter 5.)**

GENERALIZED AGGRESSIVE PERIODONTITIS

Clinical Characteristics

Generalized aggressive periodontitis usually affects individuals under the age of 30, but older patients also may be affected.[22] In contrast to localized aggressive periodontitis, evidence suggests that individuals affected with generalized aggressive periodontitis produce a poor antibody response to the pathogens present. Clinically, generalized aggressive periodontitis is characterized by "generalized interproximal attachment loss affecting at least three permanent teeth other than first molars and incisors" (Figs. 28-1, A and *B,* and 28-2, A and B). The destruction appears to occur episodically with periods of advanced destruction followed by stages of quiescence of variable length (weeks to months or years). Radiographs often show bone loss that has progressed since the previous evaluation (see Fig. 28-2, *B* and C).

As seen in localized aggressive periodontitis, patients with generalized aggressive periodontitis often have small amounts of bacterial plaque associated with the affected teeth.[22] Quantitatively, the amount of plaque seems inconsistent with the amount of periodontal destruction. Qualitatively, *P. gingivalis,* A. *actinomycetemcomitans,* and *Bacteriodes* forsythus frequently are detected in the plaque that is present.[46]

Two gingival tissue responses can be found in cases of generalized aggressive periodontitis. One is a severe, acutely inflamed tissue, often proliferating, ulcerated, and fiery red (see Fig. 28-1, A). Bleeding may occur spontaneously or with slight stimulation. Suppuration may be an important feature. This tissue response is considered to occur in the destructive stage, in which attachment and bone are actively lost. In other cases, the gingival tissues may appear pink, free of inflammation, and occasionally with some degree of stippling, although the last feature may be absent (see Fig. 28-2, A). However, despite the apparently mild clinical appearance, deep pockets can be demonstrated by probing. This tissue response has been considered by Page and Schroeder" to coincide with periods of quiescence in which the bone level remains stationary. Some patients with generalized aggressive periodontitis may have systemic manifestations such as weight loss, mental depression, and general malaise.[36] Patients with a presumptive diagnosis of generalized aggressive periodontitis must have their medical histories updated and reviewed. These patients should receive medical evaluations to rule out possible systemic involvement. As seen with localized aggressive periodontitis, cases of generalized aggressive periodontitis may be arrested spontaneously or after therapy, whereas others may continue to progress inexorably to tooth loss despite intervention with conventional treatment.

Radiographic Findings

The radiographic picture in generalized aggressive periodontitis can range from severe bone loss associated with the minimal number of teeth, as described previously, to advanced bone loss affecting the majority of teeth in the dentition (see Fig. 28-1, B). A comparison of radiographs taken at different times illustrates the aggressive nature of this disease (see Fig. 28-2, *B* and C). Page and co-workers[36] described sites in generalized aggressive periodontitis (formerly RPP) patients that demonstrated osseous destruction of 25% to 60% during a 9-week period. **Despite this extreme loss, other sites in the same patient** showed no bone loss.

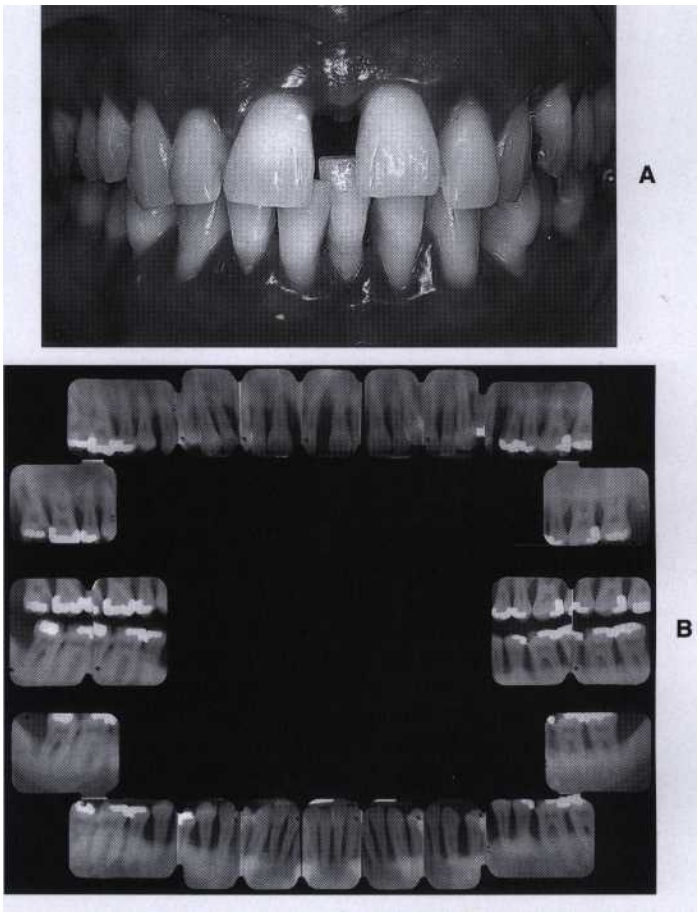

Fig. 28-1 A, Generalized aggressive periodontitis in a 30-year-old white patient. Note the generalized discoloration and smooth surface of the gingival tissues. B, Radiographs of this same patient, showing advanced generalized bone loss. (Courtesy Dr. Philip Melnick, Los Angeles, Calif.)

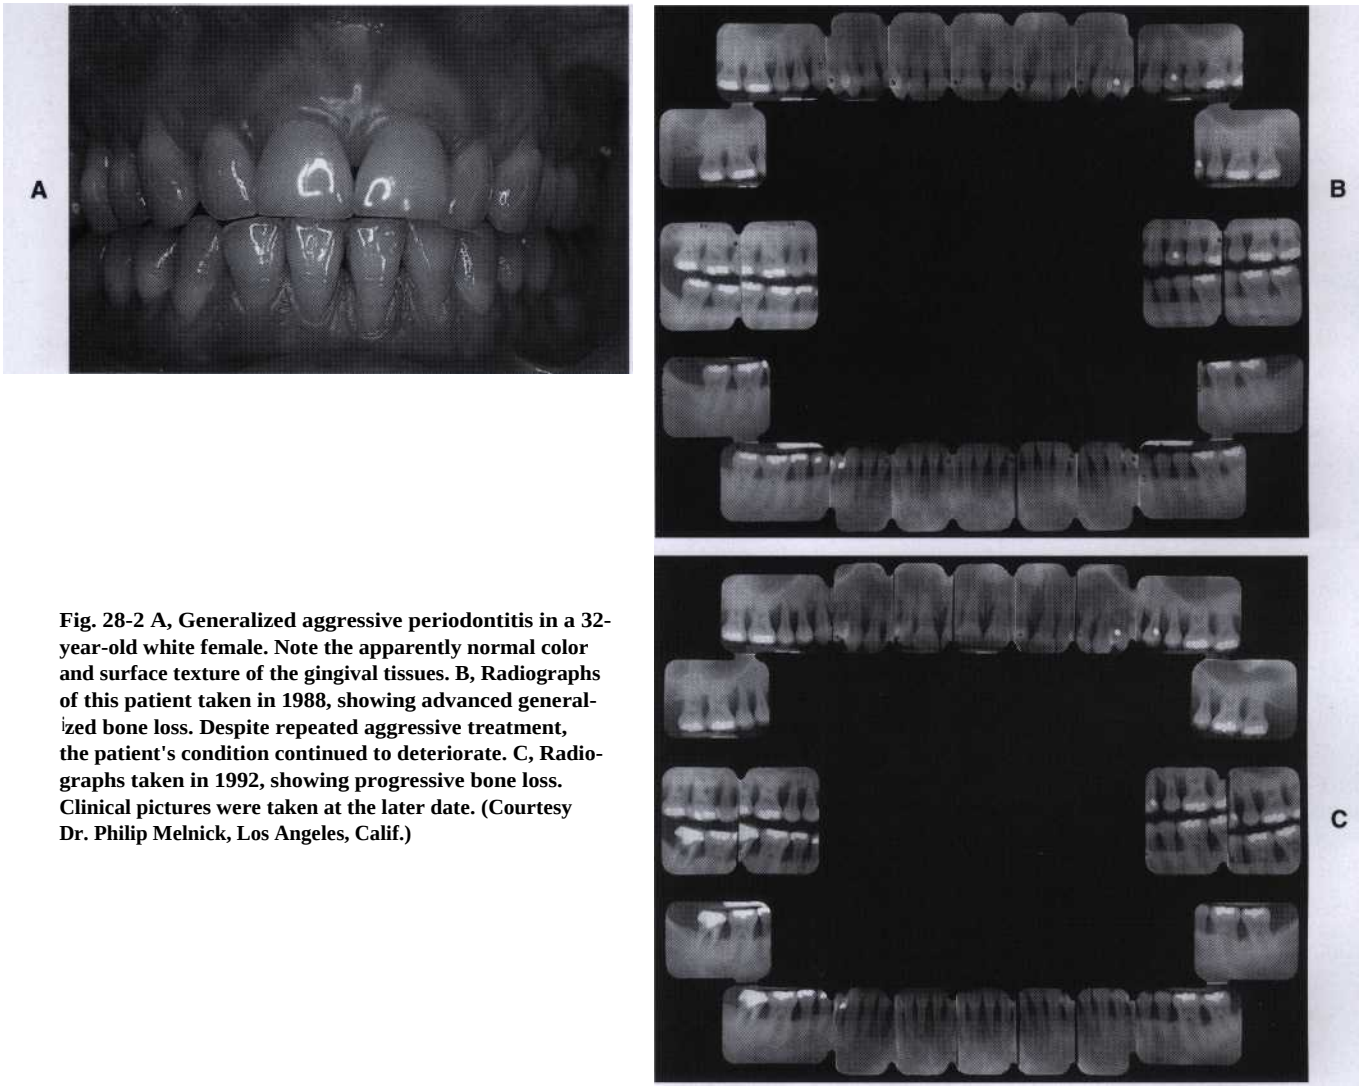

Fig. 28-2 A, Generalized aggressive periodontitis in a 32-year-old white female. Note the apparently normal color and surface texture of the gingival tissues. B, Radiographs of this patient taken in 1988, showing advanced generalized bone loss. Despite repeated aggressive treatment, the patient's condition continued to deteriorate. C, Radiographs taken in 1992, showing progressive bone loss. Clinical pictures were taken at the later date. (Courtesy Dr. Philip Melnick, Los Angeles, Calif.)

Prevalence and Distribution by Age and Sex

In a study of untreated periodontal disease conducted in Sri Lanka by Loe and colleagues,36 8% of the population had rapid progression of periodontal disease characterized by a yearly loss of attachment of 0.1 to 1.0 mm. In the U.S., a national survey of adolescents aged 14 to 17 reported that 0.13% had generalized aggressive periodontitis.27 In addition, blacks were at much higher risk than whites for all forms of aggressive periodontitis and males were more likely to have generalized aggressive periodontitis than females. (For additional epidemiologic data on aggressive periodontitis, see Chapter 5.)

RISK FACTORS FOR AGGRESSIVE PERIODONTITIS

Microbiologic Factors

Although several specific microorganisms frequently are detected in patients with localized aggressive periodontitis (*A. actinomycetemcomitans, Capnocytophaga sp., Eikenella corrodens, Prevotella intertnedia,* and *Campylobacter rectus), A. actinomycetemcomitans* has been implicated as the primary pathogen associated with this disease. As summarized by Tonetti and Mombelli,46 this link is based on the following evidence: (1) *A. actinomycetemcomitans is* found in high frequency (approximately 90%) in lesions characteristic of localized aggressive periodontitis, (2) sites with evidence of disease progression often show elevated levels of *A. actinomycetemcomitans, (3)* many patients with the clinical manifestations of localized aggressive periodontitis have significantly elevated serum antibody titers to *A. actinomycetemcomitans, (4)* clinical studies show a correlation between reduction in the subgingival load of *A. actinomycetemcomitans* during treatment and a successful clinical response, and (5) *A. actinomycetemcomitans* produces a number of virulence factors that may contribute to the disease process (see also Chapter 6).

It should be noted that not all reports support the association of *A. actinomycetemcomitans* and localized aggressive periodontitis. In some studies, *A. actinomycetemcomitans* either could not be detected in patients with this form of disease or could not be detected at the previously reported frequencies. Another study found elevated levels of P. *gingivalis, P. intennedia, Fusobacterium nucleatum, C. rectus,* and *Treponema denticola* in patients with either

localized or generalized aggressive disease, but no significant association was found between the presence of aggressive disease and A. *actinomycetemcomitans.* In addition, A. *actinomycetemcomitans* often can be detected in periodontally healthy subjects, suggesting that this microorganism may be part of the normal flora in many individuals.

Electron microscopic studies of localized aggressive periodontitis have revealed bacterial invasion of connective tissue[9,11] that reaches the bone surface.' The invading flora has been described as morphologically mixed but composed mainly of gram-negative bacteria, including cocci, rods, filaments, and spirochetes.11 Using different methods, including immunocytochemistry and electromicroscopy, several tissue-invading microorganisms have been identified as A. *actinomycetemcomitans, Capnocytophaga sputigena, Mycoplasma spp.,* and spirochetes.[39]

Immunologic Factors

Some immune defects have been implicated in the pathogenesis of aggressive periodontitis. The human leukocyte antigens (HLA), which regulate immune responses, have been evaluated as candidate markers for aggressive periodontitis. Although the findings with many HLA antigens have been inconsistent, HLA-A9 and B15 antigens are consistently associated with aggressive periodontitis (see Chapter 10).

Several investigators[10,23,24] have shown that patients with aggressive periodontitis display functional defects of polymorphonuclear leukocytes (PMNs), monocytes, or both. These defects can impair either the chemotactic attraction of PMN to the site of infection or their ability to phagocytose and kill microorganisms. Current studies have also demonstrated a hyperresponsiveness of monocytes from localized aggressive periodontitis patients with respect to their production of PGE_2 in response to lipopolysaccharide (LPS).[43] This hyperresponsive phenotype could lead to increased connective tissue or bone loss due to excessive production of these catabolic factors. Additionally, poorly functional inherited forms of monocyte FcγRII, the receptor for human IgG2 antibodies, have been shown to be disproportionately present in patients with localized aggressive periodontitis.50 These PMN and monocyte defects may be induced by the bacterial infection or may be genetic in origin. Further studies are needed to characterize the origin of these cellular alterations.

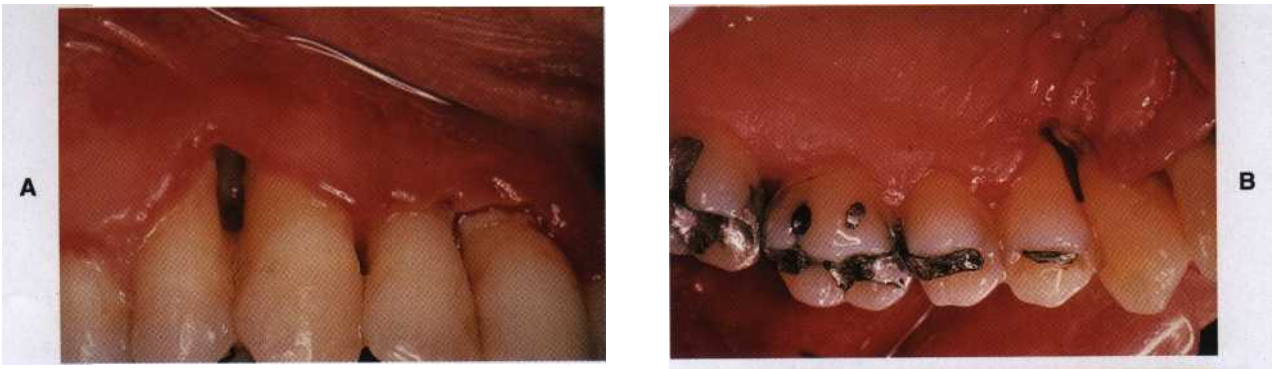
Autoimmunity has been considered to have a role in generalized aggressive periodontitis according to Anusaksathien and Dolby,' who found host antibodies to collagen, DNA, and immunoglobulin G (IgG). Possible immune mechanisms include an increase in the expression of type II major histocompatibility complex (MHC) molecules, HLA DR4[3], altered helper or suppressor T-cell function, polyclonal activation of B cells by microbial plaque, and genetic predisposition. (For additional information on the immunology of aggressive periodontitis, see Part Three.)

Genetic Factors

Results from **several studies support the concept that all individuals are** not equally susceptible to aggressive periodontitis.[46] Specifically, several authors have described a familial pattern of alveolar bone loss and have implicated genetic factors in aggressive periodontitis.[4,28,29,31] Currently, specific genes have not been identified that are responsible for these diseases. However, segregational analyses and linkage analyses of families with a genetic predisposition for localized aggressive periodontitis suggest that a major gene plays a role in this disease, which is transmitted through an autosomal dominant mode of inheritance in U.S. populations31 (see Chapter 10). It should be noted that most of the segregational studies were conducted in African-American populations and therefore other modes of inheritance may exist in different populations.

Evidence suggests that some immunologic defects associated with aggressive periodontitis may be inherited. For example, Van Dyke et a1.[4]' reported a familial clustering of the neutrophil abnormalities seen in localized aggressive periodontitis. This clustering suggests that the defect(s) may be inherited.46 Studies also have demonstrated that the antibody response to periodontal pathogens, particularly A. *actinomycetemcomitans, is* under genetic control and that the ability to mount high titers of specific, protective antibody (primarily IgG2) against A. *actinomycetemcomitans* may be race dependent.15

In summary, data support the idea that a gene of major effect exists for aggressive periodontitis. Data also support a genetic basis for some of the immunologic defects seen in patients with aggressive periodontitis. However, it is unlikely that all patients affected with aggressive periodontitis have the same genetic defect. As summarized by Tonetti and Mombelli,[46] "It seems that specific genes may be different in various populations and/or ethnic groups and therefore true heterogeneity in disease susceptibility may be present. The role of specific genes remains to be elucidated." (For additional information on genetic factors, see Chapter 10.)



Environmental Factors

The amount and duration of smoking are important variables that can influence the extent of destruction seen in young adults .[46] Patients with generalized aggressive periodontitis who smoke have more affected teeth and more loss of clinical attachment than nonsmoking patients with generalized aggressive periodontitis.[16] However, smoking may not have the same impact on attachment levels in younger patients with localized aggressive periodontitis.[42] (For additional information on smoking and periodontal disease, see Chapter 14.)

Acquired immunodeficiency syndrome (AIDS) is characterized by profound impairment of the immune system. The condition was first reported in 1981, and a viral pathogen, the human immunodeficiency virus (HIV), was identified in 1984. [111]

HIV has a strong affinity for cells of the immune system, most specifically those that carry the CD4 cell surface receptor molecule. Thus helper T lymphocytes are most profoundly affected, but monocytes, macrophages, Langerhans cells, and some neuronal and glial brain cells may also be involved.[27] Viral replication occurs continuously in the lymphoreticular tissues of lymph nodes, spleen, gut-associated lymphoid cells, and macrophages.[141] In recent years, combined therapeutic regimens consisting of antiretroviral agents and protease-inhibiting drugs have resulted in marked improvement in the health status of HIV-infected individuals and occasionally a reduction in viral plasma bioloads below detectable levels, although the infection is still transmissible.[31,50,55,146] Current evidence indicates that the virus is never completely eradicated; rather, it is sequestered at low levels in resting CD4 cells even in individuals with no detectable plasma virus.[15,30] These findings suggest that effective combination drug therapy may be necessary for the lifetime of infected individuals. Long-term control of the infection may be difficult because the antiviral agents currently used have many adverse side effects and readily develop drug-resistant varient strains.[141] In untreated or inadequately treated HIV infection, the overall effect is to gradually impair the immune system by interference with helper T lymphocytes and other immune cell functions.[142]

B lymphocytes are not infected, but the altered function of infected T lymphocytes secondarily results in B-cell dysregulation and altered neutrophil function.[76] This may place the HIV-positive individual at increased risk for malignancy and disseminated infections with microorganisms such as viruses, mycobacterioses, and mycoses.[49,100,106,117] HIV-positive individuals are also at increased risk for adverse drug reactions owing to altered antigenic regulation.

HIV has been detected in most body fluids, although it is found in high quantities only in blood, semen, and cerebrospinal fluid. Transmission occurs almost exclusively by sexual contact, illicit use of injectable drugs, or exposure to blood or blood products. Transmission following a human bite has been reported, although the risk is extremely low.'"

BOX 29-1

1993 CDC AIDS Surveillance Case Definition Conditions

- Candidiasis of bronchi, trachea, or lungs
- Candidiasis, esophageal
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 month's duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes)
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy, HIV-related
- Herpes simplex: chronic ulcer(s) (>1 month's duration) or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (1 month's duration)
- Kaposi's sarcoma
- Lymphoma, Burkitt's (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium* complex or *Mycobacterium kansasii,* disseminated or extrapulmonary
- *Mycobacterium tuberculosis,* any site (pulmonary or extrapulmonary)
- *Mycobacterium,* other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis carinii* pneumonia
- Pneumonia, recurrent
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome owing to HIV

From Centers for Disease Control: 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR 1993; 41:RR-17.

The high-risk population includes homosexual and bisexual men; users of illegal, injectable drugs; hemophiliacs or others with coagulation disorders; recipients of blood transfusions before April 1985; infants of HIV-infected mothers (in whom transmission occurs by fetal transmission, at delivery, or by breast feeding); promiscuous heterosexuals, and individuals who engage in unprotected sex with HIV-positive cohorts. Heterosexual transmission is a common cause of AIDS in the world population and is increasing significantly in the United States.[12,91] Transmission is more likely to occur through contact with HIV-infected individuals with a high plasma bioload of the virus .[97,112] HIV transmission has also been reported to occur through organ transplantation and artificial insemination.[14]

EPIDEMIOLOGY AND DEMOGRAPHICS

As of December 31,1998, 688,200 AIDS cases had been reported in the U.S.[12] The increase in numbers of patients with AIDS in the U.S. and other developed countries is due in part to prolonged survival since the advent of multidrug anti-HIV therapy.',[31,54,98,138] The World Health Organization (WHO) estimates that as many as 21 million individuals worldwide are infected with one of the 10 known subtypes of HIV.[127] This number may increase to more than 40 million people early in the 21"century.[101,127]

AIDS affects individuals of all ages, but more than 98% of cases occur among adults and adolescents over the age of 12. The majority of adult victims in the U.S. are men, 54% of whom are homosexuals or bisexuals. Approximately 6% of this group also use illicit injectable drugs. An additional 26% contract the infection exclusively through injectable drug use, and 10% of all patients with AIDS have contracted the infection through heterosexual contact.[12] The majority of women who contract AIDS are those who have sex with intravenous drug users or bisexual males.[12,96] Others were born in countries such as Haiti or one of several high-incidence African nations where heterosexual contact is the major mode of transmission. Only 1% of individuals contracted AIDS from blood products or blood transfusions in the U.S. because of stringent blood bank controls. A disproportionately high number of African-American and Hispanic male homosexuals, male and female heterosexuals, and children suffer from HIV infection. The major risk factor for this disparity appears to be a more frequent history of use of injectable drugs and needle sharing and unprotected sexual activity in these groups.[12,18,76,78,86,88]

Transmission from health care workers to patients has been documented on rare occasions (6 from 1 dentist, 1 from an orthopedic surgeon).[73] Conversely, 94 health care workers have had documented seroconversion following occupational injury, especially from patients with high plasma viral loads. The majority of these incidences involved nurses, and no documented seroconversion has been reported among dental health care workers.[11,60]

CLASSIFICATION AND STAGING

In 1982 the Centers for Disease Control (CDC) developed a surveillance case definition for AIDS based on the presence of opportunistic illnesses or malignancies secondary to defective cell-mediated immunity in HIV-positive individuals.[9] This definition was further expanded in 1985, 1987, and 1993.[10] The 1993 revision added invasive cervical cancer in women, bacillary tuberculosis, and recurrent pneumonia into the AIDS designation. Currently, any of 25 specific clinical conditions found in HIV-positive individuals can establish the diagnosis of AIDS (Box 29-1). The most significant change in the most recent CDC case definition was the inclusion of severe immunodeficiency (CD4-T4 lymphocyte count of less than 200/mm^3 or a T4 lymphocyte percentage of less than 14% of total lymphocytes) as definitive for AIDS. This change was based on recognition that severe immunodeficiency results in increased risk for opportunistic life-threatening conditions. Many HIV-positive individuals have been designated as patients with AIDS due solely to low CD4-T4 cell counts or percentages even in the absence of life-threatening conditions. New combined drug therapy for HIV, however, has resulted in

a rise of CD4 levels, often reaching or exceeding 200/mm3.[51,70] Such individuals are still considered to have AIDS although their CD4 cells may even reach normal levels. These individuals may continue to be susceptible to opportunistic infections although the risk of secondary disease generally is diminished in those who are responsive to AIDS therapy.[23]

A few weeks to a few months after initial exposure, some HIV-infected individuals may experience acute symptoms (e.g., sudden onset of an acute mononucleosis-like illness characterized by malaise, fatigue, fever, myalgia, erythematous cutaneous eruption, oral candidiasis, oral ulcerations, and thrombocytopenia).[32,71,135] This acute phase may last for up to 2 weeks, with seroconversion occurring 3 to 8 weeks later.[72,136] However, antigenic viremia may sometimes be present for an extended period of time before seroconversion occurs.[58,72,86] Some individuals experience asymptomatic HIV infection, whereas others may become asymptomatic after the initial acute infection. In any event, infected individuals eventually become seropositive for HIV antibody, but the mean time from infection until development of AIDS is estimated to be up to 12 or more years.[138]

CDC Surveillance Case Classification

AIDS patients have been grouped as follows, according to the CDC Surveillance Case Classification (1993)[10]:

Category A includes patients with acute symptoms or asymptomatic diseases, along with individuals with persistent generalized lymphadenopathy, with or without malaise, fatigue, or low-grade fever.

Category B patients have symptomatic conditions such as oropharyngeal or vulvovaginal candidiasis; herpes zoster; oral hairy leukoplakia; idiopathic thrombocytopenia; or constitutional symptoms of fever, diarrhea, and weight loss.

Category C patients are those with outright AIDS as manifested by life-threatening conditions identified by CD4+ T lymphocyte levels of less than 200 per cubic millimeter.

These staging categories reflect progressive immunologic dysfunction, but patients do not necessarily progress serially through the three stages, and the predictive value of these categories is not known.

ORAL AND PERIODONTAL MANIFESTATIONS OF HIV INFECTION

Oral lesions are very common in HIV-infected patients, although geographic and environmental variables may exist.* Previous reports indicate that most AIDS patients have head and neck lesions,"' while oral lesions are quite common in HIV positive individuals who do not yet have AIDS.[35,74,83] Several reports have identified a strong correlation between HIV infection and oral candidiasis, oral hairy leukoplakia, atypical periodontal diseases, oral Kaposi's sarcoma, and oral non-Hodgkin's lymphoma.[22,47,77,94,120,133]

*See references 24, 29, 34, 35, 53, 68, 77, 92, 94, 103, and 134.

Oral lesions less strongly associated with HIV infection include melanotic hyperpigmentation, mycobacterial infections, necrotizing ulcerative stomatitis, miscellaneous oral ulcerations, and viral infections (e.g., herpes simplex virus, herpes zoster, condyloma acuminatum). Lesions seen in HIV-infected individuals but of undetermined frequency include less-common viral infections (e.g., cytomegalovirus, molluscum contagiosum); recurrent aphthous stomatitis; and bacillary angiomatosis (epithelioid angiomatosis).[22]

Oral Hairy Leukoplakia

Oral hairy leukoplakia (OHL) primarily occurs in persons with HIV infection.[43,45] Found on the lateral borders of the tongue, it frequently has a bilateral distribution and may extend to the ventrum. This lesion is characterized by an asymptomatic, poorly demarcated keratotic area ranging in size from a few millimeters to several centimeters (Fig. 29-1). Often, characteristic vertical striations, imparting a corrugated appearance, are present, or the surface may be shaggy and may appear "hairy" when dried (Color Fig. 29-1, A). The lesion does not rub off and may resemble other keratotic oral lesions.

Microscopically, the lesion shows a hyperparakeratotic surface with projections that often resemble hairs. Beneath the parakeratotic surface are acanthosis and some characteristic balloon cells resembling koilocytes (Fig. 29-2). It has been demonstrated that these cells contain virus particles of the human herpesvirus group; these particles have been interpreted as the Epstein-Barr virus (EBV).[43,46] Epithelial dysplasia is not a feature, and in most lesions, little or no inflammatory infiltrate in the underlying connective tissue is present.[118]

OHL is found almost exclusively on the lateral borders of the tongue, although it has been reported on the dorsum of the tongue, buccal mucosa, floor of the mouth, retromolar area, and soft palate.[26,43,64] In addition, most of these lesions reveal surface colonization by *Candida* organisms, which are secondary invaders and not the cause of the lesion.

OHL was originally believed to be caused by the human papilloma virus, but subsequent evidence suggests that this condition is associated with EBV.[43,46] In the late 1980s a so-called pseudo-hairy leukoplakia was described in HIV- and EBV-negative individuals who manifested

Fig. 29-1 Hyperkeratotic areas in the lateral border of the tongue in a patient with AIDS.

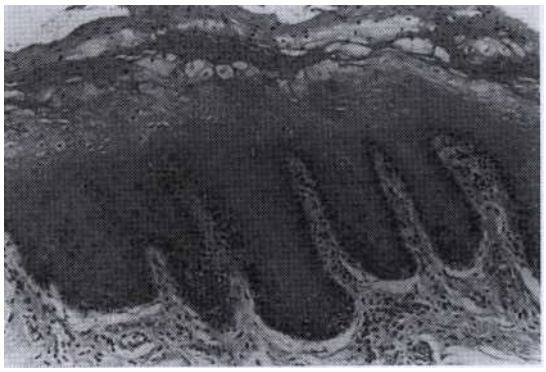

Fig. 29-2 Microscopic view of hairy leukoplakia.

with lesions clinically identical to OHL. In addition, several case reports have described OHL in EBV-infected but HIV-negative individuals suffering from a variety of immunosuppressed conditions (e.g., acute myelogenous leukemia) or who are immunosuppressed as a result of organ transplantation or extensive systemic corticosteroid therapy. 44,129 Regardless, biopsy identification of a lesion suggestive of OHL should dictate that HIV testing be performed.

The differential diagnosis of OHL must consider white lesions of the mucosa, which include dysplasia, carcinoma, frictional and idiopathic keratosis, lichen planus, tobacco-related leukoplakia, psoriasiform lesions (e.g., geographic tongue), and hyperplastic candidiasis. The microscopic confirmation of OHL of the tongue in a high-risk patient is considered to be a specific early sign of HIV infection and a strong indicator that the patient will develop AIDS.'-' However, earlier diagnosis and treatment of HIV infection appears to have resulted in a marked reduction in occurrence of OHL, although incidence studies have not been performed. Prior to the advent of effective therapy for HIV, survival analysis indicated that 83% of HIV-infected patients with hairy leukoplakia would develop AIDS within 31 months, 44 and the number of patients with hairy leukoplakia who eventually developed AIDS approached 100%. 47

It should be emphasized that the severity of the lesion is not correlated with the likelihood of developing AIDS. Thus small lesions are as diagnostically significant as extensive lesions.' 18

Oral Candidiasis

Candida, a fungus found in normal oral flora, proliferates on the surface of the oral mucosa under certain conditions. A major factor associated with overgrowth of *Candida is* diminished host resistance, as seen in debilitated patients or in patients receiving immunosuppressive therapy. The incidence of candidal infection has been demonstrated to progressively increase in relationship to diminishing immune competency. 1,28,59,80,81 Most oral candidal infections (85% to 95%) are associated with *Candida albicans,* but other species of *Candida* may be involved. 53 Currently, at least 11 strains of *Candida* have been identified, and non-C. *albicans* infections are more common among immunocompromised individuals already receiving antifungal therapy for C. *albicans.* 4,119

Candidiasis is the most common oral lesion in HIV diseases and has been found in approximately 90% of AIDS patients. 102 It usually has one of four clinical presentations: pseudomembranous, erythematous, or hyperplastic candidiasis or angular cheilitis. 94

Pseudomembranous candidiasis (thrush) presents as painless or slightly sensitive white lesions that can be readily scraped and separated from the surface of the oral mucosa. This type is most common on the hard and soft palate and the buccal or labial mucosa.

Erythematous candidiasis may be present as a component of the pseudomembranous type, appearing as red patches on the buccal or palatal mucosa, or it may be associated with depapillation of the tongue (Fig. 29-3).

Hyperplastic candidiasis is the least common form and may be seen in the buccal mucosa and tongue. It is more resistant to removal than the other types (Fig. 29-4).

In angular cheilitis, the commissures appear erythematous with surface crusting and fissuring.

Diagnosis of candidiasis is made by microscopic examination of a tissue sample or smear of material scraped from the lesion, which shows hyphae and yeast forms of the organisms. When oral candidiasis appears in patients with no apparent predisposing causes, the clinician should be alerted to the possibility of HIV infection.' Many patients at risk for HIV infection who present with oral candidiasis also have esophageal candidiasis, a diagnostic sign of AIDS.131

Although candidiasis in HIV-infected patients may respond to antifungal therapy, it is often refractory or recurrent. Traditionally, 30% of AIDS related candidiasis relapse within 4 weeks of treatment and 60% to 80% within 3 months. This relapse may result from decreasing immunocompetency or development of antifungal resistant candidial strains. As many as 10% of candidial organisms become resistant to long-term fluconazole therapy, and cross-resistance to other antifungal agents may develop to include itraconazole, amphotericin B oral suspension, and intravenous amphotericin B.65,95,99 Resistant candidiasis is more common in individuals who have low CD4 counts at baseline . 56

Recent reports indicate that the administration of effective combined antiretroviral and protease-inhibiting drugs in HIV infections has resulted in a significant decrease in incidence of oropharyngeal candidiasis and oral candidal carriage and has reduced the rate of fluconazole resistance. 19,79

Kaposi's Sarcoma

Kaposi's sarcoma (KS) is a rare, multifocal, vascular neoplasm; it was originally described in 1872 as occurring in the skin of the lower extremities of older men of Mediterranean origin. Its cause is unknown, although sexually transmitted viral infection has been suspected. Recently, a new strain of herpes virus has been identified

Fig. 29-3 Depapillation of the tongue. A smear obtained from the tongue was positive for *Candida sp.*

Fig. 29-4 Large area of mucosal necrosis extending from the lingual gingival tissue onto the floor of the mouth in a 28-year-old patient with AIDS.

Fig. 29-5 A, Kaposi's sarcoma of the palate and gingiva covered with *Candida sp. B,* **After antifungal therapy, the candidiasis has disappeared and the underlying sarcoma is more apparent. (Courtesy Dr. Frank Lucatorto, Los Angeles, Calif.)**

as closely associated with KS. This virus was originally named the *KS-herpes virus* but has now been designated *as human herpes virus-8 (HHV-8).* HHV-8 has been associated both with AIDS-related and non-AIDS-related KS.[114] However, HIV-infected individuals are 7000-fold more likely to develop KS.[63] Despite this strong association, an etiologic association between HHV-8 and KS has not been established.[62,63] The virus has been isolated from 29% of American adults and 8% of children in the non-AIDS general population. It has also been isolated from lesions of non-Hodgkin's lymphoma, Castleman's disease, other lymphoproliferative disorders, and a variety of additional abnormalities, although these findings may coincide with those of the healthy general population.[39,62,125] In contrast, one study identified HHV-8 in 53 of 54 AIDS-related KS lesions.[] Thus it appears that decreasing immunocompetence results in activation of latent HHV-8. Although the virus may be sexually transmitted, it may also be transmitted from infected mothers to children.[126]

Although KS is a malignant tumor, in its classic form it is a localized and slowly growing lesion. The KS that occurs in HIV-infected patients presents different clinical features (Figs. 29-5 to 29-7; see Color Fig. 29-1, E). In these individuals, it is a much more aggressive lesion and the majority (71%) develop lesions of the oral mucosa, particularly the palate and gingiva (see Color Fig. 29-1,[M.63] The oral cavity may often be the first or only site of the lesions

In the early stages, the oral lesions are painless, reddish-purple macules of the mucosa. As the lesions progress, they frequently become nodular and can easily be con-

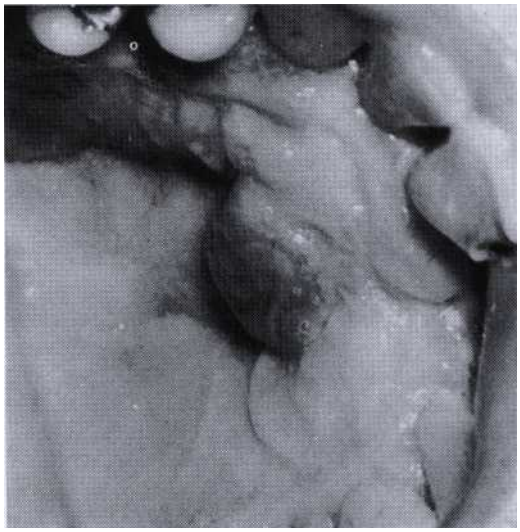

Fig. 29-6 Kaposi's sarcoma of the palate extending to the gingiva. (Courtesy Dr. Frank Lucatorto, Los Angeles, Calif.)

Fig. 29-7 Kaposi's sarcoma of the gingiva in a 26-year-old man.

fused with other oral vascular entities such as hemangioma, hematoma, varicosity, or pyogenic granuloma (when occurring in the gingiva).[121]

Lesions manifest as nodules, papules, or nonelevated macules that are usually brown, blue, or purple in color. On occasion, however, lesions may display normal pigmentation. Diagnosis is based on histologic findings.[67,109]

Microscopically, KS consists of four components: endothelial cell proliferation with the formation of atypical vascular channels; extravascular hemorrhage with hemosiderin deposition, spindle cell proliferation in association with atypical vessels; and a mononuclear inflammatory infiltrate consisting mainly of plasma cells[42] (Fig. *29-8*).

Regional and gender differences are apparent; oral KS is more common in the U.S. than in Europe and the male-to-female ratio is *20:1*.[108,132] The condition has also been reported in patients with lupus erythematosus who are receiving immunosuppressant therapy and in renal transplant patients and other individuals receiving corticosteroid or cyclosporin therapy. Case reports describe gingival KS in HIV-negative patients experiencing cyclosporin-induced gingival enlargement.[105,131] In an HIV-positive individual, the presence of KS signifies transition to outright AIDS. Before the advent of combined drug therapy for AIDS, the median survival time after onset of KS ranged from 7 to 31 months.[16,15]

The differential diagnosis of oral KS includes pyogenic granuloma, hemangioma, atypical hyperpigmentation, sarcoidosis, bacillary angiomatosis, angiosarcoma, pigmented nevi, and cat-scratch disease (skin).[109]

Bacillary (Epithelioid) Angiomatosis

Bacillary (epithelioid) angiomatosis (BA) is an infectious vascular proliferative disease with clinical and histologic features very similar to those of KS. BA is believed to be caused by rickettsia-like organisms, *Bartonellaciae henselia, quintana,* or others.[22,29,85,93,104,143] Skin lesions are similar to those seen in KS or cat-scratch disease. Gingival BA manifests as red, purple, or blue edematous soft tissue lesions that may cause destruction of periodontal ligament and bone (Fig. *29-9*).[33] The condition is more prevalent in HIV-positive individuals with low CD4 levels.[85]

Differentiation of BA from KS is based on biopsy, which reveals an "epithelioid" proliferation of angiogenic cells accompanied by an acute inflammatory cell infiltrate. The causative organism in the biopsy specimen sometimes reacts with Warthen-Starry silver stain.

Oral Hyperpigmentation

An increased incidence of oral hyperpigmentation has been described in HIV-infected individuals.[69] Oral pigmented areas often appear as spots or striations on the buccal mucosa, palate, gingiva, or tongue (Figs. *29-10* and *29-11*). In some instances, the pigmentation may relate to prolonged use of drugs such as zidovudine, ketoconazole, or clofazimine.[147] Zidovudine is also associated with excessive pigmentation of the skin and nails. On occasion, oral pigmentation may be the result of adrenocorticoid insufficiency induced in an HIV-positive individual by prolonged use of ketoconazole or by *Pneumocystis carinii* infection or cytomegalovirus or other viral infections (see Fig. *29-11*).

Atypical Ulcers and Delayed Healing

Nonspecific oral ulcerations in HIV-infected individuals may have multiple etiologies to include neoplasms such as lymphoma, KS, and squamous cell carcinoma. Recent case reports suggest that HIV-associated neutropenia may also feature oral ulcerations. Neutropenia has been successfully treated using recombinant human granulocyte

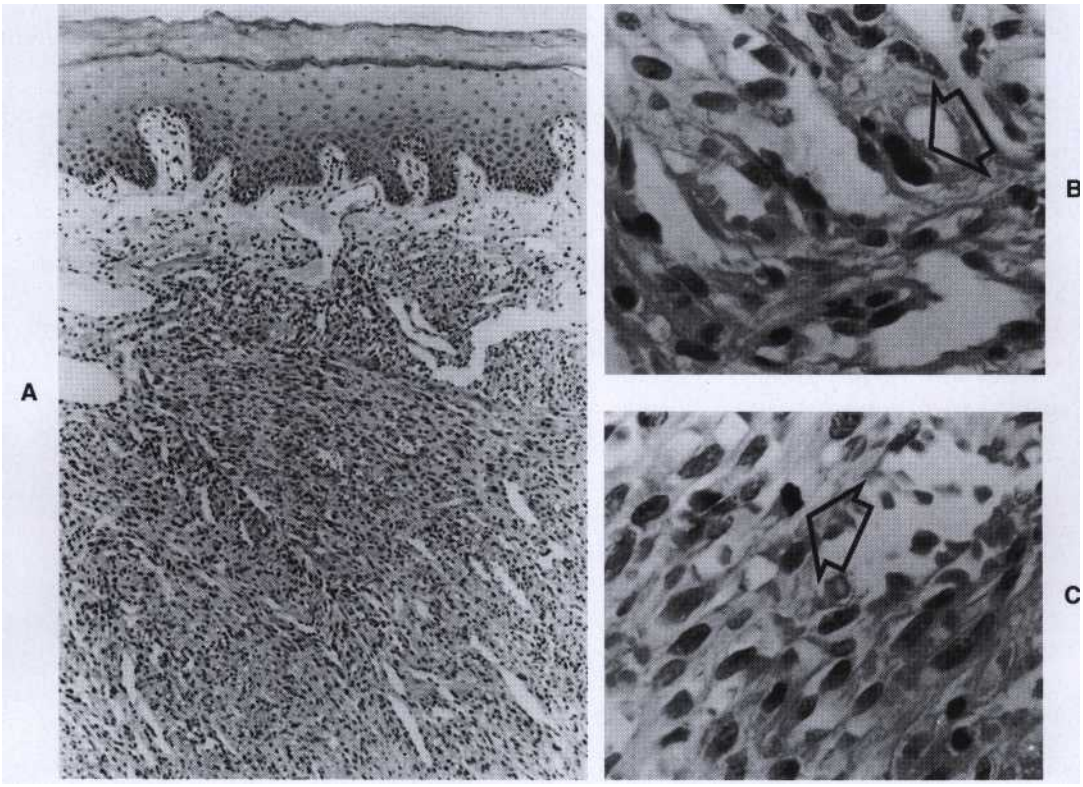

Fig. 29-8 Kaposi's sarcoma of the palate in a patient with AIDS. A, Low-power view of hyperkeratotic epithelium overlying large vascular spaces and a dense tumoral mass. (Courtesy Dr. Gerald Shklar, Boston, Mass.)

colony-stimulating factor with resultant resolution of oral ulcers.[76] Severe, prolonged oral ulcers have been successfully managed using prednisone or thalidomide, a drug that inhibits tissue necrosis factor alpha (TNF-a). Recurrence is likely, however, if either drug is discontinued.[20,36,40,61,144]

HIV-infected patients have a higher incidence of recurrent herpetic lesions and aphthous stomatitis (Figs. 29-12 and 29-13). Approximately 10% of HIV-infected patients have herpes infection,[102,124] and multiple episodes are common. Aphthae and aphthae-like lesions are common when patients are followed throughout the course of their immunosuppression.[37]

In healthy patients, herpetic and aphthous lesions are self-limiting and relatively easy to diagnose by their characteristic clinical features (i.e., herpes on the keratinizing mucosa, aphthae on the nonkeratinizing surfaces). In HIV-infected patients, the clinical presentation and course of these lesions may be altered. Herpes may involve all mucosal surfaces and extend to the skin and may persist for months.[25] Currently the CDC includes mucocutaneous herpes present for more than 1 month as a sign of AIDS.[10]

Atypical large, persistent, nonspecific, painful ulcers are common in immunocompromised individuals. If healing is delayed, these lesions are secondarily infected and may become indistinguishable from persistent herpetic or aphthous lesions.[77] A wide variety of bacterial and viral infections may produce severe oral ulcerations in HIV-infected individuals. Essentially, immunocompromised individuals are at risk from infectious agents

Fig. 29-11 Palatal hyperpigmentation in a patient with drug-induced adrenocortical insufficiency.

Fig. 29-12 Ulcerous lesion in the tongue of a patient with AIDS.

endemic to the patient's geographic location. Atypical or nonhealing ulcers may require biopsy, microbial cultures, or both to determine the etiology. Oral ulcerations have been described in association with enterobacterial organisms such as *Klebsiella pneumoniae*, *Enterobacter cloacae*, and *Escherichia coli*.[110] Such infections are rare and are usually associated with systemic involvement. Specific antibiotic therapy is indicated, and close coordination of oral therapy with the patient's physician is usually necessary.

Herpes simplex virus (HSV), varicella-zoster virus (VZV), Epstein-Barr virus (EBV), or cytomegalovirus (CMV) are frequently retrieved from nonspecific oral ulcers, indicating a possible etiologic role.[130] Recently, atypical ulcers were found to be co-infected with HSV and CMV or with EBV and CMV.[108,129] These ulcers may be more common in individuals who are neutropenic in conjunction with their HIV infection. Neutropenia may also be induced by drugs such as zidovodine, trimethoprim-sulfamethoxazole, or gancyclovir.[76] Atypical ulcers may be more severe and persistent in individuals with low CD4 cell counts, and the presence of oral CMV-induced ulcers may be indicative of systemic CMV infection."

Recurrent aphthous stomatitis (RAS) has been described in HIV-infected individuals, but the overall incidence may be no greater than that in the general population." RAS may occur, however, as a component of the initial acute illness of HIV seroconversion.[82] The incidence of major aphthae may be increased, and the oropharynx, esophagus, or other areas of the gastrointestinal tract may be involved.[2,3]

Adverse Drug Effects

A number of adverse drug-induced effects have been reported in HIV-positive patients and the dentist may be the first to recognize an oral drug reaction. Foscarnet, interferon, and 2'-3'-dideoxycytidine (DDC) occasionally

Fig. 29-13 Nonhealing ulcer in the palatal gingiva of 6 weeks' duration. Biopsy revealed Kaposi's sarcoma. (Courtesy Dr. Frank Lucatorto, Los Angeles, Calif.)

Fig. 29-14 Marginal gingival erythema of the maxillary gingiva and diffuse erythema of the mandibular attached gingiva in a 28-year-old man. Early necrosis of some of the interdental papillae is seen.

induce oral ulcerations, and erythema multiforme has been reported with use of didanosine (DDI).[17] Zidovudine and ganciclovir may induce leukopenia, resulting in oral ulcers.[84] Xerostomia and altered taste sensation have been described in conjunction with diethyldithiocarbamate (Dithiocarb). HIV-positive patients are believed to be generally more susceptible to drug-induced mucositis and lichenoid drug reactions than the general population.[6,17,52,122] In some instances, mouth ulcers and mucositis resolve if drug therapy is continued beyond 2 to 3 weeks, but when drug effects are severe or persistent, alternative therapy with different drugs should be used.

The advent of protease-inhibiting drugs used in double or triple drug therapy has been associated with a variety of generalized adverse reactions. These may include nausea, development of kidney stones, lypodystrophy (possibly including hyperlipidemia), an increase in abdominal fat mass, enlarged breast size, and development of the classic "buffalo hump" usually associated with administration of systemic corticosteroids.[8,127] Impaired glucose tolerance or diabetes mellitus may occur, apparently resulting from increased insulin resistance.[8,140] Combined drug therapy may also induce more severe liver cirrhosis in individuals with hepatitis C/HIV coinfections.[148] The dentist should remain alert for general signs and symptoms of adverse drug effects, some of which can affect oral tissues (e.g., nausea and vomiting, diabetes mellitus).

PERIODONTAL DISEASE

Considerable interest has been directed toward the nature and incidence of dental and periodontal diseases in HIV-infected individuals. Available evidence indicates that those diseases are more common among HIV-infected intravenous (IV) drug users. This appears to relate to poor oral hygiene and lack of dental care rather than decreased CD4 cell counts.[48,68,107]

Linear Gingival Erythema

A persistent, linear, easily bleeding, erythematous gingivitis (LGE) has been described in some HIV-positive patients. This may or may not serve as a precursor to rapidly progressive necrotizing ulcerative periodontitis (NUP)[35,41,83] (see Color Fig. 29-1, B and C, and Fig. 29-14). The microflora of LGE may closely mimic that of periodontitis rather than gingivitis.[41] Linear gingivitis lesions may be localized or generalized in nature. The erythematous gingivitis may (1) be limited to marginal tissue, (2) extend into attached gingiva in a punctate or a diffuse erythema, or (3) extend into the alveolar mucosa.

LGE is often unresponsive to corrective therapy, yet such lesions may undergo spontaneous remission.[89] Concomitant oral candidiasis and LGE lesions have been identified, suggesting a possible etiologic role for candidial species in LGE.[68] Recently, direct microscopic cultures from LGE lesions implicated *Candida dubliniensis* in four patients, all of whom experienced complete or partial remission after systemic antifungal therapy.[137] It is not yet known whether candidial infections are etiologic in all LGE cases.

Necrotizing Ulcerative Gingivitis

Some reports have described an increased incidence of necrotizing ulcerative gingivitis (NLJG) (Fig. 29-15) among HIV-infected individuals, although this has not been substantiated by other studies.[21,38,57,116,128]

Necrotizing Ulcerative Stomatitis

A severely destructive, acutely painful necrotizing ulcerative stomatitis (NUS) has occasionally been reported in HIV-positive patients. NUS is characterized by necrosis of significant areas of oral soft tissue and underlying bone. It may occur separately or as an extension of NUP[21] and is commonly associated with severe depression of CD4

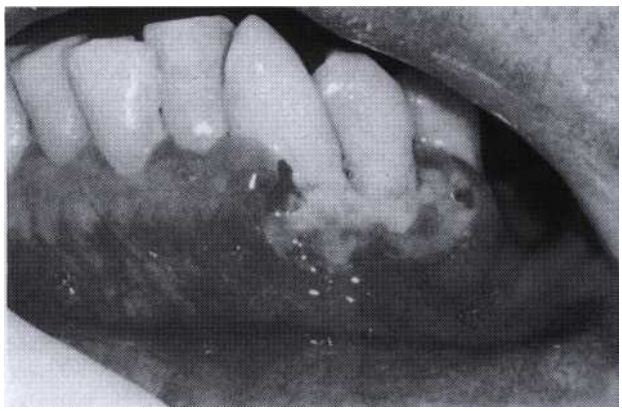

Fig. 29-15 Acute necrotizing ulcerative gingivitis (ANUG)-like lesion and ulcer involving the facial gingiva. (Courtesy Dr. Frank Lucatorto, Los Angeles, Calif.)

immune cells. The condition appears to be identical to cancrum oris (noma), a rare destructive process occasionally reported in nutritionally deprived individuals, especially those in Africa. NUS may be associated with severe immunodeficiency regardless of the cause of onset. [114]

Necrotizing Ulcerative Periodontitis

A necrotizing, ulcerative, rapidly progressive form of periodontitis occurs more frequently among HIV-positive individuals, although such lesions were described long before the onset of the AIDS epidemic. NUP may represent an extension of NUG in which bone loss and periodontal attachment loss occurs.

NUP is characterized by soft tissue necrosis, rapid periodontal destruction, and interproximal bone loss[35] (Figs. 29-16 and 29-17). Lesions may occur anywhere in the dental arches and are usually localized to a few teeth, although generalized NUP is sometimes present after marked CD4+ cell depletion. Bone is often exposed, resulting in necrosis and subsequent sequestration. NUP is severely painful at onset, and immediate treatment is necessary. On occasion, however, patients undergo spontaneous resolution of the necrotizing lesions, leaving painless, deep interproximal craters that are difficult to clean and may lead to conventional periodontitis.[35]

Some evidence suggests slight differences between the microbial flora found in NUP lesions and that found in chronic periodontitis,[87] but the bulk of data implicate a similar microbial component in both diseases.[38,90,91,115] The periodontal health of HIV-infected individuals is subject to wide variations.[113,145] Riley and associates'[113] examined 200 HIV-positive patients and found that 85 were periodontally healthy; none had NUG; 59 were suffering from gingivitis; 54 were experiencing mild, moderate, or advanced periodontitis; and only 2 had NUP. Using a different approach, Rowland and associates'[" studied 20 patients with NUG and found that 7 were HIV positive, 2 of whom had CD4+ lymphocyte depression (<400/mm3). They concluded that dentists should recognize NUG as a possible early marker for HIV infection. In contrast, Drinkard and associates[21] found no evidence of NUG in 106 HIV-positive individuals; 97 were asymptomatic, and 9 exhibited Category B symptoms.

Klein and associates[66] evaluated 181 heterosexuals with AIDS and found a larger percentage of women (91%) than men (73%) with gingivitis or periodontitis. Overall, most heterosexuals with AIDS had only gingivitis (70%) while others had moderate (27%) to severe periodontitis (27%). This study suggests that periodontal diseases are no more frequent in heterosexuals with AIDS than the general population. The finding of more frequent disease in women may reflect the fact that more women with AIDS have used illicit injectable drugs.

Swango and associates[128] reported early findings among 230 HIV-positive patients with relatively high CD4+ counts. They found no correlation between linear gingival erythema and CD4+ T -cell levels in these patients, although 6% experienced NUG-like papillary destruction. Others have reported a relationship between NUP and decreased CD4+ lymphocytes .[75,133] Glick and associates[38] reported the incidence of periodontal diseases in 700 HIV-positive individuals. They found NUP in only 6.3% but concluded that NUP is a predictive marker for severe immune deficiency because patients with NUP were 20.8 times as likely to have CD4+ lymphocyte counts <200/mm3.

It can be concluded from these studies that periodontal diseases can occur among HIV-infected individuals in all categories, but susceptibility to periodontal infections increases as the immune system becomes more compromised. Lamster and associates compared frequency of oral lesions and periodontal diseases between HIV-positive and HIV-negative individuals, some of whom were injectable drug users (IDUs). They concluded that the lifestyle associated with IDU may play a larger role in oral disease than the individual's HIV status. They also found tongue lesions consistent with hairy leukoplakia to be most common among seropositive homosexual males, whereas oral candidiasis and LGE were most common among injectable drug users.[68] The majority of HIV-positive individuals experience periodontal disease in a manner similar to the general population. Under some circumstances, however, immunocompromised individuals experience less common types of severe gingival or periodontal destruction. With proper home care and appropriate periodontal treatment and maintenance, HIV-positive individuals can anticipate reasonably good periodontal health throughout the course of their disease. The median period between initial HIV infection and outright AIDS is approximately 12 years, and the life expectancy of persons living with AIDS has been significantly prolonged with current anti-HIV drug therapy.[12] This indicates that HIV-infected patients are potential candidates for conventional periodontal treatment procedures to include periodontal surgery and implant placement. Treatment decisions should be based on the overall health status of the patient, the degree of periodontal involvement, and the motivation and ability of the patient to perform effective oral hygiene procedures. (Chapter 51 describes in detail the periodontal management of AIDS patients.)

Treatment of Periodontal Disease

Michael G. Newman

Periodontal treatment requires an interrelationship between the care of the periodontium and other phases of dentistry. The concept of total treatment is based on the elimination of gingival inflammation and the factors that lead to it (e.g., plaque accumulation favored by calculus and pocket formation, inadequate restorations, and areas of food impaction).

Total treatment requires consideration of systemic aspects, including the possibility of interaction of periodontal disease with other diseases, systemic adjuncts to local treatment, and special precautions in patient management necessitated by systemic conditions. It may also entail consideration of functional aspects for the establishment of optimal occlusal relationships for the entire dentition.

All these aspects are embodied in a master plan, which consists of a rational sequence of dental procedures that includes periodontal and other measures necessary to create a well-functioning dentition in a healthy periodontal environment.

Clinical Diagnosis

CHAPTER OUTLINE

FIRST VISIT
- **Overall Appraisal of the Patient**
- **Medical History**
- **Dental History**
- **Intraoral Radiographic Survey**
- **Casts**
- **Clinical Photographs**
- **Review of the Initial Examination**

SECOND VISIT
- **Oral Examination**
- **Examination of the Teeth**
- **Examination of the Periodontium**

THE PERIODONTAL SCREENING AND RECORDING SYSTEM

LABORATORY AIDS TO CLINICAL DIAGNOSIS
- **Nutritional Status**
- **Patients on Special Diets for Medical Reasons**
- **Blood Tests**

Proper diagnosis is essential to intelligent treatment. Periodontal diagnosis should first determine whether disease is present; then identify its type, extent, distribution, and severity; and finally provide an understanding of the underlying pathologic processes and its cause. Chapters 26 to 29 provide a detailed description of the different diseases that can afflict the periodontium. In general, they fall into three broad categories.

1. The gingival diseases (Box 30-1)
2. The various types of periodontitis (Table 30-1)
3. The periodontal manifestations of systemic diseases

Periodontal diagnosis is determined after careful analysis of the case history and evaluation of the clinical signs and symptoms, as well as the results of various tests (e.g., probing mobility assessment, radiographs, blood tests, and biopsies).

The interest should be in the patient who has the disease and not simply in the disease itself. Diagnosis must therefore include a general evaluation of the patient and consideration of the oral cavity.

Diagnostic procedures must be systematic and organized for specific purposes. It is not enough to assemble facts. The findings must be pieced together so that they provide a meaningful explanation of the patient's periodontal problem.

The following is a recommended sequence of procedures for the diagnosis of periodontal diseases.

BOX 30-1

Gingival Diseases

- Chronic marginal gingivitis
- Acute necrotizing ulcerative gingivitis
- Acute herpetic gingivostomatitis
- Allergic gingivitis
- Gingivitis associated with skin diseases
- Gingivitis associated with endocrine-metabolic disturbances
- Gingivitis associated with hematologic-immunologic disturbances
- Gingival enlargement associated with medications
- Gingival tumors

FIRST VISIT

Overall, Appraisal of the Patient

From the first meeting, the clinician should attempt an overall appraisal of the patient. This includes consideration of the patient's mental and emotional status, temperament, attitude, and physiologic age.

Medical History

Most of the medical history is obtained at the first visit and can be supplemented by pertinent questioning at subsequent visits. The health history can be obtained verbally by questioning the patient and recording his or her responses on a blank piece of paper or by means of a printed questionnaire the patient completes.

The importance of the medical history should be explained to the patient because patients often omit information that they cannot relate to their dental problems. The patient should be made aware of (1) the possible role that some systemic diseases, conditions or behavioral factors may play in the cause of periodontal disease; and (2) oral infection may have a powerful influence on the occurrence and severity of a variety of systemic diseases and conditions (see Chapters 12 and 13).

The medical history aids the clinician in the diagnosis of oral manifestations of systemic disease and in the detection of systemic conditions that may be affecting the periodontal tissue response to local factors or that require special precautions and/or modifications in treatment procedures. **For a detailed discussion of conditions requiring special precautions, see Chapters** 37 to 39.

The medical history should include reference to:

1. Is the patient under the care of a physician and, if so, what is the nature and duration of the problem and the therapy? The name, address, and telephone number of the physician should be recorded, since direct communication with him or her may be necessary.
2. Details on hospitalization and operations, including diagnosis, kind of operation, and untoward events such as anesthetic, hemorrhagic, or infectious complications, should be provided.
3. A list should be supplied of all medications being taken and whether they were prescribed or obtained over the counter. All the possible effects of these medications should be carefully analyzed to determine their effect, if any, on the oral tissues and also to avoid administering medications that would interact adversely with them. Special inquiry should be made regarding the dosage and duration of therapy with anticoagulants and corticosteroids.
4. History should be taken of all medical problems (cardiovascular, hematologic, endocrine, etc.), including infectious diseases, sexually transmitted diseases, and high-risk behavior for human immunodeficiency virus (HIV) infection.
5. Any possibility of occupational disease should be noted.
6. Abnormal bleeding tendencies such as nosebleeds, prolonged bleeding from minor cuts, spontaneous ecchymoses, tendency toward excessive bruising, and excessive menstrual bleeding should be cited.
7. History of allergy should be taken, including hay fever, asthma, sensitivity to foods, or sensitivity to drugs such as aspirin, codeine, barbiturates, sulfonamides, antibiotics, procaine, and laxatives, to dental materials such as eugenol or acrylic resins.
8. Information is needed regarding the onset of puberty and, for females, menopause, menstrual disorders, hysterectomy, pregnancies, and miscarriages.
9. Family medical history should be taken, including bleeding disorders and diabetes.

Dental History

Current Illness. Some patients may be unaware of any problems but many may report bleeding gums; loose teeth; spreading of the teeth with the appearance of spaces where none existed before; foul taste in the mouth; and an itchy feeling in the gums, relieved by digging with a toothpick. There may also be pain of varied types and duration, including constant, dull, gnawing pain, dull pain after eating; deep, radiating pains in the jaws; acute throbbing pain; sensitivity when chewing; sensitivity to heat and cold; burning sensation in the gums; and extreme sensitivity to inhaled air.

A preliminary oral examination is done to explore the source of the patient's chief complaint and to determine whether immediate emergency care is required. If **this is the case, the problem is addressed after consideration of the medical history (see Chapters** 45 and 46).

The dental history should include reference to:

1. A list of visits to the dentist should be supplied, including frequency; date of the most recent visit; nature of the treatment; and oral prophylaxis or cleaning by a dentist or hygienist, including frequency and date of most recent cleaning.
2. The patient's oral hygiene regimen should be noted, including toothbrushing frequency, time of day, method, type of toothbrush and dentifrice, and interval at which brushes are replaced. Other methods for mouth care, such as mouthwashes, finger massage,

TABLE 30-1

Features of Types of Periodontitis

Parameter	CP	AP	PPP	LIP	NUP
Age (years)	35+	20-35	<11	11-19	15-35
Calculus	Moderate to abundant	Scanty to moderate	Scanty	Moderate	Scanty
Disease progression	Slow	Rapid	Rapid	Rapid	Rapid
Distribution	Generalized; associated with etiologic factors	Generalized; no consistent pattern	Primary molars and incisors	First molar and incisors, and no more than two other teeth	?
Prevalence	US: >50% Sri Lanka: 81 %	US: 4-5% (?) Sri Lanka: 11	?	<0.50%

Association with systemic problems	No	Some cases	Yes	Yes	Yes
Response to therapy	Very good	Variable	Poor	Good	Variable

AP Aggressive periodontitis; CP, chronic periodontitis; LIP, localized juvenile periodontitis; NUP, necrotizing ulcerative periodontitis; PPP, prepubertal periodontitis.
Prevalence in adolescents 14-17 years of age in the United States.

interdental stimulation, water irrigation, and dental floss.

3. Any orthodontic treatment, including duration and approximate date of termination, should be noted.
4. If the patient is experiencing pain in the teeth or in the gums, the manner in which the pain is provoked, its nature and duration, and the manner in which it is relieved should all be noted.
5. Bleeding gums should be cited, including when first noted; whether it occurs spontaneously, on brushing or eating, at night, or with regular periodicity; whether it is associated with the menstrual period or other specific factors; and the duration of the bleeding and the manner in which it is stopped.
6. A bad taste in the mouth and areas of food impaction should be recorded.
7. Do the teeth feel "loose" or insecure? Is there difficulty in chewing? Any tooth mobility should be recorded.
8. What are the patient's general dental habits? If there is any grinding or clenching of the teeth during the day or at night, it should be noted. Do the teeth or jaw muscles feel "sore" in the morning? Are there other habits, such as tobacco smoking or chewing, nail biting, or biting on foreign objects?
9. History of previous periodontal problems should be noted, including the nature of the condition and, if previously treated, the type of treatment received (surgical or nonsurgical) and approximate period of termination of previous treatment. If, in the opinion of the patient, the present problem is a recurrence of previous disease, what does he or she think caused it?

Intraoral Radiographic Survey

The radiographic survey should consist of a minimum of 14 intraoral films and four posterior bite-wing films (Fig. 30-1).

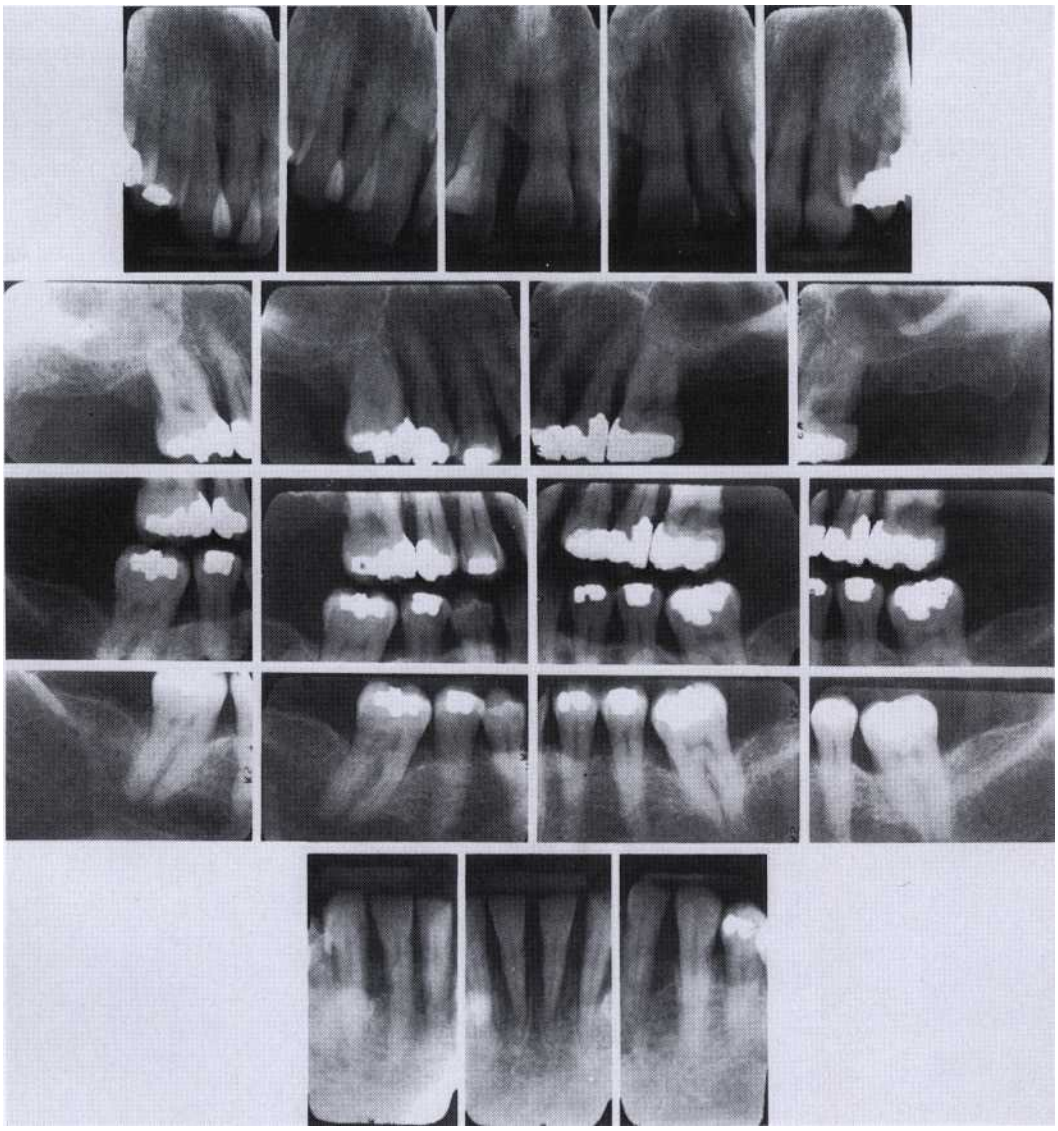

Fig. 30-1 Full-mouth intraoral radiographic series (16 periapical films and four bite-wing films) used as an adjunct in periodontal diagnosis.

Panoramic radiographs are a simple and convenient method of obtaining a survey view of the dental arch and surrounding structures (see Fig. 30-1). They are helpful for the detection of developmental anomalies, pathologic lesions of the teeth and jaws, and fractures (Fig. 30-2), as well as dental screening examinations of large groups. They provide an informative overall radiographic picture of the distribution and severity of bone destruction in periodontal disease, but *a complete intraoral series is required for periodontal diagnosis and treatment* planning. Chapter 31 gives a detailed description of radiographic interpretation in periodontics.

Casts

Casts from dental impressions are extremely useful adjuncts in the oral examination. They indicate the position of the gingival margins and the position and inclination of the teeth, proximal contact relationships, and food impaction areas. In addition, they provide a view of lingual-cuspal relationships. They are important records of the dentition before it is altered by treatment. Finally, casts also serve as visual aids in discussions with the patient and are useful for pre- and post-treatment comparisons, as well as for reference at checkup visits.

Clinical Photographs

Color photographs are not essential, but they are useful for recording the appearance of the tissue before and after treatment. Photographs cannot always be relied on for comparing subtle color changes in the gingiva, but they do depict gingival morphologic changes.

Review of the Initial Examination

If no emergency care is required, the patient is dismissed and instructed as to when to report for the second visit. Before this visit, a correlated examination is made of the radiographs and casts to relate the radiographic changes to unfavorable conditions represented on the casts. The casts are checked for evidence of abnormal wear, plunger cusps, uneven marginal ridges, malposed or extruded teeth, crossbite relationships, or other conditions that could cause occlusal disharmony or food impaction. Such areas are marked on the casts to serve as a reference during the detailed examination of the oral cavity. The radiographs and casts are valuable diagnostic aids; however, it is *the clinical findings in the oral cavity that constitute the basis for diagnosis.*

SECOND VISIT

Oral Examination

Oral Hygiene. The cleanliness of the oral cavity is appraised in terms of the extent of accumulated food debris, plaque, materia alba, and tooth surface stains (Fig. 30-3). Disclosing solution may be used to detect plaque that would otherwise be unnoticed. The amount of plaque detected, however, is not necessarily related to the severity of the disease present. For example, aggressive periodontitis is a destructive type of periodontitis in which plaque is scanty. Qualitative assessments of plaque are more meaningful, and their value in diagnosis is discussed in Chapter 34.

Mouth Odors. Halitosis, also termed *fetor ex ore, fetor oris,* and *oral malodor, is* foul or offensive odor emanating from the oral cavity. Mouth odors may be of diagnostic significance, and their origin may be either oral or extraoral (remote).

Halitosis is caused primarily by volatile sulfur compounds, specifically, hydrogen sulfyde and methyl mercaptan, which result from the bacterial putrefaction of proteins containing sulfur aminoacids. These products

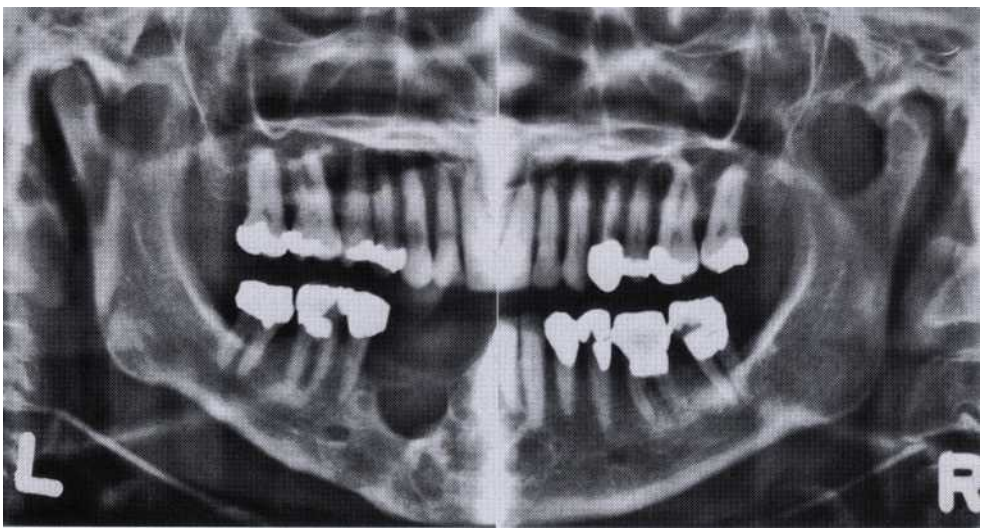

Fig. 30-2 Panoramic radiograph showing temporomandibular joints and "cystic" spaces in the jaw. Areas of periodontal bone loss are not seen in detail. (Compare with Fig. 30-1.)

could be involved in the transition from health to gingivitis and then to periodontitis.[47]

Local sources of mouth odors are mainly the tongue and the gingival sulcus[49] and include retention of odoriferous food particles on and between the teeth, coated tongue, necrotizing ulcerative gingivitis (NUG), dehydration states, caries, artificial dentures, smoker's breath, and healing surgical or extraction wounds. The fetid odor that is a characteristic of NUG is easily identified. Chronic periodontitis with pocket formation may also cause unpleasant mouth odor from any accumulated debris and the increased rate of putrefaction of the saliva.'

Extraoral sources of mouth odors include various infections or lesions of the respiratory tract (bronchitis, pneumonia, bronchiectasis, or others) and odors that are excreted through the lungs from aromatic substances in the bloodstream, such as metabolites from ingested foods or excretory products of cell metabolism. Alcoholic breath, the acetone odor of diabetes, and the uremic breath that accompanies kidney dysfunction are examples of the last group.

Examination of the Oral Cavity. The entire oral cavity should be carefully examined. The examination should include the lips, floor of the mouth, tongue, palate, and oropharyngeal region, as well as the quality and quantity of saliva. Although findings may not be related to the periodontal problem, they should enable the dentist to detect any pathologic changes present in the mouth. Textbooks in oral medicine and oral diagnosis cover these topics in detail.

Examination of Lymph Nodes. Because periodontal, periapical, and other oral diseases may result in lymph node changes, the diagnostician should routinely examine and evaluate head and neck lymph nodes. Lymph nodes can become enlarged and/or indurated as a result of an infectious episode, malignant metastases, or residual fibrotic changes.

Inflammatory nodes become enlarged, palpable, tender, and fairly immobile. The overlying skin may be red and warm. Patients are often aware of the presence of "swollen glands." Primary herpetic gingivostomatitis, NUG, and acute periodontal abscesses may produce lymph node enlargement. After successful therapy, lymph nodes return to normal in a matter of days or a few weeks.

Examination of the Teeth

The teeth are examined for caries, developmental defects, anomalies of tooth form, wasting, hypersensitivity, and proximal contact relationships.

Wasting Disease of the Teeth. *Wasting is defined as any gradual loss of tooth substance characterized by the formation of smooth, polished surfaces, without regard to the possible mechanism of this loss.* The forms of wasting are erosion, abrasion, and attrition.

Erosion (cuneiform defect) is a sharply defined wedge-shaped depression in the cervical area of the facial tooth surface.[48] The long axis of the eroded area is perpendicular to the vertical axis of the tooth (Fig. 30-4). The surfaces are smooth, hard, and polished. Erosion generally affects a group of teeth. In the early stages, it may be confined to the enamel, but it generally extends to involve the underlying dentin as well as the cementum.

The cause of erosion is not known. Decalcification by acid beverages[31] or citrus fruits, along with the combined effect of acid salivary secretion and friction[,33] are suggested causes. Sognnaes[53] refers to these lesions as *dentoalveolar ablations* and attributes them to forceful frictional actions between the oral soft tissues and the adjacent hard tissues. In patients with erosion, the salivary pH, buffering capacity, and calcium and phosphorus content have been reported as normal, with the mucin level elevated.[,3°]

Abrasion refers to the loss of tooth substance induced by mechanical wear other than that of mastication. Abrasion results in saucer-shaped or wedge-shaped indentations with a smooth, shiny surface. Abrasion starts on exposed cementum surfaces rather than on the enamel and extends to involve the dentin of the root. A sharp "ditching" around the cementoenamel junction appears due to the softer cemental surface, as compared with the much harder enamel surface.

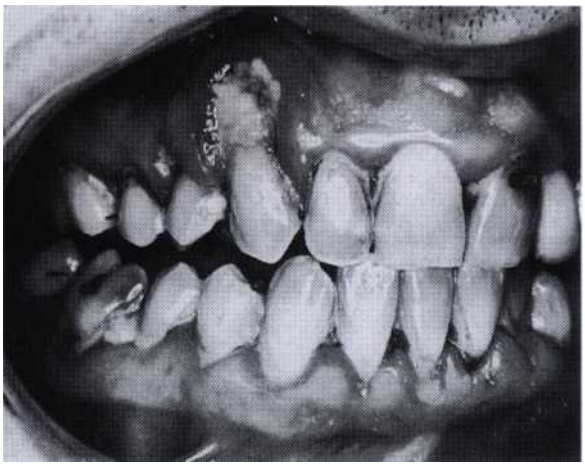

Fig. 30-3 Poor oral hygiene. Gingival inflammation associated with plaque, materia alba, and calculus in a patient with hemophilia.

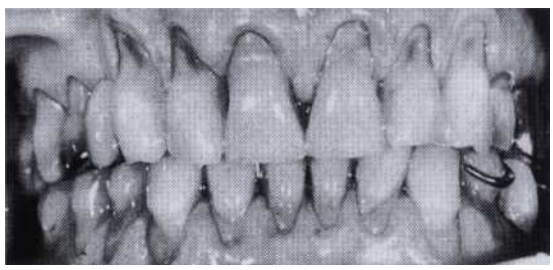

Fig. 30-4 Erosion involving the enamel, cementum, and dentin.

Fig. 30-5 Abrasion attributed to aggressive toothbrushing. Involvement of the roots is followed by undermining of the enamel.

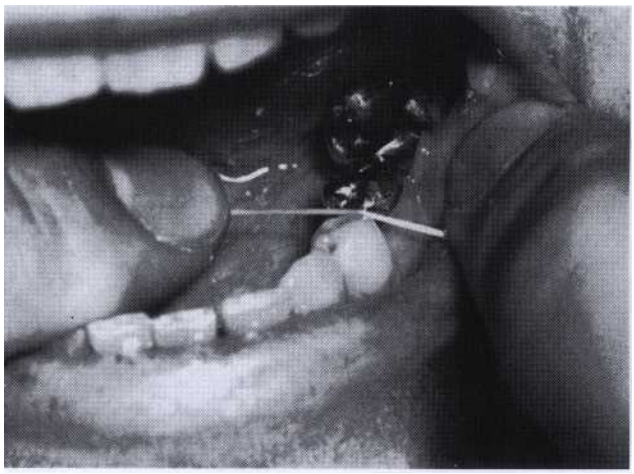

Fig. 30-6 Tightness of contact points checked with dental floss.

Continued exposure to the abrasive agent, combined with decalcification of the enamel by locally formed acids, may result in loss of enamel, followed by loss of the dentin of the crown (Fig. 30-5).

Toothbrushing" with an abrasive dentifrice and the action of clasps are common causes of abrasion; the former is by far the more prevalent. The degree of tooth wear from toothbrushing depends on the abrasive effect of the dentifrice and the angle of brushing.[28,29] Horizontal brushing at right angles to the vertical axis of the teeth results in the severest loss of tooth substance. Occasionally, abrasion of the incisal edges occurs as a result of habits such as holding objects (e.g., a bobby pin or tacks) between the teeth.

Attrition is occlusal wear resulting from functional contacts with opposing teeth.

Dental Stains. These are pigmented deposits on the teeth. They should be carefully examined to determine their origin (see Chapter 11).

Hypersensitivity. Root surfaces exposed by gingival recession may be hypersensitive to thermal changes or tactile stimulation. Patients often direct the operator to the sensitive areas. These may be located by gentle exploration with a probe or cold air.

Proximal Contact Relations. Slightly open contacts permit food impaction. The tightness of contacts should be checked by means of clinical observation and with dental floss (Fig. 30-6). Abnormal contact relationships may also initiate occlusal changes such as a shift in the median line between the central incisors, labial version of the maxillary canine, buccal or lingual displacement of the posterior teeth, and an uneven relationship of the marginal ridges.

Tooth Mobility. All teeth have a slight degree of physiologic mobility, which varies for different teeth and at different times of the day." It is greatest on arising in the morning and progressively decreases. The increased mobility in the morning is attributed to slight extrusion of the tooth because of limited occlusal contact during sleep. During the waking hours, mobility is reduced by chewing and swallowing forces, which intrude the teeth in the sockets. These 24-hour variations are less marked in persons with a healthy periodontium than in those with occlusal habits such as bruxism and clenching.

Single-rooted teeth have more mobility than multirooted teeth, with incisors having the most. Mobility is principally in a horizontal direction, although some axial mobility occurs, to a much lesser degree.[39]

Tooth mobility occurs in two stages:

1. The initial or intrasocket stage is where the tooth moves within the confines of the periodontal ligament. This is associated with viscoelastic distortion of the ligament and redistribution of the periodontal fluids, interbundle content, and fibers.[23] This initial movement occurs with forces of about 100 lb and is of the order of 0.05 to 0.10 mm (50 to 100 microns).[34]
2. The secondary stage, which occurs gradually and entails elastic deformation of the alveolar bone in response to increased horizontal forces.[36] When a force of 500 lbs is applied to the crown, the resulting displacement is about 100 to 200 microns for incisors, 50 to 90 microns for canines, 8 to 10 microns for premolars, and 40 to 80 microns for molars.[34]

When a force such as that applied to teeth in occlusion is discontinued, the teeth return to their original position in two stages: the first is an immediate, springlike elastic recoil; the second is a slow, asymptomatic recovery movement. The recovery movement is pulsating and is apparently associated with the normal pulsation of the periodontal vessels, which occurs in synchrony with the cardiac cycle.[35]

Many attempts have been made to develop mechanical or electronic devices for the precise measurement of

tooth mobility.[35,38,40,11] Even though standardization of the grading of mobility would be helpful in diagnosing periodontal disease and in evaluating the outcome of treatment, these devices are not widely used. As a general rule, mobility is graded clinically with a simple method such as the following: the tooth is held firmly between the handles of two metallic instruments or with one metallic instrument and one finger (Fig. 30-7), and an effort is made to move it in all directions; abnormal mobility most often occurs faciolingually. Mobility is graded according to the ease and extent of tooth movement as follows:

Normal mobility
Grade I: Slightly more than normal.
Grade II: Moderately more than normal.
Grade III: Severe mobility faciolingually and/or mesiodistally, combined with vertical displacement.

Mobility beyond the physiologic range is termed *abnormal* or *pathologic.* It is pathologic in that it exceeds the limits of normal mobility values; the periodontium is not necessarily diseased at the time of examination.

Increased mobility is caused by one or more of the following factors:

1. *Loss of tooth support (bone loss)* can result in mobility. The amount of mobility depends on the severity and distribution of bone loss at individual root surfaces, the length and shape of the roots, and the root size compared with that of the crown.42 A tooth with short, tapered roots is more likely to loosen than one with normal-size or bulbous roots with the same amount of bone loss. Because bone loss usually results from a combination of factors and does not occur as an isolated finding, the severity of tooth mobility does not necessarily correspond to the amount of bone loss.
2. *Trauma from occlusion (i.e.,* injury produced by excessive occlusal forces or incurred because of abnormal occlusal habits such as bruxism and clenching) is a common cause of tooth mobility. Mobility is also increased by hypofunction. Mobility produced by trauma from occlusion occurs initially as a result of resorption of the cortical layer of bone, leading to reduced fiber support, and later as an adaptation phenomenon resulting in a widened periodontal space.
3. *Extension of inflammation from the gingiva or from the periapex into the periodontal ligament* results in changes that increase mobility. The spread of inflammation from an acute periapical abscess may increase tooth mobility in the absence of periodontal disease.
4. *Periodontal surgery* temporarily increases tooth mobility for a short period.[43-46]
5. *Tooth mobility is increased in pregnancy and is sometimes associated with the menstrual cycle or the use o f hormonal contraceptives.* It occurs in patients with or without periodontal disease, presumably because of physicochemical changes in the periodontal tissues.
5. *Pathologic processes of the jaws that destroy the alveolar bone and/or the roots o f the teeth* can also result in mobility. Osteomyelitis and tumors of the jaws belong in this category.

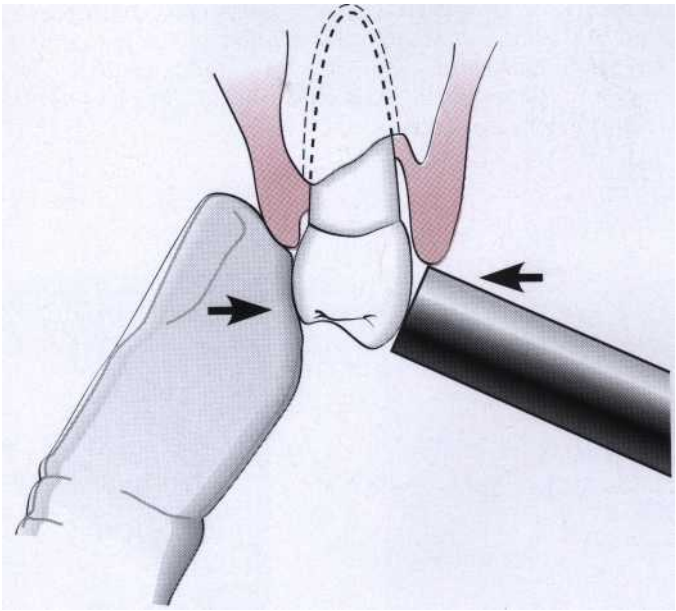

Fig. 30-7 Tooth mobility checked with one metal instrument and one finger.

6. One study[13] has suggested that pockets around mobile teeth harbor higher proportions of *Campylobacter rectus* and *Peptostreptococcus micros,* and possibly of *Porphyromonas gingivalis* than nonmobile teeth. This hypothesis needs further verification.

Trauma from Occlusion. *Trauma from occlusion* refers to tissue injury produced by occlusal forces, not to the occlusal forces themselves (see Chapter *24).* The criterion that determines if an occlusal force is injurious is whether it causes damage in the periodontal tissues; therefore the diagnosis of trauma from occlusion is made from the condition of the periodontal tissues. The periodontal findings are then used as a guide for locating the responsible occlusal relationships.

Periodontal findings that suggest the presence of trauma from occlusion include excessive tooth mobility, particularly in teeth showing radiographic evidence of a widened periodontal space (see Chapter 31); vertical or angular bone destruction; infrabony pockets; and pathologic migration, especially of the anterior teeth (see following discussion).

Pathologic Migration of the Teeth. Alterations in tooth position should be carefully noted, particularly with a view toward identifying abnormal forces, a tongue-thrusting habit, or other habits that may be contributing factors (see Chapter *24).* Premature tooth contacts in the posterior region that deflect the mandible anteriorly contribute to destruction of the periodontium of the maxillary anterior teeth and to pathologic migration (Fig. 30-8). Pathologic migration of anterior teeth in young persons may be a sign of localized aggressive (juvenile) periodontitis.

Sensitivity to Percussion. Sensitivity to percussion is a feature of acute inflammation of the periodontal ligament. Gentle percussion of a tooth at different angles to the long axis often aids in localizing the site of inflammatory involvement.

Dentition with the jaws Closed. Examination of the dentition with the jaws closed can detect conditions such as irregularly aligned teeth, extruded teeth, improper proximal contacts, and areas of food impaction, all of which may favor plaque accumulation.

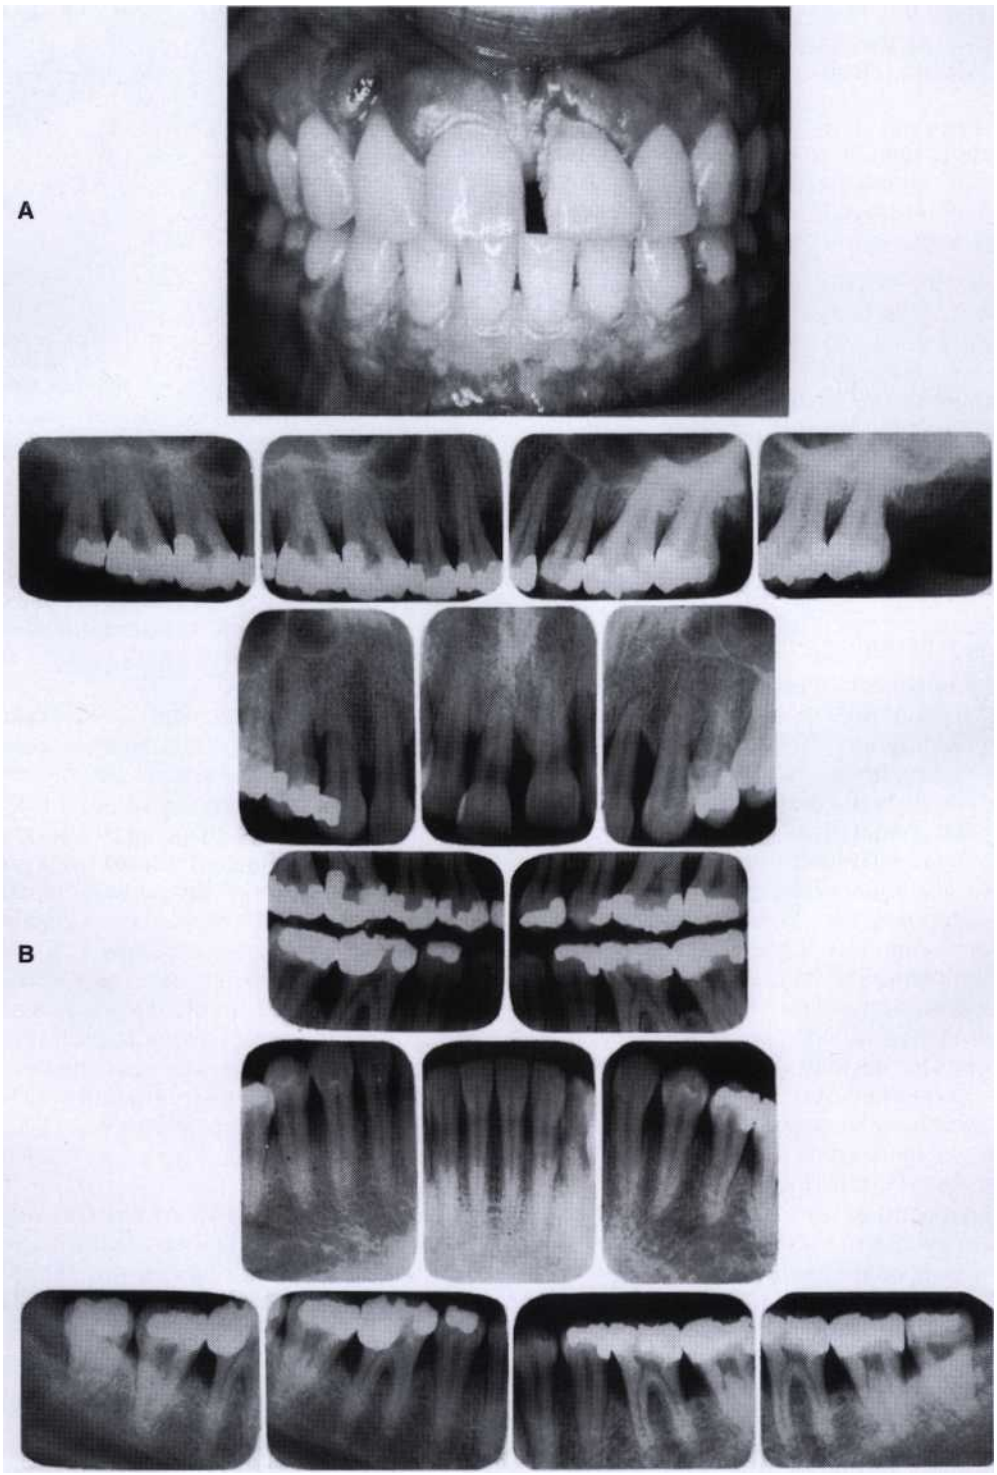

Fig. 30-8 Periodontal disease with pathologic migration of the anterior teeth. A, Clinical picture. B, Radiographic view.

Excessive overbite, seen most often in the anterior region, may cause impingement of the teeth on the gingiva and food impaction, followed by gingival inflammation, gingival enlargement, and pocket formation. The real significance of excessive overbite for gingival health, however, is controversial.'

In *open bite* relationships, abnormal vertical spaces exist between the maxillary and mandibular teeth. The condition occurs most often in the anterior region, although posterior open bite is occasionally seen. Reduced mechanical cleansing by the passage of food may lead to accumulation of debris, calculus formation, and extrusion of teeth.

In *crossbite,* the normal relationship of the mandibular **teeth to the maxillary teeth is reversed, with the maxillary teeth** being lingual to the mandibular teeth. Crossbite may be bilateral or unilateral, or it may affect only a pair of antagonists. Trauma from occlusion, food impaction, spreading of the mandibular teeth, and associated gingival and periodontal disturbances may be caused by crossbite.

Functional Occlusal Relationships. Examination of functional occlusal relationships is an important part of the diagnostic procedure. Dentitions that appear normal when the jaws are closed may present marked functional abnormalities. Systematic procedures for the detection and correction of functional abnormalities are presented in Chapter 52.

Examination of the Periodontium

The periodontal examination should be systematic, starting in the molar region in either the maxilla or the mandible and proceeding around the arch. This avoids overemphasis of spectacular findings at the expense of other conditions, which, although less striking, may be equally important. It is important to detect the earliest signs of gingival and periodontal disease.

Charts to record the periodontal and associated findings provide a guide for a thorough examination and record of the patient's condition (Fig. 30-9). They are also used for evaluating the response to treatment and for comparison at recall visits. However, excessively complicated mouth charting may lead to identification of a frustrating maze of minutiae rather than clarification of the patient's problem. Computerized dental examination systems using high-resolution graphics and voice-activated technology permit easy retrieval and comparison of data.8

A method for periodontal screening and recording (PSR) has been developed jointly by the American Academy of Periodontology and the American Dental Association, with the support of the Procter & Gamble Company.41 This method is designed for the general dental practitioner, and its purpose is to identify patients requiring periodontal care and to determine, in general terms, the type of care required. This method is presented at the end of this chapter.

Plaque and Calculus. There are many methods for assessing plaque and calculus accumulation." The presence of supragingival plaque and calculus can be directly observed and the amount measured with a calibrated probe. For the detection of subgingival calculus, each tooth surface is carefully checked to the level of the gingival attachment with a sharp no. 17 or no. 3A explorer (Fig. 30-10). Warm air may be used to deflect the gingiva and aid in visualization of the calculus.

Although the radiograph may sometimes reveal heavy calculus deposits interproximally (see Chapter 31) and even on the facial and lingual surfaces, it cannot be relied on for the thorough detection of calculus.

Gingiva. The gingiva must be dried before accurate observations can be made (Fig. 30-11). Light reflection from moist gingiva obscures detail. In addition to visual examination and exploration with instruments, firm but gentle palpation should be used for detecting pathologic alterations in normal resilience, as well as for locating areas of pus formation.

Each of the following features of the gingiva should be considered: color, size, contour, consistency, surface texture, position, ease of bleeding, and pain (see Chapters 17 and 18). No deviation from the norm should be overlooked. The distribution of gingival disease and its acuteness or chronicity should also be noted.

From a clinical point of view, gingival inflammation can produce two basic types of tissue response: edematous and fibrotic. Edematous tissue response is characterized by a smooth, glossy, soft, red gingiva. In the fibrotic tissue response, some of the characteristics of normalcy persist; the gingiva is more firm, stippled, and opaque, although it is usually thicker, and its margin appears rounded (Color Fig. 30-1).

Use of Clinical Indices in Dental Practice. There has been a tendency to extend the use of indices originally designed for epidemiologic studies into dental practice. A detailed description of these indices can be found in Chapter 5. Of all the indices that have been proposed, the Gingival Index and the Sulcus Bleeding Index appear to be the most useful and most easily transferred to clinical practice.

The *Gingival Index* (Loe and Silness) provides an assessment of gingival inflammatory status that can be used in practice to compare gingival health before and after Phase I therapy or before and after surgical therapy. It can also be used to compare gingival status at recall visits. Attaining good intra- and interexaminer calibration is imperative in the dental office.

The Sulcus *Bleeding Index* (Miihlemann and Son) provides an objective, easily reproducible assessment of the gingival status. It is extremely useful for detecting early inflammatory changes and the presence of inflammatory lesions located at the base of the periodontal pocket, an area inaccessible to visual examination. Because it is easily understood by the patient, the Sulcus Bleeding Index can be used to enhance the patient's motivation for plaque control.

Periodontal Pockets. Examination for periodontal pockets must include consideration of the following: presence and distribution on each tooth surface, pocket depth, level of attachment on the root, and type of pocket (suprabony or intrabony).

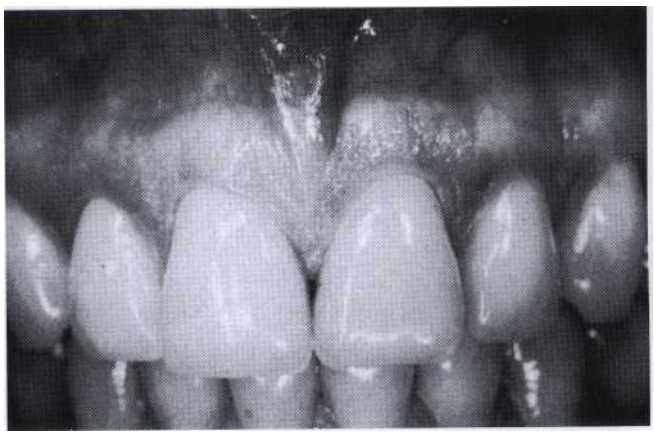

Fig. 30-11 Normal gingiva. Normal surface features are revealed by drying the gingiva.

SIGNS AND SYMPTOMS. Although probing is the only reliable method of detecting pockets, clinical signs such as color changes (bluish-red marginal gingiva or bluish-red vertical zone extending from the gingival margin to the attached gingiva); a "rolled" edge separating the gingival margin from the tooth surface; or an enlarged, edematous gingiva may suggest their presence. The presence of bleeding, suppuration, and loose, extruded teeth may also denote the presence of a pocket (Figs. 30-12 to 30-16 and see Color Fig. 30-1).

Periodontal pockets are generally painless but may give rise to symptoms such as localized or sometimes radiating pain or sensation of pressure after eating, which gradually diminishes. A foul taste in localized areas, sensitivity to hot and cold, and toothache in the absence of caries is also sometimes present.

DETECTION OF POCKETS. The only accurate method of detecting and measuring periodontal pockets is careful exploration with a periodontal probe. Pockets are not detected by radiographic examination. The periodontal pocket is a soft tissue change. Radiographs indicate areas of bone loss where pockets may be suspected; they do not show pocket presence or depth, and consequently they show no difference before or after pocket elimination unless bone has been modified.

Gutta percha points or calibrated silver points [19] can be used with the radiograph to assist in determining the level of attachment of periodontal pockets (Fig. 30-17). They may be used effectively for individual pockets or in clinical research, but their routine use throughout the mouth would be rather cumbersome. Clinical examination and probing are more direct and efficient.

POCKET PROBING. The two different pocket depths are (1) biologic or histologic depth and (2) clinical or probing depth [21] (Fig. 30-18) (see Chapter 1).

The biologic depth is the distance between the gingival margin and the base of the pocket (the coronal end of the junctional epithelium). This can be measured only in carefully prepared and adequately oriented histologic sections. The probing depth is the distance to which an ad hoc instrument (probe) penetrates into the pocket. The depth of penetration of a probe in a pocket depends on factors such as size of the probe, force with which it is introduced, direction of penetration, resistance of the tissues, and convexity of the crown. Probes presently used are described in Chapter 41.

Probe penetration can vary depending on the force of introduction, the shape and size of the probe tip and the degree of tissue inflammation.' Several studies have been made to determine the depth of penetration of a probe in a sulcus or pocket. Armitage and colleagues' used beagle dogs to evaluate the penetration of a probe using a standardized force of 25 grams. They reported that in healthy specimens, the probe penetrated the epithelium to about two thirds of its length; in gingivitis specimens, it stopped 0.1 mm short of its apical end; and in periodontitis specimens, the probe tip consistently went past the most apical cells of the junctional epithelium (Fig. 30-19).

In humans, the probe tip penetrates to the most coronal intact fibers of the connective tissue attachment . [25,52] The depth of penetration of the probe in the connective tissue apical to the junctional epithelium in a periodontal pocket is about 0.3 mm. [25,10,54] This is important in evaluating differences in probing depth before and after treatment, as the reduction in probe penetration may be a result of reduced inflammatory response rather than gain in attachment . [24,26]

The probing forces have been explored by several investigators [12,5';] forces of 0.75 N have been found to be well tolerated and accurate.' [6] Interexaminer error (depth discrepancies between examiners) was reported to be as much as 2.1 mm, with an average of 1.5 mm, in the same areas. [18]

PROBING TECHNIQUE. The probe should be inserted parallel to the vertical axis of the tooth and "walked" circumferentially around each surface of each tooth to detect the areas of deepest penetration (Fig. 30-20).

In addition, special attention should be directed to detecting the presence of interdental craters and furcation involvements. To detect an interdental crater, the probe should be placed obliquely from both the facial and lingual surfaces so as to explore the deepest point of the pocket located beneath the contact point (Fig. 30-21). In multirooted teeth the possibility of furcation involvement should be carefully explored. The use of specially designed probes (e.g., Nabers probe) allows an easier and more accurate exploration of the horizontal component of furcation lesions (Fig. 30-22).

LEVEL OF ATTACHMENT VERSUS POCKET DEPTH. Pocket depth is the distance between the base of the pocket and the gingival margin. It may change from

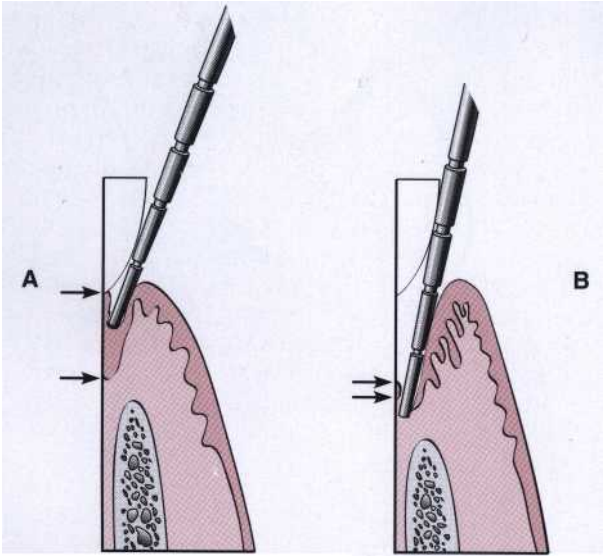

Fig. 30-19 A, In a normal sulcus with a long junctional epithelium (between arrows), the probe penetrates about one third to one half the length of the junctional epithelium. B, In a periodontal pocket with a short junctional epithelium (between arrows), the probe penetrates beyond the apical end of the junctional epithelium.

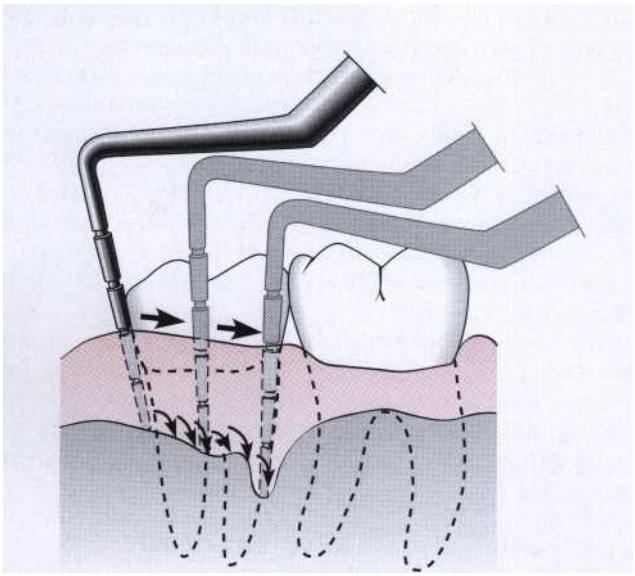

Fig. 30-20 "Walking" the probe to explore the entire pocket.

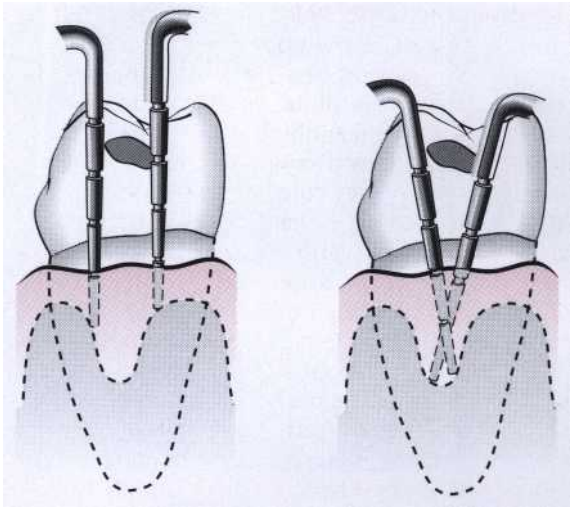

Fig. 30-21 Vertical insertion of the probe (left) may not detect interdental craters; oblique positioning of the probe (right) reaches the depth of the crater.

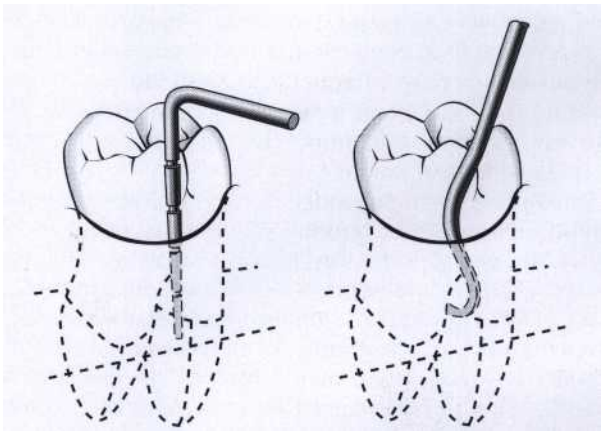

Fig. 30-22 Exploring with a periodontal probe (left) may not detect furcation involvement; specially designed instruments (Nabers probe) (right) can enter the furcation area.

time to time even in untreated periodontal disease owing to changes in the position of the gingival margin, and therefore it may be unrelated to the existing attachment of the tooth.

The level of attachment, on the other hand, is the distance between the base of the pocket and a fixed point on the crown, such as the cementoenamel junction. Changes in the level of attachment can be due only to gain or loss of attachment and afford a better indication of the degree of periodontal destruction. *Shallow pockets attached at the level of the apical third of the root connote more severe destruction than deep pockets attached at the coronal third of the roots* (see Chapter 22 and Figs. 22-19 and 22-20).

DETERMINING THE LEVEL OF ATTACHMENT. When the *gingival margin is located on the anatomic crown,* the level of attachment is determined by subtracting from the depth of the pocket the distance from the gingival margin to the cementoenamel junction. If both are the same, the loss of attachment is zero.

When the *gingival margin coincides with the cementoenamel junction,* the loss of attachment equals the pocket depth.

When the *gingival margin is located apical to the cementoenamel junction,* the loss of attachment is greater than the pocket depth, and therefore the distance between the cementoenamel junction and the gingival margin should be added to the pocket depth. Drawing the gingival

margin on the chart where pocket depths are entered helps clarify this important point.

BLEEDING ON PROBING. The insertion of a probe to the bottom of the pocket elicits bleeding if the gingiva is inflamed and the pocket epithelium is atrophic or ulcerated. Noninflamed sites rarely bleed. In most cases, bleeding on probing is an earlier sign of inflammation than gingival color changes" (see Chapter 17). However, sometimes color changes are found with no bleeding on probing.'[5] Depending on the severity of inflammation, bleeding can vary from a tenuous red line along the gingival sulcus to profuse bleeding.' After successful treatment, bleeding on probing ceases .[3]

To test for bleeding after probing, the probe is carefully introduced to the bottom of the pocket and gently moved laterally along the pocket wall. Sometimes bleeding appears immediately after removal of the probe; other times it may be delayed a few seconds. Therefore the clinician should recheck for bleeding 30 to 60 seconds after probing.

As a single test, bleeding on probing is not a good predictor of progressive attachment loss; however its absence is an excellent predictor of periodontal stability.' When present in multiple sites of advanced disease, bleeding on probing is a good indicator of progressive attachment loss.'" Armitage analyzed the literature on this subject up to 1996, performing a meta-analysis of the various papers and concluded that the presence of bleeding on probing in a "treated and maintained patient population" is an important risk predictor for increased loss of attachment.'

Insertion of a soft wooden interdental stimulator in the interdental space produces a similar bleeding response[3] and can be used by the patient to self-examine the gingiva for the presence of inflammation.'[°]

WHEN TO PROBE. Probing of pockets is done at various times for diagnosis, and for monitoring the course of treatment and maintenance. The initial probing of moderate or advanced cases is usually hampered by the presence of heavy inflammation and abundant calculus and cannot be done very accurately. The purpose of this initial probing, together with the clinical and radiographic examination is done, however, with the main purpose of determining whether the tooth can be saved or should be extracted. After the patient has performed an adequate plaque control for some time and calculus has been removed, the major inflammatory changes disappears, and a more accurate probing of the pockets can be performed. This second probing is for the purpose of accurately establishing the level of attachment and degree of involvement of roots and furcations. Data obtained from this probing provides valuable information for treatment decisions.

Further along periodontal treatment probings are done to determine changes in pocket depth and to ascertain healing progress after different procedures.

PROBING AROUND IMPLANTS. Since periimplantitis can create pockets around implants, probing around them becomes part of examination and diagnosis. To prevent scratching of the implant surface, plastic periodontal probes should be used instead of the usual steel probes used for the natural dentition.

Determination of Disease Activity. The determination of pocket depth or attachment levels does not provide information on whether the lesion is in an active or inactive state. Currently there is no sure method to determine activity or inactivity of a lesion. Inactive lesions may show little or no bleeding on probing and minimal amounts of gingival fluid; the bacterial flora, as revealed by dark-field microscopy, consists mostly of coccoid cells. Active lesions bleed more readily on probing and have large amounts of fluid and exudate; their bacterial flora shows a greater number of spirochetes and motile bacteria." In patients with aggressive periodontitis, progressing and nonprogressing sites may show no differences in bleeding on probing."

The precise determination of disease activity has a direct influence on diagnosis, prognosis, and therapy. The goals of therapy may change, depending on the state of the periodontal lesion. Chapter 34 describes in more detail the current state of knowledge in this important area.

Amount of Attached Gingiva. It is important to establish the relation between the bottom of the pocket and the mucogingival line. *The width of the attached gingiva is the distance between the mucogingival junction and the projection on the external surface of the bottom of the gingival sulcus or the periodontal pocket.* It should not be confused with the width of the keratinized gingiva, because the latter also includes the marginal gingiva (Fig. 30-23).

The width of the attached gingiva is determined by subtracting the sulcus or pocket depth from the total width of the gingiva (gingival margin to mucogingival line). This is done by stretching the lip or cheek to demarcate the mucogingival line while the pocket is being probed (Fig. 30-24). The amount of attached gingiva is generally considered to be insufficient when stretching of the lip or cheek induces movement of the free gingival margin.

Other methods used to determine the amount of attached gingiva include pushing the adjacent mucosa coronally with a dull instrument or painting the mucosa with Schiller's potassium iodide solution, which stains keratin.

Degree of Gingival Recession. During periodontal examination, it is necessary to record the data regarding the amount of gingival recession. This measurement is taken with a periodontal probe from the cementoenamel junction to the gingival crest.

Alveolar Bone Loss. Alveolar bone levels are evaluated by clinical and radiographic examination. Probing is helpful for determining (1) the height and contour of the facial and lingual bones obscured on the radiograph by the dense roots and (2) the architecture of the interdental bone. Transgingival probing, performed after the area is anesthetized, is a more accurate method of evaluation and provides additional information on bone architecture[",ZZ.ss] (see Chapter 62).

Palpation. Palpating the oral mucosa in the lateral and apical areas of the tooth may help locate the origin of radiating pain that the patient cannot localize. Infection deep in the periodontal tissues and the early stages of a periodontal abscess may also be detected by palpation.

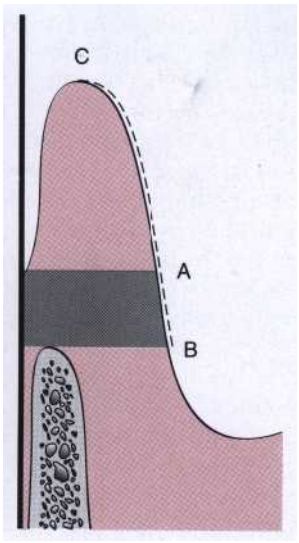

Fig. 30-23 The shaded area shows the attached gingiva, which extends between the projection on the external surface of the bottom of the pocket (A) and the mucogingival junction (8). The keratinized gingiva may extend from the mucogingival junction (8) to the gingival margin (C).

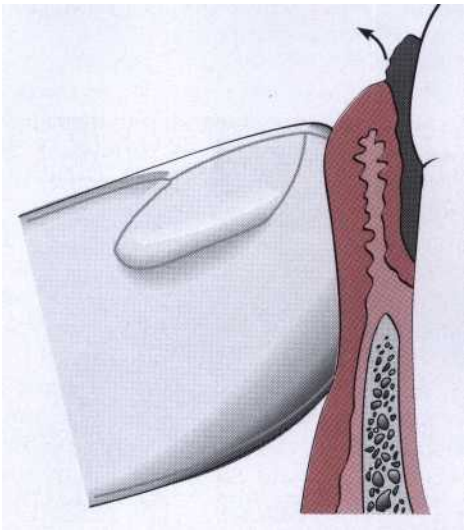

Fig. 30-25 Purulent exudate expressed from a periodontal pocket by digital pressure.

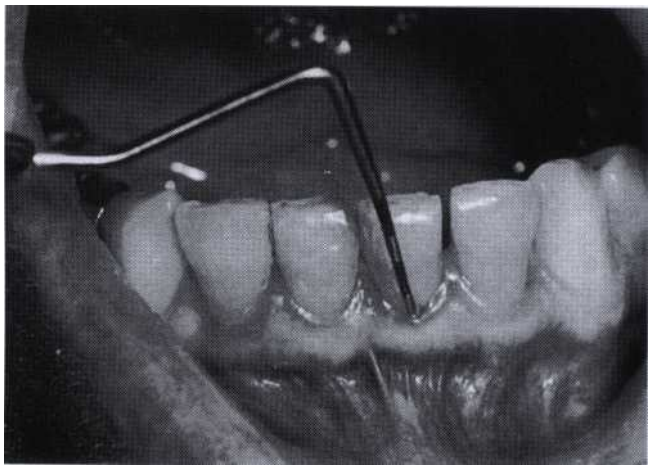

Fig. 30-24 To determine the width of the attached gingiva, the pocket is probed at the same time that the lip (or cheek) is extended to demarcate the mucogingival line.

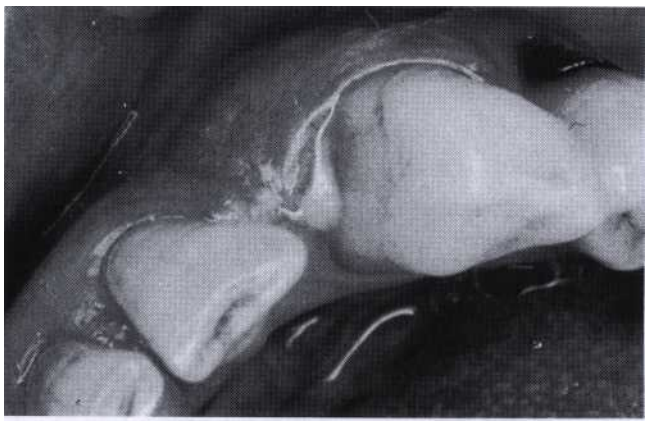

Fig. 30-26 Pus formation on the mesial surface of the mandibular canine.

Suppuration. The presence of an abundant number of neutrophils in the gingival fluid transforms it into a purulent exudate.' Several studiesb-'- [10-20] have evaluated the association between suppuration and the progression of periodontitis and reported that this sign is present in a very low percentage of sites with the disease (3 to 5%). [4] Therefore it is not by itself a good indicator.

Clinically, the presence of pus in a periodontal pocket is determined by placing the ball of the index finger along the lateral aspect of the marginal gingiva and applying pressure in a rolling motion toward the crown (Fig. 30-25). Visual examination without digital pressure is not enough. The purulent exudate is formed in the inner pocket wall, and therefore the external appearance may give no indication of its presence. Pus formation does not occur in all periodontal pockets, but digital pressure often reveals it in pockets where its presence is not suspected (Fig. 30-26).

Periodontal Abscess. A periodontal abscess is a localized accumulation of pus within the gingival wall of a periodontal pocket (see Chapter 22). Periodontal abscesses may be acute or chronic.

The *acute periodontal abscess* appears as an ovoid elevation of the gingiva along the lateral aspect of the root (Figs. 30-27 to 30-29). The gingiva is edematous and red, with a smooth, shiny surface. The shape and consistency of the elevated area vary; the area may be domelike and

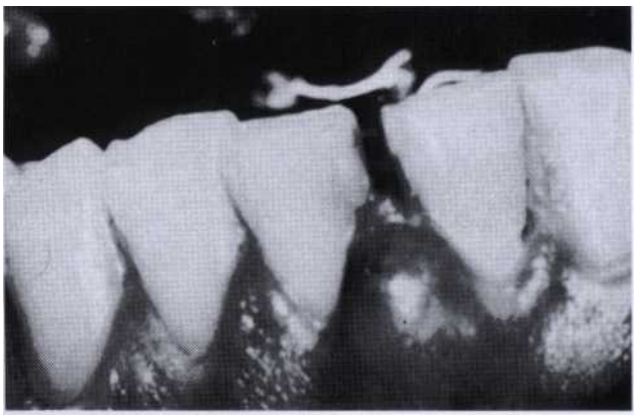

Fig. 30-27 Acute periodontal abscess between the lower central incisors.

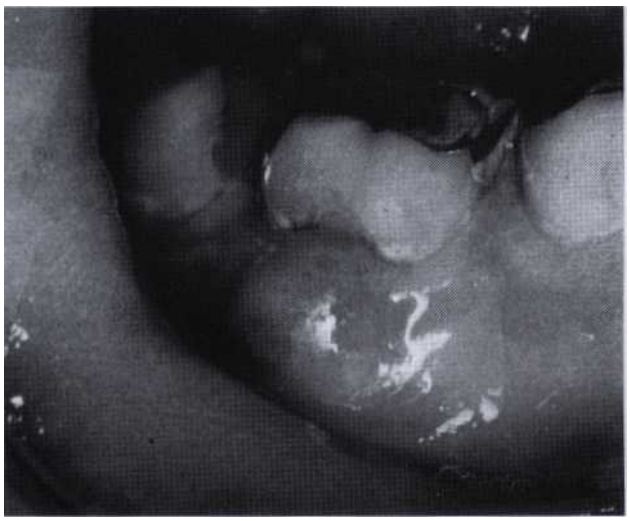

Fig. 30-29 Acute periodontal abscess in the wall of a deep pocket.

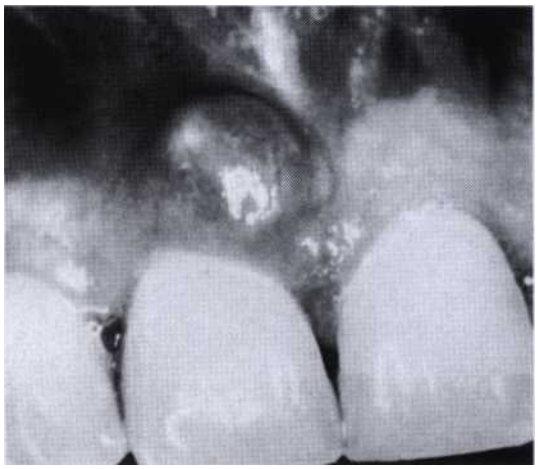

Fig. 30-28 Acute periodontal abscess associated with a deep periodontal pocket facial and mesial of upper central incisor.

relatively firm, or pointed and soft. In most cases, pus may be expressed from the gingival margin with gentle digital pressure.

The acute periodontal abscess is accompanied by symptoms such as throbbing, radiating pain; exquisite tenderness of the gingiva to palpation; sensitivity of the tooth to palpation; tooth mobility; lymphadenitis; and, less frequently, systemic effects such as fever, leukocytosis, and malaise. Occasionally, the patient may have symptoms of an acute periodontal abscess without any notable clinical lesion or radiographic changes.

The *chronic periodontal abscess* usually presents a sinus that opens onto the gingival mucosa somewhere along the length of the root. There may be a history of intermittent exudation. The orifice of the sinus may appear as a difficult-to-detect pinpoint opening, which, when probed, reveals a sinus tract deep in the periodontium (Fig. 30-30). The sinus may be covered by a small, pink, beadlike mass of granulation tissue (Fig. 30-31). The chronic periodontal abscess is usually asymptomatic. However, the patient may report episodes of dull, gnawing pain; slight elevation of the tooth; and a desire to bite down on and grind the tooth. The chronic periodontal abscess often undergoes acute exacerbations, with all the associated symptoms.

Diagnosis of the periodontal abscess requires correlation of the history and clinical and radiographic findings. The suspected area should be probed carefully along the gingival margin in relation to each tooth surface to detect a channel from the marginal area to the deeper periodontal tissues. Continuity of the lesion with the gingival margin is clinical evidence that the abscess is periodontal.

The abscess is not necessarily located on the same surface of the root as the pocket from which it is formed. A pocket at the facial surface may give rise to a periodontal abscess interproximally. It is common for a periodontal abscess to be located at a root surface other than that along which the pocket originated, because drainage is more likely to be impaired when a pocket follows a tortuous course.

In children a sinus orifice along the lateral aspect of a root is usually the result of periapical infection of a deciduous tooth. In the permanent dentition such an orifice may be caused by a periodontal abscess, as well as by apical involvement. The orifice may be patent and draining, or it may be closed and appear as a red, nodular mass (Fig. 30-32). Exploration of such masses with a probe usually reveals a pinpoint orifice that communicates with an underlying sinus.

Periodontal Abscess and Gingival Abscess. The principal differences between the periodontal abscess and the gingival abscess are the location and history

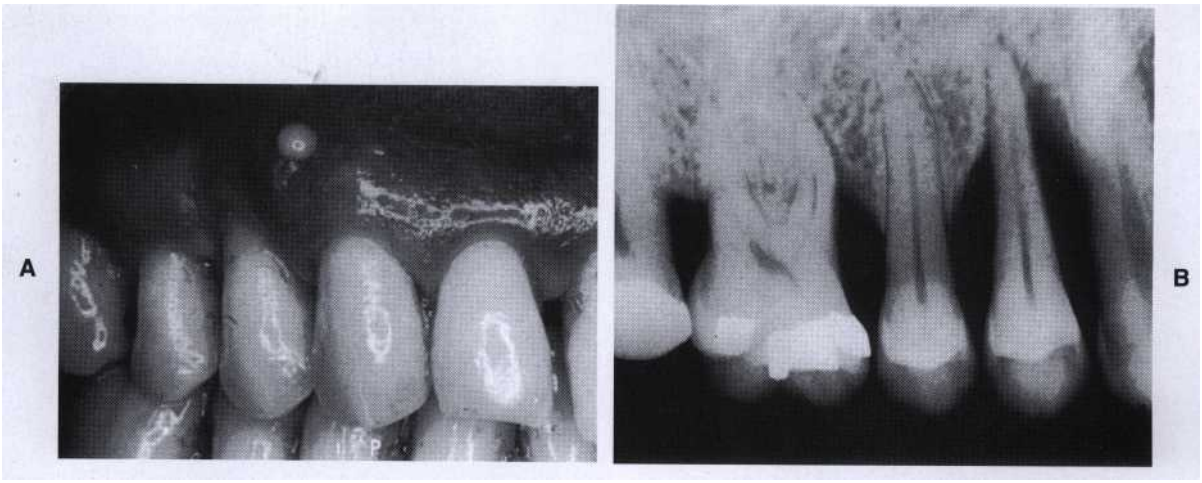

Fig. 30-30 **Suppuration from a chronic periodontal abscess. A, Suppurative draining sinus between the canine and first premolar. B, Radiograph showing extensive bone destruction in the area of the draining sinus.**

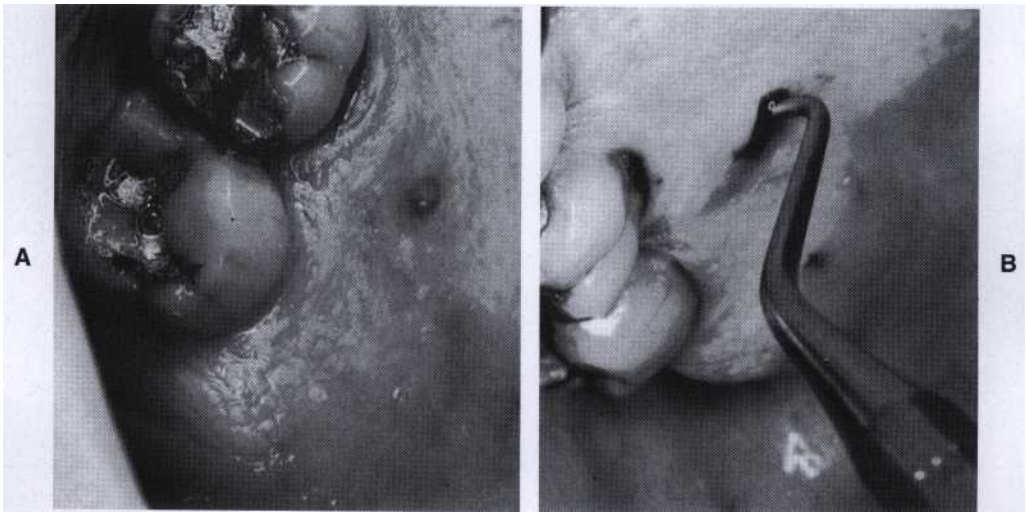

Fig. 30-31 **Pinpoint orifice of a sinus from a palatal periodontal abscess. A, Pinpoint orifice on the palate indicative of a sinus from a periodontal abscess. B, Probe extends into the abscess deep in the periodontium.**

(see Chapters 18 and 65). The gingival abscess is confined to the marginal gingiva, and it often occurs in previously disease-free areas (Fig. 30-33). It is usually an acute inflammatory response to forcing of foreign material into the gingiva. The periodontal abscess involves the supporting periodontal structures and generally occurs in the course of chronic destructive periodontitis.

Periodontal Abscess and Periapical Abscess. Several characteristics can be used as guidelines in differentiating a periodontal abscess from a periapical abscess. If the tooth is nonvital, the lesion is most likely periapical. However, a previously nonvital tooth can have a deep periodontal pocket that can abscess. Moreover, a deep periodontal pocket can extend to the apex and cause pulpal involvement and necrosis.

An apical abscess may spread along the lateral aspect of the root to the gingival margin. However, when the apex and lateral surface of a root are involved by a single lesion that can be probed directly from the gingival margin, the lesion is more likely to have originated in a periodontal abscess.

Radiographic findings are sometimes helpful in differentiating between a periodontal and a periapical lesion (see Chapter 31). Early acute periodontal and periapical abscesses present no radiographic changes. Ordinarily, a radiolucent area along the lateral surface of the root suggests the presence of a periodontal abscess, whereas apical rarefaction suggests a periapical abscess. However, acute periodontal abscesses that show no radiographic changes often cause symptoms in teeth with long-standing, radiographically detectable periapical lesions that are not con-

Fig. 30-32 Nodular mass at the orifice of a draining sinus.

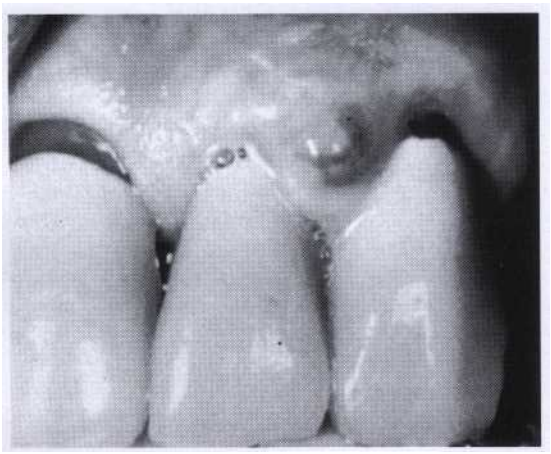

Fig. 30-33 Gingival abscess between upper lateral incisor and canine. The area is essentially free of gingivitis.

tributing to the patient's complaint. Clinical findings, such as the presence of extensive caries, pocket formation, lack of tooth vitality, and the existence of continuity between the gingival margin and the abscess area, often prove to be of greater diagnostic value than radiographic appearance.

A draining sinus on the lateral aspect of the root suggests periodontal rather than apical involvement; a sinus from a periapical lesion is more likely to be located further apically. However, sinus location is not conclusive. In many instances, particularly in children, the sinus from a periapical lesion drains on the side of the root rather than at the apex (see Chapter 65).

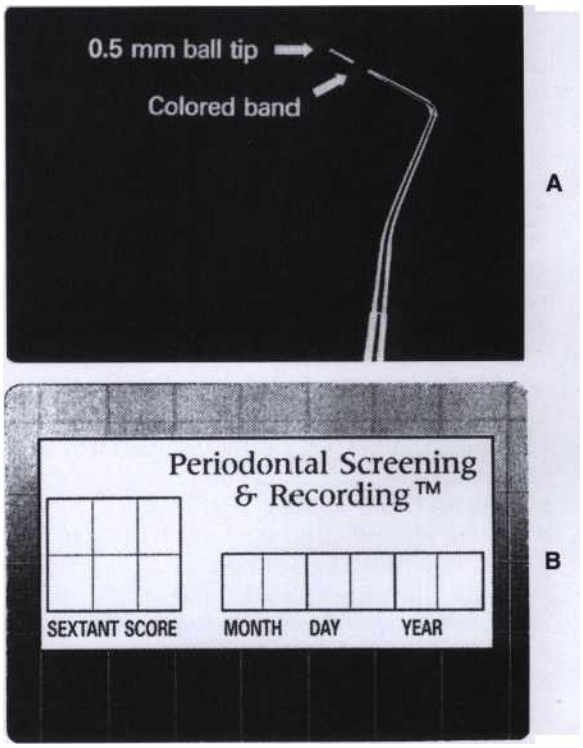

Fig. 30-34 A, Periodontal probe especially designed for the PSR system. Note the ball tip and the color coding, 3.5 to 5.5 mm from the probe tip. B, Special sticker to be placed in the patient's chart with the code for each sextant. (From the American Dental Association and the American Academy of Periodontology: Periodontal Screening & Recording Training Manual, 1992. Reprinted with permission from the American Dental Association.)

THE PERIODONTAL SCREENING AND RECORDING SYSTEM*

The Periodontal Screening & RecordingTM (PSR®) system is designed for easier and faster screening and recording of the periodontal status of a patient by a general practitioner or a dental hygienist.[34] It uses a specially designed probe that has a 0.5-mm ball tip and is color coded from 3.5 to 5.5 mm (Fig. 30-34, A).

The patient's mouth is divided into six sextants (maxillary right, anterior, and left; mandibular left, anterior, and right). Each tooth is probed, with the clinician walking the probe around the entire tooth to examine at least six points around each tooth: mesiofacial, midfacial, distofacial, and the corresponding lingual/palatal areas. The deepest finding is recorded in each sextant, along with other findings, according to the following code:

Code 0: In the deepest sulcus of the sextant, the probe's colored band remains completely visible. Gingival tissue is healthy and does not bleed on gentle probing. No calculus or defective margins are found. These patients require only appropriate preventive care.

***Periodontal Screening & RecordingTm and PSR° are service marks and trademarks of the American Dental Association.**

Code 1: The colored band of the probe remains completely visible in the deepest sulcus of the sextant; no calculus or defective margins are found, but some bleeding after gentle probing is detected. Treatment for these patients consists of subgingival plaque removal and appropriate oral hygiene instructions.

Code 2: The probe's colored band is still completely visible, but there is bleeding on probing, and supragingival or subgingival calculus and/or defective margins are found. Treatment should include plaque and calculus removal, correction of plaque-retentive margins of restorations, and oral hygiene instruction.

Code 3: The colored band is partially submerged. This indicates the need for a comprehensive periodontal examination and charting of the affected sextant to determine the necessary treatment plan. If two or more sextants score Code 3, a comprehensive full-mouth examination and charting is indicated.

Code 4: The colored band completely disappears in the pocket, indicating a depth greater than 5.5 mm. In this case a comprehensive full-mouth periodontal examination, charting, and treatment planning are needed.

*Code *:* When any of the following abnormalities are seen, an asterisk (*) is entered, in addition to the code number: furcation involvement, tooth mobility, mucogingival problem, or gingival recession extending to the colored band of the probe (3.5 mm or greater).

The code finding for each sextant and the date are entered on a sticker (Fig. 30-34, B), which is placed on the patient's record.

LABORATORY AIDS TO CLINICAL DIAGNOSIS

When unusual gingival or periodontal problems are present and cannot be explained by local causes, the possibility of contributing systemic factors must be explored. The dentist must understand the oral manifestations of systemic disease so that he or she can question the patient's physician regarding the type of systemic disturbance that may be involved in individual cases.

Numerous laboratory tests aid in the diagnosis of systemic diseases. Descriptions of the manner in which they are performed and the interpretation of findings are provided in standard texts on the subject. Tests pertinent to the diagnosis of disturbances often manifested in the oral cavity are referred to briefly here.

Nutritional Status

If, when examining a patient, it is the dentist's impression that a nutritional deficiency exists, this suspicion must be corroborated by a medical evaluation of the patient's nutritional status. Nutritional therapy in the treatment of periodontal disturbances must be based on a demonstrated need, which is best determined by a nutritionist.

Certain signs and symptoms have been identified with different nutritional deficiencies. However, many patients with nutritional disease do not exhibit classic signs of deficiency disorders, and different types of deficiency produce comparable clinical findings. Clinical findings are suggestive, but definitive diagnosis of nutritional deficiencies and their nature requires the combined information revealed by the history, clinical and laboratory findings, and therapeutic trial. Clinical findings identified with specific nutritional deficiencies and the oral manifestations of nutritional disorders are described in Chapter *12.*

Patients on Special Diets for Medical Reasons

Patients on low-residue, nondetergent diets often develop gingivitis because the prescribed foods lack cleansing action and the tendency for plaque and food debris to accumulate on the teeth is increased. Because fibrous foods are contraindicated, special effort is made to compensate for the soft diet by emphasizing the patient's oral hygiene procedures. Patients on salt-free diets should not be given saline mouthwashes, nor should they be treated with saline preparations without consulting their physician. Diabetes, gallbladder disease, and hypertension are examples of conditions in which particular care should be taken to avoid the prescription of contraindicated foodstuffs.

Blood Tests

Analyses of blood smears, red and white blood cell counts, white blood cell differential counts, and erythrocyte sedimentation rates are used to evaluate the presence of blood dyscrasias and generalized infections. Determination of coagulation time, bleeding time, clot retraction time, prothrombin time, capillary fragility test, and bone marrow studies may be required at times. They may be useful aids in the differential diagnosis of certain types of periodontal diseases; the reader is referred to books on hematology for a consideration of this subject.

Chapter 38 describes the use of these tests for the evaluation and management of medically compromised patients.

Radiographic Aids in the Diagnosis of Periodontal Disease

Fermin A. Carranza and Henry H. Takei

CHAPTER OUTLINE

RADIOGRAPHS IN THE DIAGNOSIS OF PERIODONTAL DISEASE
- **Normal Interdental Septa**
- **Distortions Produced by Variations in Radiographic Technique**
- **Bone Destruction in Periodontal Disease**
- **Radiographic Changes in Periodontitis**
- **Radiographic Appearance of Interdental Craters**
- **Radiographic Appearance of Furcation Involvements**
- **Radiographic Appearance of the Periodontal Abscess**
- **Radiographs and Clinical Probing**
- **Radiographic Changes in Localized, Aggressive Periodontitis**
- **Radiographic Changes in Trauma from Occlusion**
- **Additional Radiographic Criteria in the Diagnosis of Periodontal Disease**
- **Skeletal Disturbances Manifested in the jaws**

RADIOGRAPHS IN THE DIAGNOSIS OF PERIODONTAL DISEASE

The radiograph is a valuable aid in the diagnosis of periodontal disease, determination of the prognosis, and evaluation of the outcome of treatment. However, *it is an adjunct to the clinical examination, not a substitute for it.*

The radiograph reveals alterations in calcified tissue; it does not reveal current cellular activity but shows the effects of past cellular experience on the bone and roots. Special techniques that are not yet in routine clinical usage are required to show changes in the soft tissues of the periodontium.

Normal Interdental Septa

Radiographic evaluation of bone changes in periodontal disease is based mainly on the appearance of the interdental septa, because the relatively dense root structure obscures the facial and lingual bony plates. The interdental septum normally presents a thin radiopaque border, adjacent to the periodontal ligament and at the crest, that is referred to as the *lamina dura* (Fig. 31-1). This appears radiographically as a continuous white line, but in reality it is perforated by numerous small foramina, traversed by blood vessels, lymphatics, and nerves, which pass between the periodontal ligament and the bone. *Because the lamina dura represents the bone surface lining the tooth socket, the shape and position of the root and changes in the angulation of the x-ray beam produce considerable variations in its appearance."*

The width and shape of the interdental septum and the angle of the crest normally vary according to the convexity of the proximal tooth surfaces and the level of the cementoenamel junction of the approximating teeth.[27] The interdental space and therefore the interdental septum between teeth with prominently convex proximal surfaces are wider anteroposteriorly than are those between teeth with relatively flat proximal surfaces. The faciolingual diameter of the bone is related to the width of the proximal root surface. The angulation of the crest of the interdental septum is generally parallel to a line between the cementoenamel junctions of the approximating teeth (see Fig. 31-1). When there is a difference in the levels of the cementoenamel junctions, the crest of the Interdental bone appears angulated rather than horizontal.

Distortions Produced by Variations in Radiographic Technique

Variations in technique produce artifacts that limit the diagnostic value of the radiograph. The bone level, pattern of bone destruction, and width of the periodontal ligament space,[31] as well as the radiodensity, trabecular pattern, and marginal contour of the interdental septum are modified by altering the exposure and development time, type of film, and x-ray angulation.[17] Standardized, reproducible techniques are required to obtain reliable radiographs for pretreatment and posttreatment comparisons.'[6,22,29] A grid calibrated in millimeters, superimposed on the finished film, is helpful for comparing bone levels in radiographs taken under similar conditions[6] (Fig. 31-2).

The following discussion includes useful facts regarding the effects of angulation. The long cone paralleling technique projects the most realistic image of the level of the alveolar bone' (Fig. 31-3). The bisection-of-the-angle technique increases the projection and makes the bone margin appear closer to the crown; the level of the facial bone margin is distorted more than that of the lingual margin (see Fig. 31-3). Shifting the cone mesially or distally without changing the horizontal plane projects the x-rays obliquely and changes the shape of the interdental bone on the radiograph, the radiographic width of the periodontal ligament space, and the appearance of the lamina dura. It may also distort the extent of furcation involvement (Fig. 31-4).[11]

Prichard[21] established the following four criteria to determine adequate angulation of periapical radiographs:

1. The radiograph should show the tips of molar cusps with little or none of the occlusal surface showing.
2. Enamel caps and pulp chambers should be distinct.
3. Interproximal spaces should be open.
4. Proximal contacts should not overlap unless teeth are out of line anatomically.

Fig. 31-1 Crest of interdental septum normally parallel to a line drawn between the cementoenamel junction of adjacent teeth (arrow). Note also the radiopaclue lamina dura around the roots and interdental septum.

Bone Destruction in Periodontal Disease

The radiograph does not reveal minor destructive changes in bone[3,4,23]; therefore slight radiographic changes in the periodontal tissues mean that the disease has progressed beyond its earliest stages. *The earliest signs of periodontal disease must be detected clinically.*

The radiographic image tends to show less severe bone loss than that actually present.[31] The difference between the alveolar crest height and the radiographic appearance ranges from 0 to 1.6 mm,[25] mostly accounted for by x-ray angulation.

Amount of Bone Loss. The radiograph is an indirect method for determining the amount of bone loss in periodontal disease; it shows the amount of remaining bone rather than the amount lost. The amount of bone lost is estimated to be the difference between the physiologic bone level of the patient and the height of the remaining bone.
