The distance from the cementoenamel junction (CEJ) to the alveolar crest has been analyzed by several investigators.[12,14,25] Most studies have been conducted in adolescents and the general consensus seems to be a distance of 2 mm; this distance may be greater in older patients.

Distribution of Bone Loss. The distribution of bone loss is an important diagnostic sign. It points to the location of destructive local factors in different areas of the mouth and in relation to different surfaces of the same tooth.

Pattern of Bone Destruction. *In periodontal disease, the interdental septa undergo changes that affect the*

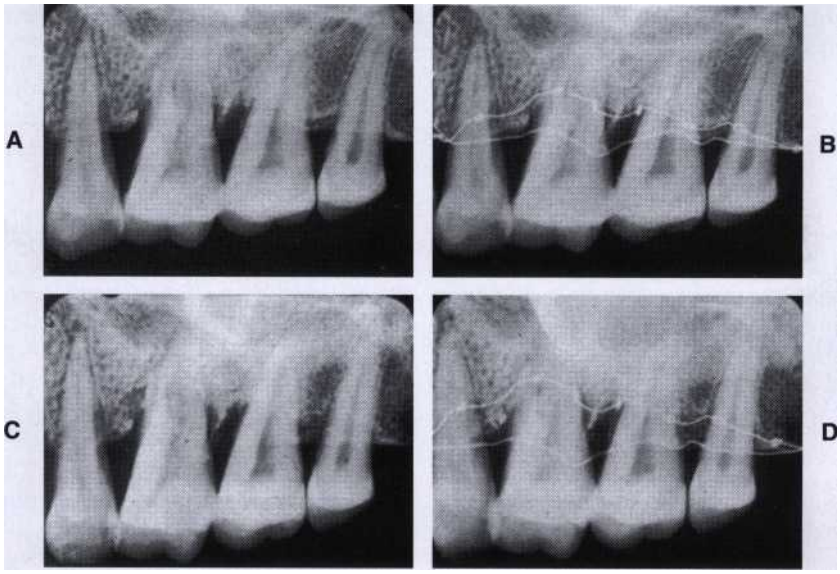

Fig. 31-3 Long cone paralleling technique and bisection of the angle technique compared. A, Long cone technique. Radiograph of dried specimen. B, Long cone technique. Same specimen. The smooth wire is on the margin of the facial plate and the knotted wire is on the lingual plate to show their relative positions. C, Bisection of the angle technique. Same specimen. D, Bisection of the angle technique. Same specimen. Both bone margins are shifted toward the crown, the facial margin (smooth wire) more than the lingual margin (knotted wire), creating the illusion that the lingual bone margin has shifted apically. (Courtesy Dr. Benjamin Patur, Hartford, CT.)

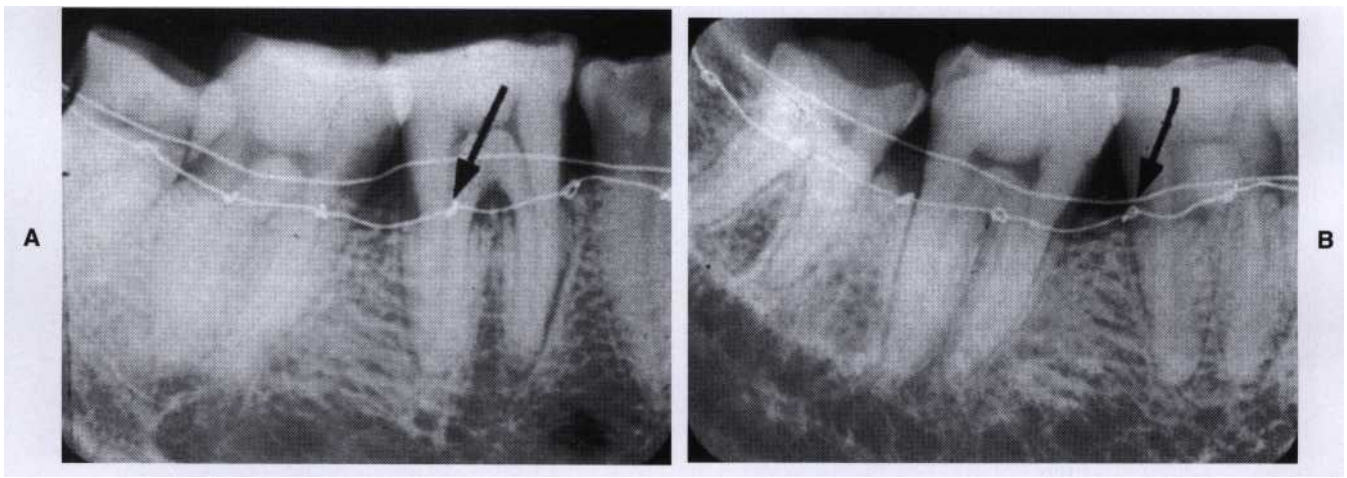

Fig. 31-4 Distortion by oblique projection. A, Long cone technique. The smooth wire is on the facial bony plate, the knotted wire on the lingual. Note the knot (arrow) near the center of the distal root of the first molar, which shows bifurcation involvement. B, Long cone technique. Cone is placed distally, projecting the rays mesially and obliquely. The oblique projection shifts the image of all structures mesially. *The structures closest to the cone shift the most.* This creates the illusion that the knot (arrow) has moved distally. Note that the bifurcation involvement shown in A is obliterated in B. (Courtesy Dr. Benjamin Patur, Hartford, CT.)

lamina dura, crestal radiodensity, size and shape of the medullary spaces, and height and contour of the bone. The interdental septa may be reduced in height, with the crest horizontal and perpendicular to the long axis of the adjacent teeth (Fig. 31-5), or they may have angular or arcuate defects (Fig. 31-6). The former condition is called *horizontal bone loss,* the latter *angular* or *vertical bone loss* (see Chapter 23).

Radiographs do not indicate the internal morphology or depth of the craterlike interdental defects, which appear as angular or vertical defects, nor do they reveal the extent of involvement on the facial and lingual surfaces. There are several reasons for this. Facial and lingual surface bone destruction is obscured by the dense root structure, and bone destruction on the mesial and distal root surfaces may be partially hidden by a dense mylo-

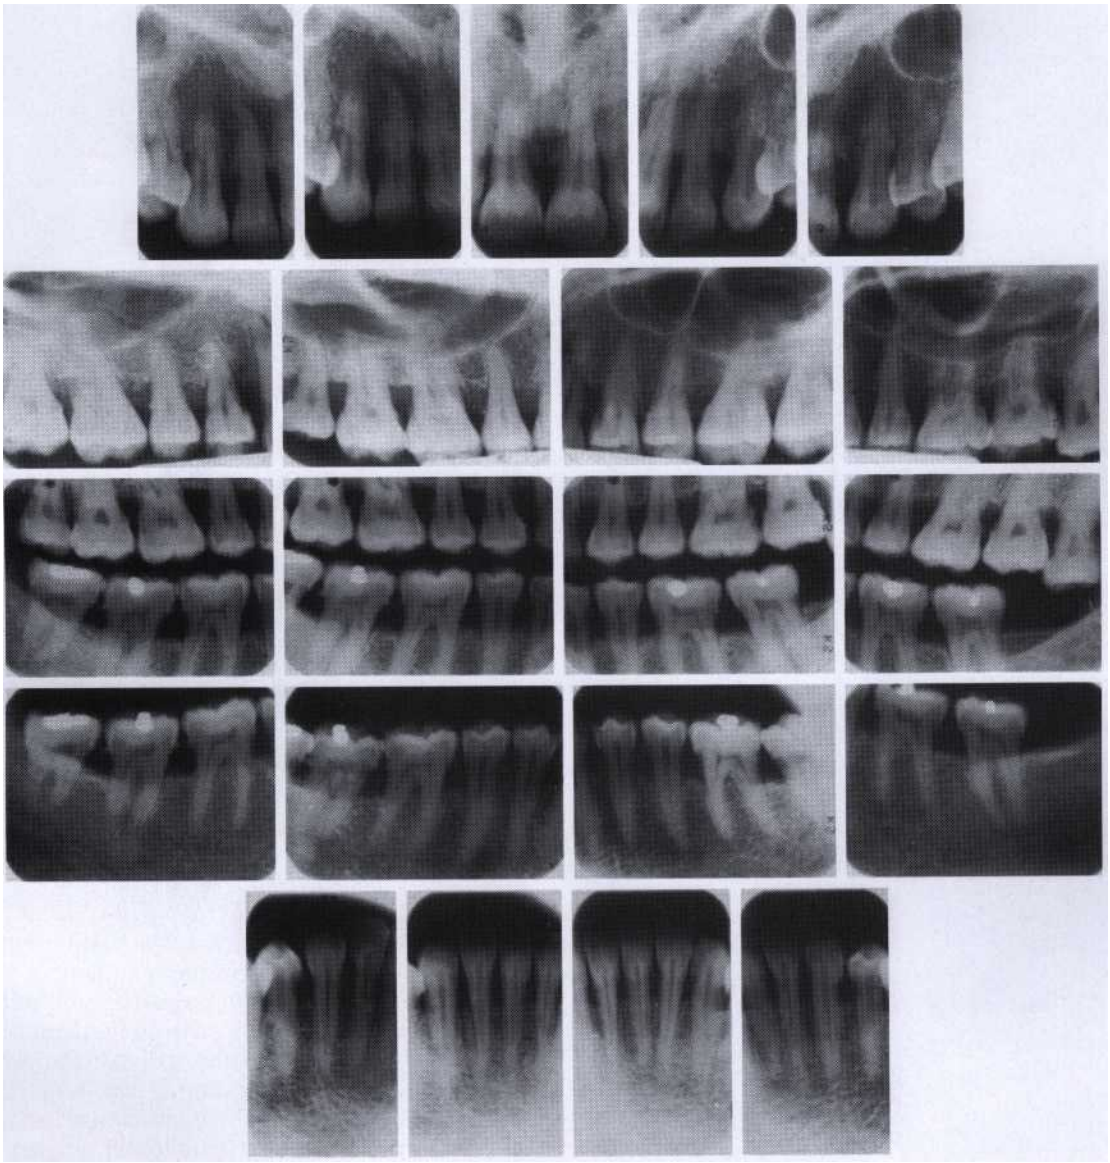

Fig. 31-5 Generalized horizontal bone loss.

hyoid ridge (Fig. 31-7). In most cases it can be assumed that bone losses seen interdentally continue in either the facial or lingual aspects creating a troughlike lesion. The true lesion can only be detected by clinically probing the defect.

Dense cortical plates on the facial and lingual surfaces of the interdental septa obscure destruction that occurs in the intervening cancellous bone. Thus it is possible to have a deep crater in the bone between the facial and lingual plates without radiographic indications of its presence. For destruction of the interproximal cancellous bone to be recorded radiographically, the cortical bone must be involved. A reduction of only 0.5 or 1.0 mm in the thickness of the cortical plate is sufficient to permit radiographic visualization of destruction of the inner cancellous trabeculae."

Interdental vertical lesions in the posterior area with thick facial or lingual bone may not be isolated in the interdental area but may continue facially or lingually or both to form a troughlike defect that cannot be seen radiographically. These lesions may terminate on either the radicular surface or may communicate with the adjacent interdental area to form one continuous lesion (Fig. 31-8).

Fig. 31-9 shows two adjacent interdental lesions connecting on the radicular surface to form one interconnecting osseous lesion. Along with clinical probing of these lesions, the use of a radiopaque pointer placed in these radicular defects will demonstrate the extent of the bone loss.

Gutta percha packed around the teeth increases the usefulness of the radiograph for detecting the morphologic changes of osseous craters and involvement of the facial and lingual surfaces (Fig. 31-10). However, this is a cumbersome technique and is seldom performed. Surgical exposure and visual examination provide the most

definitive information regarding the bone architecture produced by periodontal destruction.20

Radiographic Changes in Periodontitis

The following is the sequence of radiographic changes in periodontitis and the tissue changes that produce them:

1. *Fuzziness and a break in the continuity of the lamina dura* at the mesial or distal aspect of the crest of the interdental septum have been considered as the earliest radiographic changes in periodontitis (Fig. 31-11). These result from the extension of gingival inflammation into the bone causing widening of the vessel channels and a reduction in calcified tissue at the septal margin.

These changes are however highly dependent on the radiographic technique (angulation of the tube, placement of the film) and on anatomical variations (thickness and density of the interdental bone, position of adjoining teeth). No correlation has been found between crestal lamina dura in radiographs and the presence or absence of clinical inflammation, bleeding on probing, periodontal pockets, or loss of attachment.[1,24] Therefore it can be concluded that the presence of an intact crestal lamina dura may be an indicator of periodontal health, whereas its absence lacks diagnostic relevance.2

2. *A wedge-shaped radiolucent area is* formed at the mesial or distal aspect of the crest of the septal bone (see Fig. 31-11, B). The apex of the area is pointed in the direction of the root. This is produced by resorption of the bone of the lateral aspect of the interdental septum, with an associated widening of the periodontal space.
3. The destructive process extends across the crest of the interdental septum and *the height is reduced.* Fingerlike radiolucent projections extend from the crest into the septum (see Fig. 31-11, C). The radiolucent projections into the interdental septum are the result of the deeper extension of the inflammation into the bone. Inflammatory cells and fluid, proliferation of connective tissue cells, and increased osteoclasis cause increased bone resorption along the endosteal margins of the medullary spaces. The radiopaque projections, separating the radiolucent spaces, are the composite images of the partially eroded bony trabeculae.

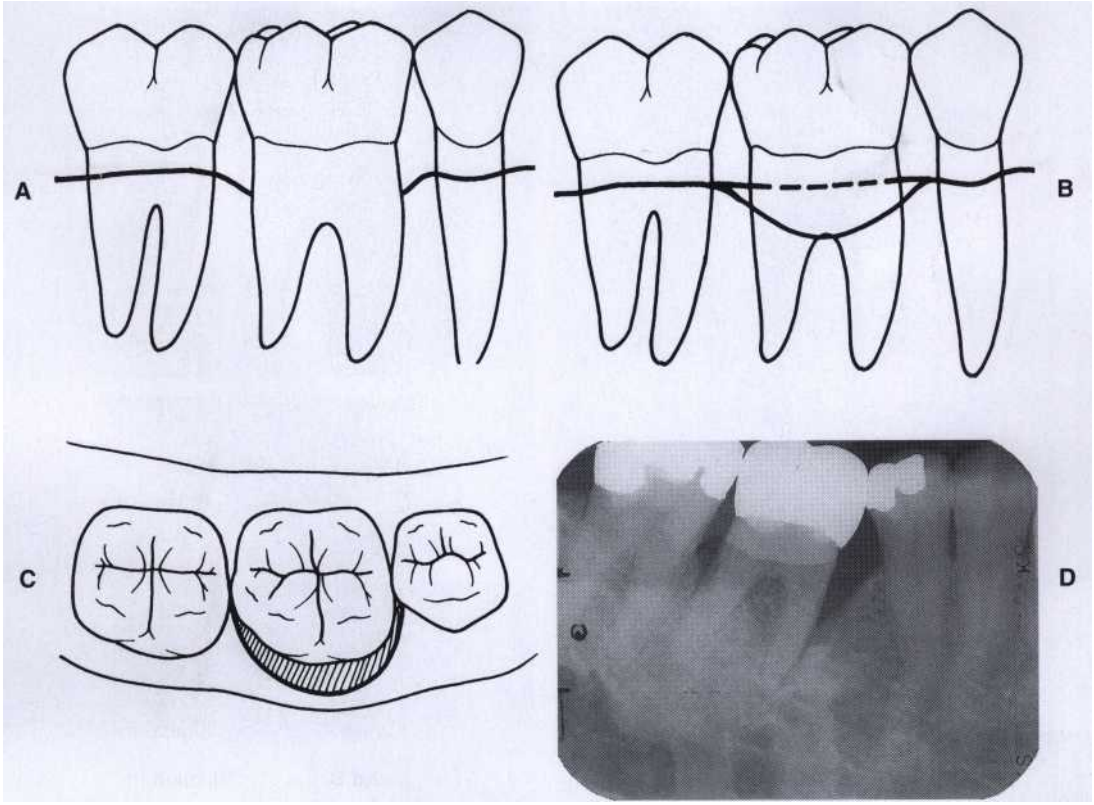

Fig. 31-9 A, Interdental mesial and distal lesions. B, Facial or lingual outlines of actual lesion. C, Occlusal view of lesion. D, Actual radiograph of mesial and facial lesions.

Fig. 31-10 Gutta percha aids in detecting bone defects. A, Gutta percha packed around teeth shows interproximal and facial and lingual bone loss. B, Same area without gutta percha gives little indication of the extent of bone involvement.

4. The height of the interdental septum (see Fig. 31-11, D) is progressively reduced by the extension of inflammation and the resorption of bone.

Radiographic Appearance of Interdental Craters

Interdental craters are seen as irregular areas of reduced radiopacity on the alveolar bone crests[26]; they are generally not sharply demarcated from the rest of the bone, with which they blend gradually. Radiographs do not accurately depict the morphology or depth of interdental craters, which sometimes appear as vertical defects.

Radiographic Appearance of Furcation Involvements

Definitive diagnosis of furcation involvement is made by clinical examination, which includes careful probing with a specially designed probe (Nabers probe). Radiographs are helpful but show artifacts that make it

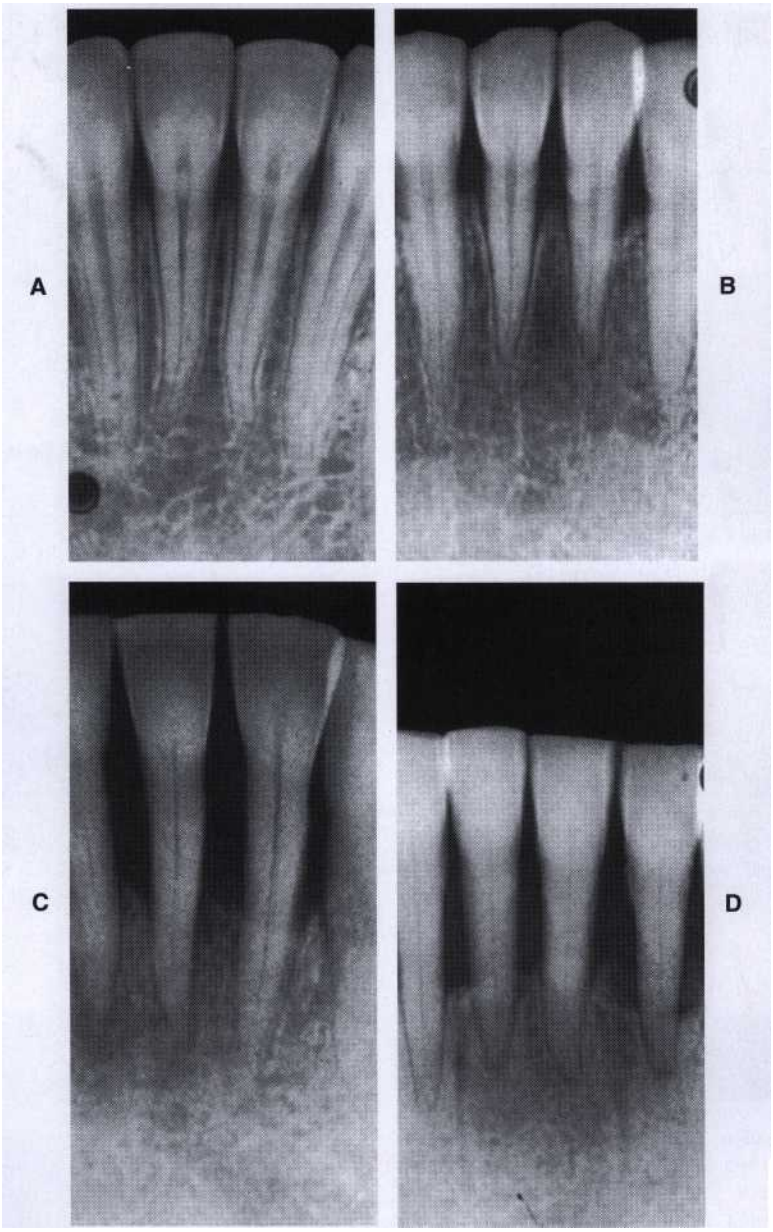

Fig. 31-11 Radiographic changes in periodontitis. A, Normal appearance of interdental septa. B, Fuzziness and a break in the continuity of the lamina dura at the crest of the bone distal to the central incisor *(left).* **There are wedge-shaped radiolucent areas at the crests of the other interdental septa. C, Radiolucent projections from the crest into the interdental septum indicate extension of destructive processes. D, Severe bone loss.**

possible for furcation involvement to be present without detectable radiographic changes.

As a general rule, bone loss is always greater than it appears in the radiograph. Variations in the radiographic technique may obscure the presence and extent of furcation involvement. A tooth may present marked bifurcation involvement in one film (Fig. 31-12, *A)* but appear to be uninvolved in another (see Fig. 31-12, B). Radiographs should be taken at different angles to reduce the risk of missing furcation involvement.

The recognition of large, clearly defined radiolucency in the furcation area presents no problem (see Fig. 31-12, A), but less clearly defined radiographic changes produced by furcation involvement are often overlooked. To assist in the radiographic detection of furcation involvement, the following diagnostic criteria are suggested:

1. The slightest radiographic change in the furcation area should be investigated clinically, especially if there is bone loss on adjacent roots (Fig. 31-13).
2. Diminished radiodensity in the furcation area in which outlines of bony trabeculae are visible (Fig. 31-14) suggests furcation involvement.
3. Whenever there is marked bone loss in relation to a single molar root, it may be assumed that the furcation is also involved (Figs. 31-15 and 31-16).

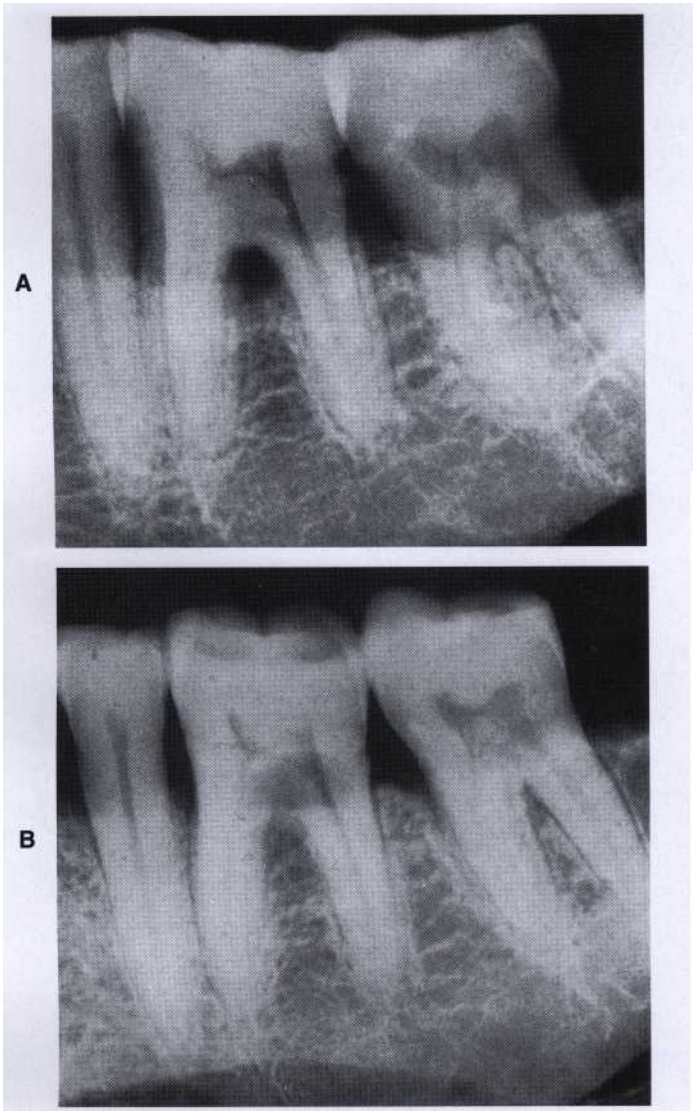

Fig. 31-12 A, Furcation involvement indicated by triangular radiolucency in bifurcation area of mandibular first molar. The second molar presents only a slight thickening of the periodontal space in the bifurcation area. B, Same area, different angulation. The triangular radiolucency in the bifurcation of the first molar is obliterated, and involvement of the second molar bifurcation is apparent.

Fig. 31-13 Early furcation involvement suggested by fuzziness in the bifurcation of the mandibular first molar, particularly when associated with bone loss on the roots.

Fig. 31-14 Furcation involvement of mandibular first and second molars indicated by thickening of periodontal space in furcation area. The furcation of the third molar is also involved, but the thickening of the periodontal space is partially obscured by the external oblique line.

Fig. 31-15 Furcation involvement of the first molar, associated with bone loss on the distal root.

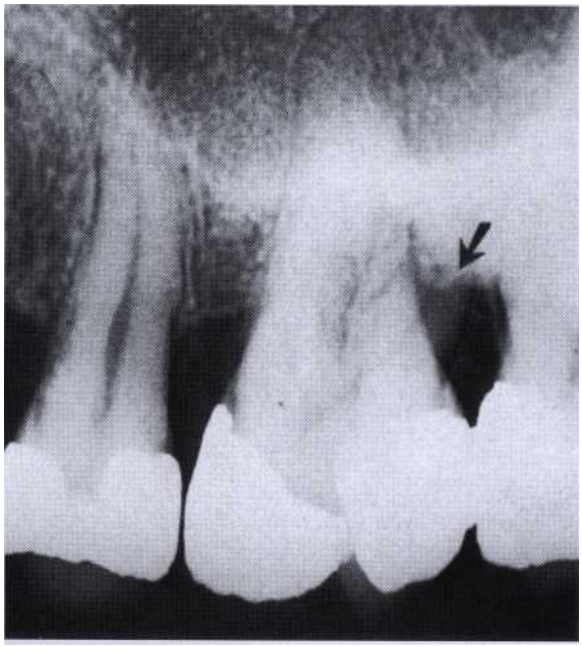

Fig. 31-16 Furcation involvement of the first molar partially obscured by the radiopaclue lingual root. The horizontal line across the distobuccal root demarcates the apical portion (arrow), which is covered by bone, from the remainder of the root, where the bone has been destroyed.

Fig. 31-18 Typical radiographic appearance of periodontal abscess on right central incisor.

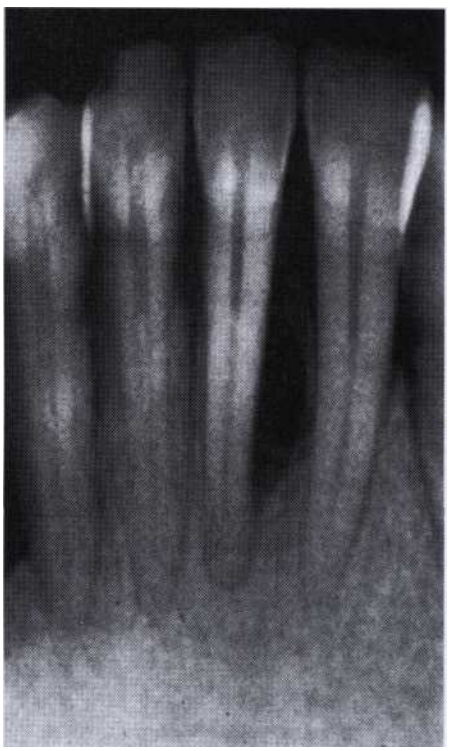

Fig. 31-17 Radiolucent area on the lateral aspect of the root with chronic periodontal abscess.

Radiographic Appearance of the Periodontal Abscess

The typical radiographic appearance of the periodontal abscess is that of a discrete area of radiolucency along the lateral aspect of the root (Figs. 31-17 and 31-18). *However, the radiographic picture is often not typical* (Fig. 31-19) because of many variables such as the following:

1. *The stage of the lesion.* In the early stages the acute periodontal abscess is extremely painful but presents no radiographic changes.
2. *The extent of bone destruction and the morphologic changes of the bone.*
3. *The location of the abscess.* Lesions in the soft tissue wall of a periodontal pocket are less likely to produce radiographic changes than those deep in the supporting tissues. Abscesses on the facial or lingual surface are obscured by the radiopacity of the root; interproximal lesions are more likely to be visualized radiographically.

Therefore *the radiograph alone cannot be relied on for the diagnosis of a periodontal abscess.*

Radiographs and Clinical Probing

Regenerative and resective flap designs and incisions require prior knowledge of the underlying osseous topography. Careful probing of these pocket areas after scaling

Fig. 31-19 Chronic periodontal abscess. A, Periodontal abscess in the right central and lateral incisor area. B, Extensive bone destruction and thickening of the periodontal ligament space around the right central incisor.

Fig. 31-20 A, Radiograph of maxillary cuspid. Does not show facial bone loss. B, Radiograph of same maxillary cuspid with gutta percha points placed in the facial pocket to indicate bone loss.

and root planing often require local anesthesia and definitive radiographic evaluation of the osseous lesions. Radiographs taken with periodontal probes or other indicators (e.g., Hirschfeld pointers) placed into the anesthetized pocket show the true extent of the bone lesion. As indicated previously, the attachment level on the radicular surface or interdental lesions with thick facial or lingual bone cannot be visualized in the radiograph. The use of radiopaque indicators is an efficient diagnostic aid for the clinician to better visualize every aspect of the defect. Figs. *31-20,* A and B, are examples of probes placed in pockets to indicate the bone level.

Radiographic Changes in Localized, Aggressive Periodontitis

Juvenile periodontitis is characterized by a combination of the following radiographic features:

1. Bone loss may occur initially in the maxillary and mandibular incisor and/or first molar areas, usually bilaterally, and results in vertical, arclike destructive patterns (Fig. *31-21).*
2. Loss of alveolar bone may become generalized as the disease progresses but remains less pronounced in the premolar areas.

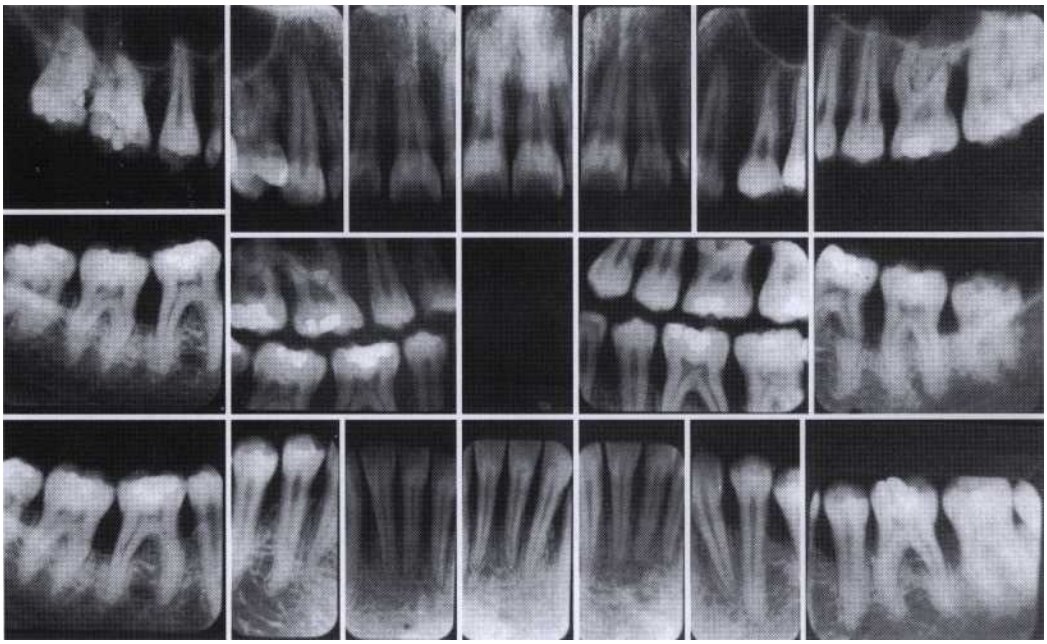

Fig. 31-21 Localized aggressive periodontitis. The accentuated bone destruction in the anterior and first molar areas is considered to be characteristic of this disease.

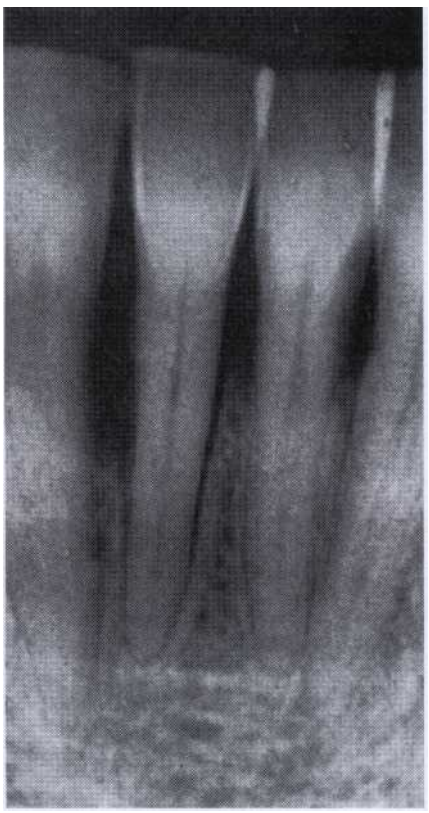

Fig. 31-22 Widened periodontal space caused by trauma from occlusion. Note the increased density of the surrounding bone caused by new bone formation in response to increased occlusal forces.

Radiographic Changes in Trauma from Occlusion

Trauma from occlusion can produce radiographically detectable changes in the lamina dura, morphology of the alveolar crest, width of the periodontal space, and density of the surrounding cancellous bone.

Traumatic lesions manifest themselves more clearly in faciolingual aspects, because mesiodistally, the tooth has the added stability provided by the contact areas with adjacent teeth. Therefore slight variations in the proximal surfaces may indicate greater changes in the facial and lingual aspects. *The radiographic changes listed below are not pathognomonic o f trauma from occlusion and have to be interpreted in combination with clinical findings,* particularly tooth mobility, presence of wear facets, pocket depth, and analysis of occlusal contacts and habits.

The *injury phase* of trauma from occlusion produces a loss of the lamina dura that may be noted in apices, furcations, and/or marginal areas. This loss of lamina dura results in widening of the periodontal ligament space (Fig. 31-22). This change, particularly when incipient or circumscribed, may easily be confused with technical variations due to x-ray angulation or malposition of the tooth; it can be diagnosed with certainty only in radiographs of the highest quality.

The *repair phase* of trauma from occlusion results in an attempt to strengthen the periodontal structures to better support the increased loads. Radiographically, this is manifested by a widening of the periodontal ligament space, which may be generalized or localized.

Although microscopic measurements have determined that there are normal variations in the width of the periodontal space in the different regions of the root,

these are not generally detected in radiographs. When variations in width between the marginal area and midroot or between the midroot and apex are detected, it means that the tooth is being subjected to increased forces. Successful attempts to reinforce the periodontal structures by widening of the periodontal space is accompanied by increased width of the lamina dura and sometimes by condensation of the perialveolar cancellous bone.

More advanced traumatic lesions may result in deep angular bone loss, which, when combined with marginal inflammation, may lead to intrabony pocket formation. In terminal stages these lesions extend around the root apex, producing a wide radiolucent periapical image (cavernous lesions).

Root resorption may also occur as a result of excessive forces on the periodontium, particularly those caused by orthodontic appliances. Although trauma from occlusion produces many root resorption areas, they are usually of a magnitude insufficient to be detected radiographically.

Additional Radiographic Criteria in the Diagnosis of Periodontal Disease

The following diagnostic criteria can be used to aid in the diagnosis of periodontal disease:

Radiopaque horizontal line across the roots. This line demarcates the portion of the root where the labial and/or lingual bony plate has been partially or completely destroyed from the remaining bone-supported portion (Fig. 31-23).

Vessel canals in the alveolar bone. Hirschfeld[13] described linear and circular radiolucent areas produced by interdental canals and their foramina, respectively (Fig. 31-24). These canals indicate the course of the vascular supply of the bone and are normal radiographic findings. The radiographic image of the canals is often so prominent, particularly in the anterior region of the mandible, that they might be confused with radiolucency resulting from periodontal disease.

Differentiation between treated and untreated periodontal disease. It is sometimes necessary to determine whether the reduced bone level is the result of periodontal disease that is no longer destructive (usually after treatment and proper maintenance) or if destructive periodontal disease is present. Clinical examination is the basic determinant. However, radiographically detectable alterations in the normal clear-cut peripheral outline of the septa are corroborating evidence of destructive periodontal disease.

Skeletal Disturbances Manifested in the jaws

Skeletal disturbances may produce changes in the jaws that affect the interpretation of radiographs from the periodontal perspective. Destruction of tooth-supporting bone may occur in the following diseases:

Osteitis fibroua cystica (Recklinghausen's disease of bone) develops in advanced primary or secondary hyperparathyroidism and causes osteoclastic resorption of bone with fibrous replacement and hemorrhage with hemosiderin deposition, creating a mass known as *brown tumors* (see Figs. 12-1 and 12-2). It often appears as a cystic lesion of the jaw. This disease results in a diffuse granular mottling, scattered "cyst-like" radiolucent areas throughout the jaws, and a

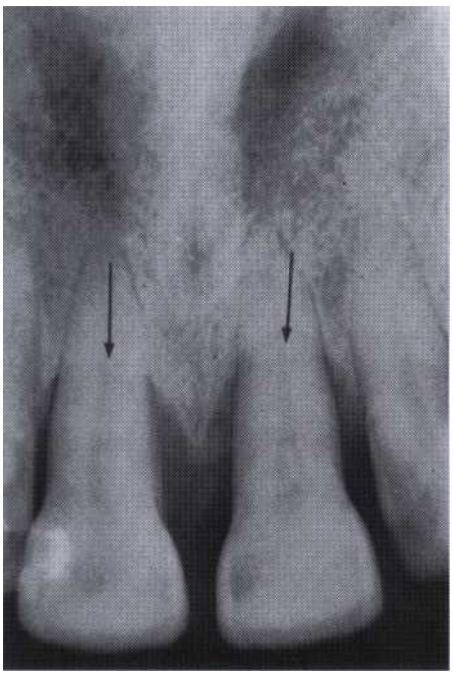

Fig. 31-23 Horizontal lines across the roots of the central incisors (arrows). The area of the roots below the horizontal lines is partially or completely denuded of the facial and/or lingual bony plates.

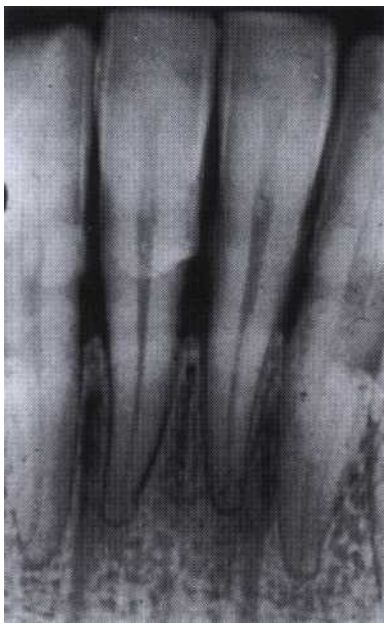

Fig. 31-24 Prominent vessel canals in the mandible.

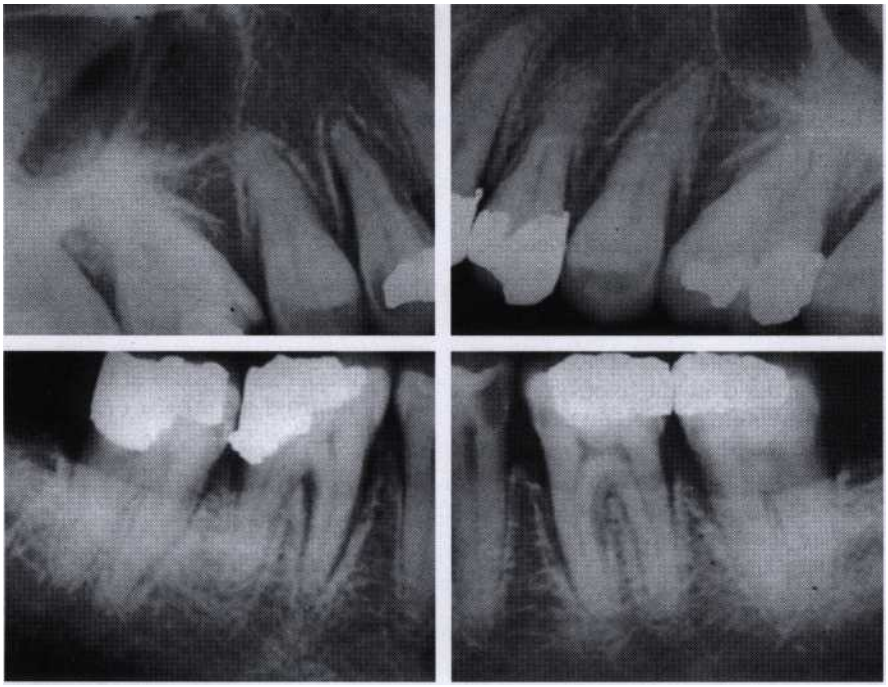

Fig. 31-28 Scleroderma, showing typical uniform widening of the periodontal ligament and thickening of the lamina dura. (Courtesy Drs. David F. Mitchell and Anand P. Chaudhry.)

generalized disappearance of the lamina dura.[28] Correction of the parathyroid hyperfunction usually results in rapid reversion of the bone to normal.

In *Paget's disease,* the normal trabecular pattern is replaced by a hazy, diffuse meshwork of closely knit, fine trabecular markings, with the lamina dura absent (Fig. 31-25), or scattered radiolucent areas may contain irregularly shaped radiopaque zones.[10,32]

Fibrous dysplasia may appear as a small radiolucent area at a root apex or as an extensive radiolucent area with irregularly arranged trabecular markings.' There may be enlargement of the cancellous spaces, with distortion of the normal trabecular pattern ("ground glass" appearance) and obliteration of the lamina dura (Fig. 31-26).

Langerhans' cell histiocytosis results from disturbances in immunoregulation, and its different forms comprise the diseases formerly called *Hand-Schuller-Christian disease, Letterer-Siwe disease, Gaucher's disease* and *eosinophilic granuloma.*[5,32] They appear as single or multiple radiolucent areas, which may be unrelated to the teeth or entail destruction of the tooth-supporting bone (Fig. 31-27).

Numerous radiolucent areas occur when the jaws are involved by *multiple myeloma.*

In *osteopetrosis* (marble-bone disease, Albers-Schonberg disease)[7,32] the outlines of the roots may be obscured by diffuse radiopacity of the jaws. In less severe cases the increased density is confined to the bone in relation to the nutrient canals and the lamina dura.

In *scleroderma,* the periodontal ligament is uniformly widened at the expense of the surrounding alveolar bone' (Fig. 31-28).

CLINICAL RISK ASSESSMENT FOR PERIODONTAL DISEASE

DEFINITIONS

Risk assessment is defined by numerous components .2.7 Risk is the probability that an individual will get a specific disease in a given period. The risk of developing the disease will vary from individual to individual. Risk factors may be environmental, behavioral, or biologic factors that, when present, increase the likelihood that an individual will get the disease. They are part of the "causal chain" and directly related to disease occurrence. Risk factors are identified through longitudinal studies of patients with the disease of interest. Exposure to a risk factor or factors may occur at a single point in time; over multiple, separate points in time; or continuously. However, to be identified as a risk factor, the exposure must occur prior to disease onset. Interventions often can be identified and, when implemented, can help modify risk factors. The term *risk detenninant/background characteristic,* which is sometimes substituted for the term *risk factor,* should be reserved for those risk factors that cannot be modified.

Risk indicators are *probable* or *putative* risk factors that have been identified in cross-sectional studies but not confirmed through longitudinal studies. *Risk predictors/markers,* although associated with increased risk for disease, do not cause the disease. These factors also are identified in cross-sectional and longitudinal studies.

RISK FACTORS FOR PERIODONTAL DISEASE

The following is a discussion on the risk factors for periodontal disease (Table 32-1).

Tobacco Smoking

Tobacco smoking is a well-established risk factor for periodontitis.2.29 A direct relationship exists between smoking and the prevalence of periodontal disease (see Chapter 5). This association is independent of other factors such as oral hygiene or age.18 Studies comparing the response to periodontal therapy in smokers, previous

TABLE 32-1

Risk Elements for Periodontal Disease

Risk Factors	Risk Determinants/ Background Characteristics	Risk Indicators	Risk Markers/ Predictors
Tobacco smoking	Genetic factors	HIV/AIDS	Previous history of periodontal disease
Diabetes	Age	Osteoporosis	Bleeding on probing
Pathogenic bacteria	Gender	Infrequent dental visits	
Microbial tooth deposits	Socioeconomic status		
	Stress		

HIV, human immunodeficiency virus; AIDS, acquired immunodeficiency syndrome.

smokers and nonsmokers have shown that smoking has a negative impact on the response to therapy. However, former smokers respond similarly to nonsmokers.' These studies demonstrate the impact intervention strategies can have in patients who smoke (see Chapter 14).

Diabetes

Diabetes is a clear risk factor for periodontitis.[2] Epidemiologic data demonstrate that the prevalence and severity of periodontitis is significantly higher in patients with type I and type II diabetes than in those without diabetes and that the level of diabetic control is an important variable in this relationship (see Chapter 5).

Pathogenic Bacteria and Microbial Tooth Deposits

It is well documented that accumulation of bacterial plaque at the gingival margin results in the development of gingivitis and that the gingivitis can be reversed with the implementation of oral hygiene measures .[24] These studies demonstrate a causal relationship between accumulation of bacterial plaque and gingival inflammation. However, a causal relationship between plaque accumulation and periodontitis has been more difficult to establish. Often, patients with severe loss of attachment have minimal levels of bacterial plaque on the affected teeth, indicating that the *quantity* of plaque is not of major importance in the disease process. However, although quantity may not indicate risk, there is evidence that the composition, or *quality,* of the complex plaque biofilm is of importance. In terms of quality of plaque, three specific bacteria have been identified as etiologic agents for periodontitis: *Actinobacillus actinomycetemcomitans, Porphyromonas gingivalis,* and *Bacteroides forsythus.*[12] *P. gingivalis* and *B. forsythus* are often found in chronic periodontitis, whereas *A. actinomycetemcomitans is* often associated with aggressive periodontitis. Cross-sectional and longitudinal studies support the delineation of these three bacteria as risk factors for periodontal disease. Additional evidence that they are causal agents include (1) their elimination or suppression impacts the success of therapy, (2) there is a host reponse to these pathogens, (3) virulence factors are associated with these pathogens and (4) inoculation of these bacteria into animal models induces periodontal disease.[16] Although not completely supported by these criteria for causation, there also is moderate evidence that *Campylobacter rectus, Eubacterium nodatum, Fusobacterium nucleatum, Prevotella intermedia/nigrescens, Peptostreptococcus micros, Streptococcus intermedius* and *Treponema denticola* are etiologic factors in periodontitis.[12] Therefore the quantity of plaque present may not be as important as the quality of the plaque in determining risk for periodontitis.

Anatomic factors such as furcations, root concavities, developmental grooves, cervical enamel projections, enamel pearls, and bifurcation ridges may predispose the periodontium to disease as a result of their potential to harbor bacterial plaque and present a challenge to the clinician during instrumentation. Similarly, the presence of subgingival and/or overhanging margins can result in increased plaque accumulation, increased inflammation, and increased bone loss. Although not clearly defined as risk factors for periodontitis, anatomic and restorative factors that influence plaque accumulation may play a role in disease susceptibility for specific teeth.[8]

The presence of calculus, which serves as a reservoir for bacterial plaque, has been suggested as a risk factor for periodontitis. Although the presence of some calculus in healthy individuals receiving routine dental care does not result in significant loss of attachment, the presence of calculus in other groups of patients, such as those not receiving regular care and patients with poorly controlled diabetes, can have a negative impact on periodontal health .[27]

RISK DETERMINANTS/BACKGROUND CHARACTERISTICS FOR PERIODONTAL DISEASE

Genetic Factors

There is evidence that genetic differences between individuals may explain why some patients develop periodontal disease and others do not. Studies conducted in twins have shown that genetic factors influence clinical measures of gingivitis, probing pocket depth, attachment loss, and interproximal bone height.[25,26] The familial

aggregation seen in localized and generalized aggressive periodontitis also is indicative of genetic involvement in these diseases (see Chapter 27). A specific interleukin 1 (IL-1) genotype has been associated with severe chronic periodontitis.[20] Immunologic alterations, such as neutrophil abnormalities,[17] monocytic hyperresponsiveness to lipopolysaccharide stimulation in patients with localized aggressive periodontitis,[34] and alterations in the monocyte/macrophage FcyRII receptor for IgG2 also appear to be under genetic control .[43] In addition, genetics plays a role in regulating the titer of the protective IgG2 antibody response to A. **actinomycetemcomitans** in patients with aggressive periodontitis" (see Chapter 10).

Age

Both the prevalence and severity of periodontal disease increases with age .[9,28,29] It is possible that degenerative changes related to aging may increase susceptibility to periodontitis. However, it also is possible that the attachment loss and bone loss seen in older individuals is a result of prolonged exposure to other risk factors over a person's life, creating a cumulative effect over time. In support of this, studies have shown minimal loss of attachment in aging subjects enrolled in preventive programs throughout their lives.[30,31] Therefore it is suggested that periodontal disease is not an inevitable consequence of the aging process and that aging alone does not increase disease susceptibility. However, it remains to be determined whether changes related to the aging process, such as intake of medications, decreased immune function, and altered nutritional status interact with other well-defined risk factors to increase susceptibility to periodontitis.

Evidence of loss of attachment may be of more consequence in younger patients. The younger the patient, the longer they have for exposure to causative factors. In addition, aggressive periodontitis in young individuals often is associated with an unmodifiable risk factor such as a genetic predisposition to disease.[29] Therefore young individuals with periodontal disease may be at greater risk for continued disease as they age.

Gender

Gender plays a role in periodontal disease.' United States national surveys conducted since 1960 demonstrate that males have more loss of attachment than females.[38,40,41] In addition, males have poorer oral hygiene than females, as evidenced by higher levels of plaque and calculus.[1,39,41] Therefore it appears that gender differences in prevalence and severity of periodontitis are related to preventive practices rather than any genetic factor.

Socioeconomic Status

Gingivitis and poor oral hygiene can be related to lower socioeconomic status (SES) .[2,38,40] This can most likely be attributed to decreased dental awareness and decreased frequency of dental visits when compared with more educated individuals of higher SES. After adjusting for other risk factors such as smoking and poor oral hygiene, lower SES alone does not result in increased risk for periodontitis (see Chapter 5).

Stress

The incidence of necrotizing ulcerative gingivitis increases during periods of emotional and physiologic stress, suggesting a link between the two.[11,35] Emotional stress may interfere with normal immune function[6,16] and may result in increased levels of circulating hormones that can have an impact on the periodontium.[32] Stressful life events such as bereavement and divorce appear to lead to a greater prevalence of periodontal disease,[14] and there is an apparent association between psychosocial factors and risk behaviors such as smoking, poor oral hygiene, and chronic periodontitis.[10] Adult patients with periodontitis who are resistant to therapy are more stressed than those who respond to therapy.' Individuals with financial strain, distress, depression, or inadequate coping mechanisms have more severe loss of attachment.[13] Although epidemiologic data on the relationship between stress and periodontal disease is limited, it appears that stress may be a putative risk factor for periodontitis.[29]

RISK INDICATORS FOR PERIODONTAL DISEASE

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

It has been hypothesized that the immune dysfunction associated with human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) increases susceptibility to periodontal disease. Early reports on the periodontal status of patients with AIDS or individuals who are HIV seropositive revealed that these patients often had severe periodontal destruction characteristic of necrotizing ulcerative periodontitis.[44] More recent reports, however, have failed to demonstrate significant differences in the periodontal status of individuals with HIV infection and healthy controls .[23,37] The apparent discrepancy in these reports may have been due to the inclusion of patients with AIDS (as opposed to patients who were exclusively HIV seropositive) in some studies .[29] Conflicting results also exist in studies examining the level of immunosuppression and severity of periodontal destruction. In a 20-month study of 114 homosexual and bisexual men, the relative risk of longitudinal attachment loss >3 mm was 4.8 when CD4 counts were less than 400/mm^3 and increased to 6.16 when CD4 counts were less than 200/mm^3, suggesting a correlation between the severity of periodontal disease and the level of immunosuppression.[7] In contrast, a study of 119 individuals with HIV, 73 patients with AIDS and 156 individuals who were HIV seronegative found no significant differences in bleeding on probing, pocket formation, or attachment loss among the three groups and no significant associations by odds ratio analysis between these clinical parameters and CD4 T -cell counts .[33] Therefore although it seems reasonable to hypothesize that HIV infection and immunosuppression are risk factors for periodontal disease, the evidence is not conclusive .[2,29]

Osteoporosis

Osteoporosis has been suggested as another risk factor for periodontitis. Although studies in animal models indicate that osteoporosis does not initiate periodontitis, there is evidence that the reduced bone mass seen in osteoporosis may aggravate periodontal disease progression.[4,22] However, reports in humans are conflicting. In a study of 12 women with osteoporosis and 14 healthy women, Von Wowern et al[42] reported that the women with osteoporosis had greater loss of attachment than the control subjects. In contrast, Kribbs[19] examined pocket depth, bleeding on probing, and gingival recession in women with and without osteoporosis. Although the two groups had significant differences in bone mass, no differences in periodontal status were noted. However, it appears that a link may exist between osteoporosis and periodontitis, and additional studies may need to be conducted to clearly determine if osteoporosis is a true risk factor for periodontal disease.

Infrequent Dental Visits

Identifying failure to visit the dentist on a regular basis as a risk factor for periodontitis is controversial.[27] One study demonstrated an increased risk for severe periodontitis in patients who had not visited the dentist for three or more years, whereas another demonstrated that there was no more loss of attachment or bone loss in individuals who did not seek dental care when compared with those that did over a 6-year period. However, the ages of the subjects in these two studies were different, which may explain the differences in the results. Additional longitudinal and intervention studies are necessary to determine if infrequency of dental visits is a risk factor for periodontal disease.

RISK MARKERS/PREDICTORS FOR PERIODONTAL DISEASE

Previous History of Periodontal Disease

A history of previous periodontal disease is a good clinical predictor of risk for future disease.[27] Patients with the most severe existing loss of attachment are at the greatest risk for future loss of attachment. Conversely, patients currently free of periodontitis have decreased risk for developing loss of attachment than those who currently have periodontitis (see Chapter 5).

Bleeding on Probing

Bleeding on probing is the best clinical indicator of gingival inflammation.[27] Although bleeding on probing alone does not serve as a predictor for loss of attachment, bleeding on probing coupled with increasing pocket depth may serve as an excellent predictor for future loss of attachment. Lack of bleeding on probing does appear to serve as an excellent indicator of periodontal health.

CLINICAL RISK ASSESSMENT FOR PERIODONTAL DISEASE

Information concerning individual risk for developing periodontal disease is obtained through careful evaluation of the patient's demographic data, medical history, dental history, and clinical examination (Table 32-2). The elements that contribute to increased risk that can be identified through the collection of demographic data include the patient's age, gender, and SES. The medical history may reveal elements such as a history of diabetes, smoking, HIV/AIDS, or osteoporosis, as well as the perceived level of stress. The dental history can reveal a

TABLE 32-2

Clinical Risk Assessment for Periodontal Disease

Demographic Data	Medical History	Dental History	Clinical Examination
Age	Diabetes	Family history of early tooth loss	Plaque accumulation
• Duration of exposure to risk elements	Tobacco smoking	• Genetic predisposition to aggressive disease	• Microbial sampling for putative periodontal pathogens
• Postmenopausal women	HIV/AIDS	Previous history of periodontal disease	Calculus
• Evidence of aggressive disease	Osteoporosis	Frequency of dental care	Bleeding on probing
Gender	Stress		Extent of loss of attachment
• Males			• Aggressive forms of disease
Preventive practices			Tooth examination

SES			• Anatomic factors
• Dental awareness			Restorative factors
• Frequency of care			

AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency syndrome; SES, socioeconomic status.

family history of early tooth loss (suggestive of a genetic predisposition for aggressive periodontitis), a previous history of periodontal disease, and information concerning the frequency of oral health care in the past. Important elements identified during the clinical examination can include the location and extent of bacterial plaque accumulation, the presence of plaque retentive factors such as overhanging restorations and subgingival margins, the presence of anatomic plaque-retentive areas such as grooves and furcation involvements, the presence of calculus, the extent of attachment loss, and the presence or absence of bleeding on probing.

Once an at-risk patient is identified and a diagnosis is made, their treatment plan may be modified accordingly (Fig. 32-1). For example, a patient with a history of cigarette smoking should be informed of the relationship between smoking and periodontitis. They also should be informed of the impact of smoking on their prognosis and the likelihood of success of their periodontal therapy should they continue to smoke. Part of their recommended treatment plan for initial therapy may include referral to a smoking cessation program, or implementation of self-administered smoking cessation aids. As another example, a patient diagnosed with severe, chronic periodontitis may be encouraged to be tested for the IL-1 positive genotype. If positive, their treatment may involve the administration of systemic antimicrobial agents and/or host modifiers that would not be used in a patient without this genetic marker. If alterations in the host response are identified, the prognosis and treatment plan may be modified. Previously identified risk elements also may need to be reassessed at the reevaluation stage of treatment. This is especially important in patients who do not respond favorably to periodontal therapy (see Fig. 32-1).

In summary, risk assessment involves identifying elements that either may predispose a patient to developing periodontal disease or may influence the progression of disease that already exists. In either case, these patients may require modification of their prognosis and treatment plan. In addition to an evaluation of the factors

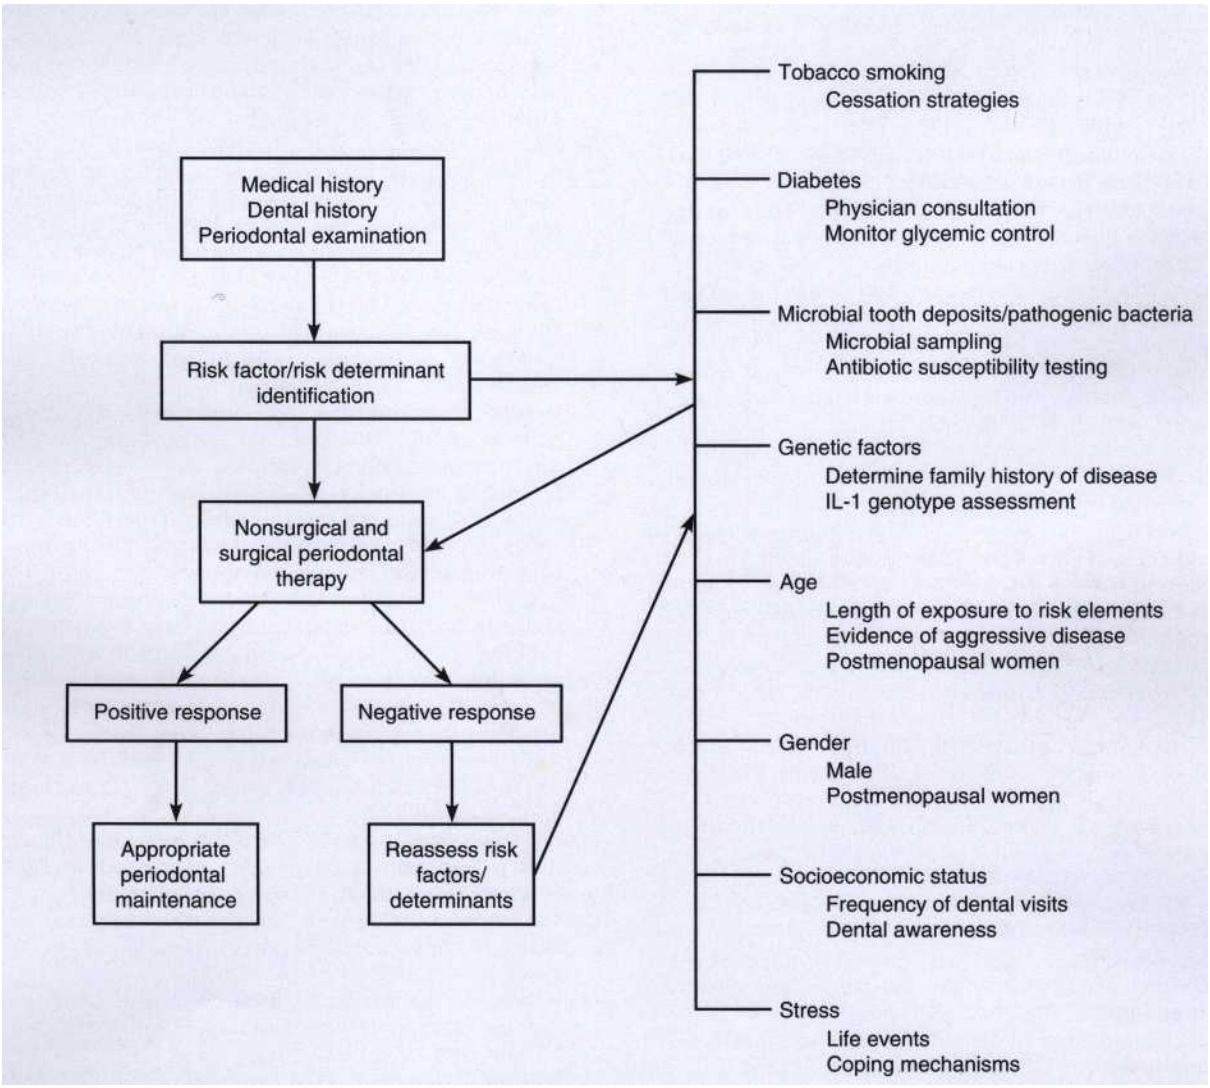

Fig. 32-1 Risk assessment in periodontal therapy. The major risk elements to be considered in the diagnosis and treatment of periodontal disease are indicated. The importance of risk assessment before the initiation of therapy is highlighted, as well as the need for reassessment after a negative response to therapy.

contributing to their risk, these patients should be educated concerning their risk and, when appropriate, suitable intervention strategies implemented.

Prognosis for Patients with Periodontitis
REEVALUATION OF PROGNOSIS AFTER PHASE I THERAPY

DEFINITION OF PROGNOSIS

The prognosis is a prediction of the probable course, duration, and outcome of a disease based on a general knowledge of the pathogenesis of the disease and the presence of risk factors for the disease. It is established after the diagnosis is made and before the treatment plan is established. The prognosis is based on specific information about the disease and the manner in which it can be treated, but it also can be influenced by the clinician's previous experience with treatment outcomes (successes and failures) as they relate to the particular case.

Prognosis is often confused with the term *risk.* Risk generally deals with the likelihood that an individual will get a disease in a specified period (see Chapter 5). Risk factors are those characteristics of an individual that put them at increased risk for getting a disease. In contrast, prognosis is the prediction of the course or outcome of a disease. Prognostic factors are characteristics that predict the outcome of disease once the disease is present. In some cases, risk factors and prognostic factors are the same (see Chapter 5). For example, patients with diabetes or patients who smoke are more at risk for acquiring periodontal disease, and once they have it, they generally have a worse prognosis.

DETERMINATION OF A PROGNOSIS

The factors often considered when determining the prognosis are listed in Table 33-1. Although some of these factors may be more important than others when assigning a prognosis,[29,30] consideration of each may be beneficial to the clinician. In most cases, careful analysis of these factors allows the clinician to establish one of the following prognoses[28]:

Excellent prognosis: No bone loss, excellent gingival condition, good patient cooperation, no systemic/environmental factors.

Good prognosis: One or more of the following: adequate remaining bone support, adequate possibilities to control etiologic factors and establish a maintainable dentition, adequate patient cooperation, no systemic/environmental factors or if systemic factors are present, they are well controlled.

Fair prognosis: One or more of the following: less-than-adequate remaining bone support, some tooth mobility, grade I furcation involvement, adequate maintenance possible, acceptable patient cooperation, presence of limited systemic/environmental factors.

Poor prognosis: One or more of the following: moderate-to-advanced bone loss, tooth mobility, grade I and II

TABLE 33-1

Factors to be Considered When Determining a Prognosis

Overall Clinical Factors	Systemic/Environmental Factors	Local Factors	Prosthetic/Restorative Factors
Patient age	Smoking	Plaque/calculus	Abutment selection
Disease severity	Systemic disease/condition	Subgingival restorations	Caries
Plaque control	Genetic factors	Anatomic factors:	Nonvital teeth
Patient compliance	Stress	Short, tapered roots	Root resorption
		Cervical enamel projections	
		Enamel pearls	
		Bifurcation ridges	
		Root concavities	
		Developmental grooves	
		Root proximity	
		Furcation involvement	
		Tooth mobility	

furcation involvements, difficult-to-maintain areas and/or doubtful patient cooperation, presence of systemic/environmental factors.

Questionable prognosis: One or more of the following: advanced bone loss, grade II and III furcation involvements, tooth mobility, inaccessible areas, presence of systemic/environmental factors.

Hopeless prognosis: One or more of the following: advanced bone loss, nonmaintainable areas, extraction(s) indicated, presence of uncontrolled systemic/environmental factors.

It should be recognized that excellent, good, and hopeless prognoses are the only prognoses that can be established with a reasonable degree of accuracy. Fair, poor, and even questionable prognoses depend on a large number of factors that can interact in an unpredictable number of ways .[6,11,42] In many of these cases, it may be advisable to establish a provisional prognosis until phase I therapy is completed and evaluated.

The *provisional prognosis* allows the clinician to initiate treatment of teeth that have a doubtful outlook in the hope that a favorable response may tip the balance and allow teeth to be retained. The reevaluation phase in the treatment sequence allows the clinician to examine the tissue response to scaling, oral hygiene, and root planing, as well as to the possible use of chemotherapeutic agents where indicated. The patient's compliance with the proposed treatment plan also can be determined.

Overall versus Individual Tooth Prognosis

Prognosis can be divided into *overall prognosis* and *individual tooth prognosis.* The overall prognosis is concerned with the dentition as a whole. Factors that may influence the overall prognosis include patient age, current severity of disease, systemic factors, smoking, the presence of plaque, calculus and other local factors, patient compliance, and prosthetic possibilities (see Table 33-1). The overall prognosis answers the following questions:

Should treatment be undertaken?
Is it likely to succeed?
When prosthetic replacements are needed, are the remaining teeth able to support the added burden of the prosthesis?

The prognosis for individual teeth is determined after the overall prognosis and is affected by it." For example, in a patient with a poor overall prognosis, the dentist likely would not attempt to retain a tooth that has a questionable prognosis because of local conditions. Many of the factors listed under Local Factors and Prosthetic/Restorative Factors in Table 33-1 have a direct effect on the prognosis for individual teeth in addition to any overall systemic or environmental factors that may be present.

FACTORS TO CONSIDER WHEN DETERMINING A PROGNOSIS

Please refer to Table 33-1 during the following discussion.

Overall Clinical Factors

Patient Age. For two patients with comparable levels of remaining connective tissue attachment and alveolar bone, the prognosis is generally better in the older of the two. For the younger patient, the prognosis is not as good because of the shorter time frame in which the periodontal destruction has occurred. In some cases this may be because the younger patient suffers from an aggressive type of periodontitis or disease progression may have increased due to systemic disease or smoking. In addition, although the younger patient would ordinarily be expected to have a greater reparative capacity, the occurrence of so much destruction in a relatively short

period would exceed any naturally occurring periodontal repair.

Disease Severity. Studies have demonstrated that a patient's history of previous periodontal disease may be indicative of their susceptibility for future periodontal breakdown (see Chapter 5). Therefore the following variables should be carefully recorded because they are important for determining the patient's past history of periodontal disease: pocket depth, level of attachment, degree of bone loss, and type of bony defect. They are determined by clinical and radiographic evaluation (see Chapters 30 and 31).

The determination of the level of clinical attachment reveals the approximate extent of root surface that is devoid of periodontal ligament; the radiographic examination shows the amount of root surface still invested in bone. Pocket depth is less important than level of attachment, because it is not necessarily related to bone loss. In general, a tooth with deep pockets and little attachment and bone loss has a better prognosis than one with shallow pockets and severe attachment and bone loss. However, deep pockets are a source of infection and may contribute to progressive disease.

Prognosis is adversely affected if the base of the pocket (level of attachment) is close to the root apex. The presence of apical disease as a result of endodontic involvement also worsen the prognosis. However, surprisingly good apical and lateral bone repair can sometimes be obtained by combining endodontic and periodontal therapy (see Chapter 65).

The prognosis also can be related to the height of remaining bone. Assuming bone destruction can be arrested, is there enough bone remaining to support the teeth? The answer is readily apparent in extreme cases, that is, when there is so little bone loss that tooth support is not in jeopardy (Fig. 33-1) or when bone loss is so severe that the remaining bone is obviously insufficient for proper tooth support (Fig 33-2). Most patients, however, do not fit into these extreme categories. The height of remaining bone is usually somewhere in between, making bone level assessment alone insufficient for determining the overall prognosis.

The type of defect also must be determined. The prognosis for horizontal bone loss depends on the height of the existing bone, because it is unlikely that clinically significant bone height regeneration will be induced by therapy. In the case of angular, intrabony defects, if the contour of the existing bone and the number of osseous walls are favorable, there is an excellent chance that therapy could regenerate bone to approximately the level of the alveolar crest.[40]

When greater bone loss has occurred on one surface of a tooth, the bone height on the less involved surfaces should be taken into consideration when determining the prognosis. Because of the greater height of bone in relation to other surfaces, the center of rotation of the tooth will be nearer the crown (Fig. 33-3). This results in a more favorable distribution of forces to the periodontium and less tooth mobility.[44]

In dealing with a tooth with a questionable prognosis, the chances of successful treatment should be weighed against any benefits that would accrue to the adjacent teeth if the tooth under consideration were extracted. Heroic attempts to retain a hopelessly involved tooth may jeopardize the adjacent teeth. Extraction of the questionable tooth may be followed by partial restoration of the bone support of the adjacent teeth (Fig. 33-4).

Plaque Control. Bacterial plaque **is the primary etiologic factor associated with periodontal disease (see Chapter 6).** Therefore effective removal of plaque on a daily basis by the patient is critical to the success of periodontal therapy and to the prognosis.

Patient Compliance/Cooperation. The prognosis for patients with gingival and periodontal disease is critically dependent on the patient's attitude, desire to retain the natural teeth, and willingness and ability to maintain good oral hygiene. Without these, treatment cannot succeed. Patients should be clearly informed of the important role they must play for treatment to succeed. If patients are unwilling or unable to perform adequate plaque control and to receive the timely periodic maintenance checkups and treatments deemed necessary by the dentist, then the dentist can (1) refuse to accept the patient for treatment or (2) extract teeth that have a hopeless or poor prognosis and perform scaling and root planing on the remaining teeth. The dentist should make it clear to the patient and in the patient record that further treatment is needed but will not be performed because of a lack of patient cooperation.

Systemic/Environmental Factors

Smoking. Epidemiologic evidence suggests that smoking may be the most important environmental risk factor impacting the development and progression of periodontal disease (see Chapter 5). Therefore it should be made clear to the patient that a direct relationship exists between smoking and the prevalence and incidence of periodontitis. In addition, patients should be informed that smoking affects not only the severity of periodontal destruction, but also the healing potential of the periodontal tissues. As a result, patients who smoke do not respond as well to conventional periodontal therapy as patients who have never smoked.[38,39] Therefore the prognosis in patients who smoke and have slight-to-moderate periodontitis is generally fair to poor. In patients with severe periodontitis, the prognosis may be poor to hopeless.

However, it should be emphasized that smoking cessation can affect the treatment outcome and therefore the prognosis.[3,14] Patients with slight to moderate periodontitis who stop smoking can often be upgraded to a good prognosis, whereas those with severe periodontitis who stop smoking may be upgraded to a fair prognosis.

Systemic Disease/Condition. The **patient's systemic background affects overall prognosis in several ways.** For example, evidence from epidemiologic studies clearly demonstrates that the prevalence and severity of periodontitis is significantly higher in patients with type I and type II diabetes than in those without diabetes and that the level of control of the diabetes is an important

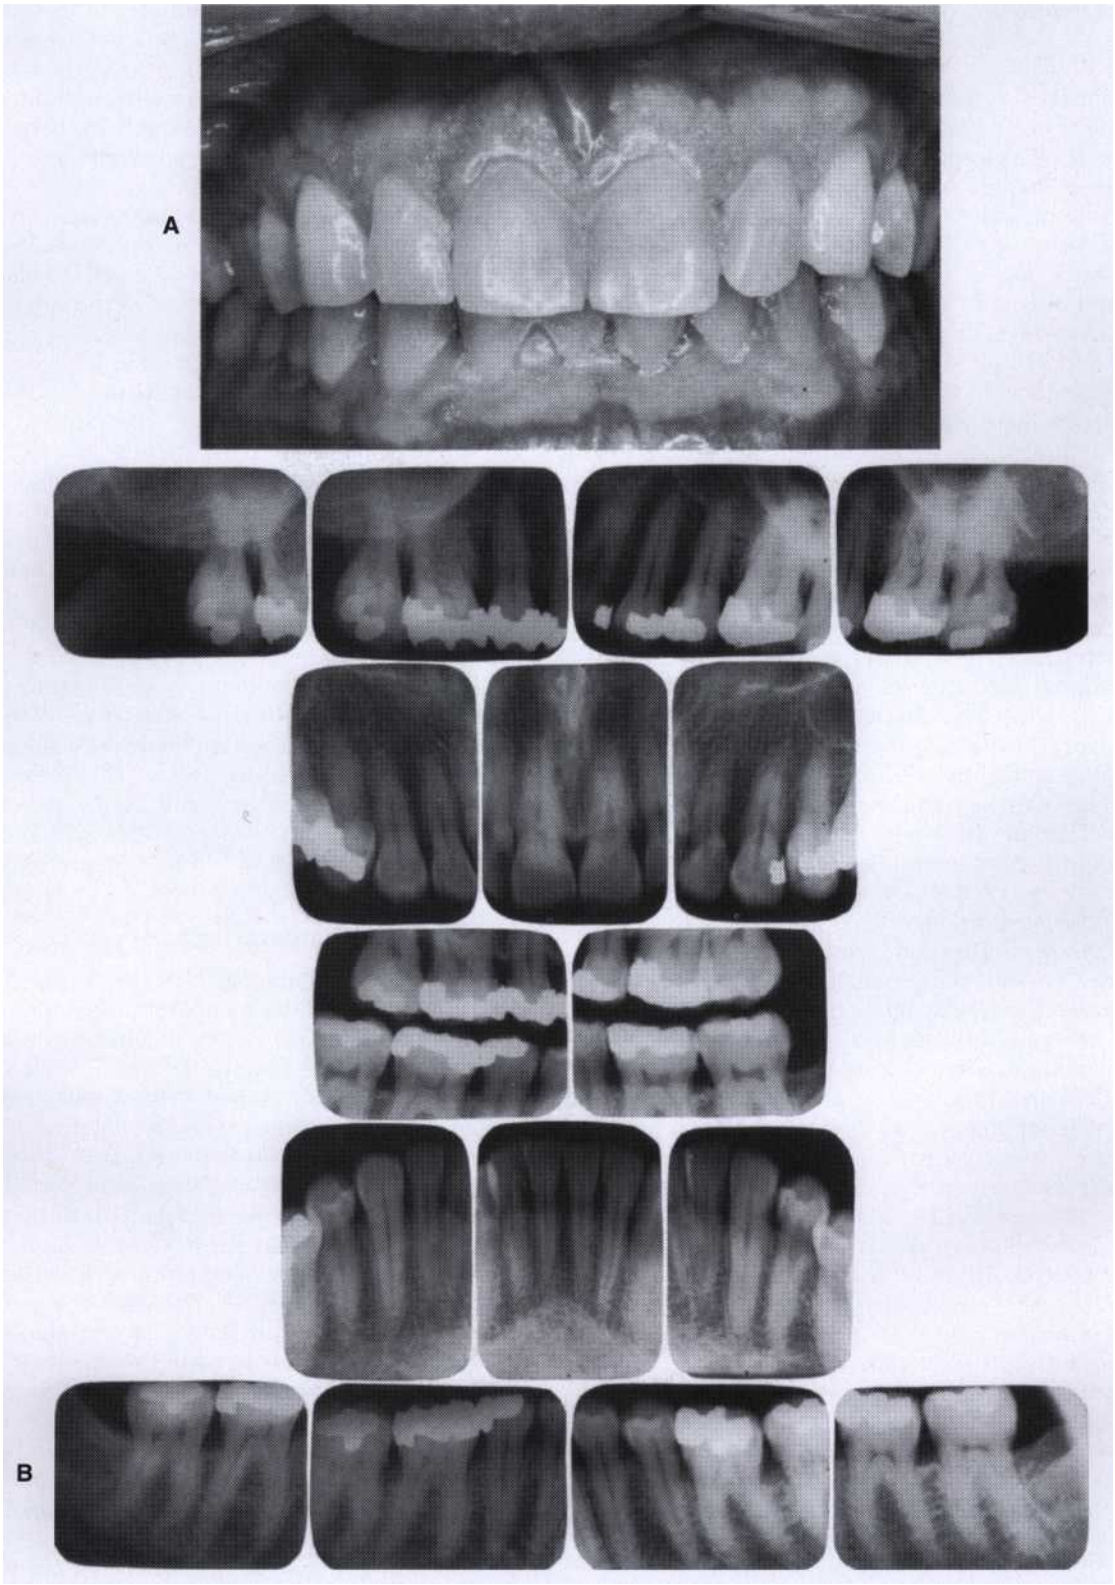

Fig. 33-1 Chronic periodontitis, overall prognosis good. A, Gingival inflammation, poor oral hygiene, and pronounced anterior overbite in a systemically healthy, nonsmoking 42-year-old man. B, Although local factors are present, the patient presents with adequate remaining bone support and a good prognosis, provided local factors can be controlled.

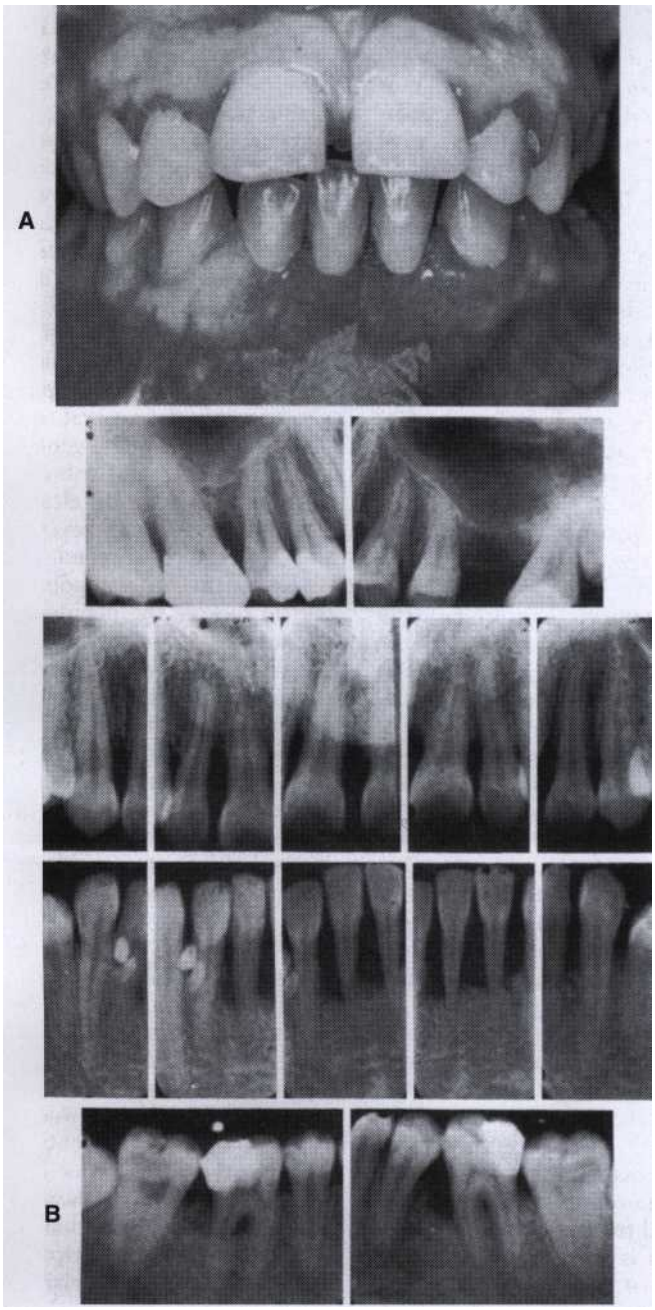

Fig. 33-2 Localized aggressive periodontitis in a 17-year-old girl, overall prognosis fair. A, Gingival inflammation, periodontal pockets, and pathologic migration. B, Severe bone destruction.

variable in this relationship (see Chapter 5). Therefore patients at risk for diabetes should be identified as early as possible and informed of the relationship between periodontitis and diabetes. Similarly, patients diagnosed with diabetes must be informed of the impact of diabetic control on the development and progression of periodontitis. It follows that the prognosis in these cases is dependent on patient compliance relative to both their medical and dental status. Well-controlled patients with diabetes with slight-to-moderate periodontitis who comply with their recommended periodontal treatment

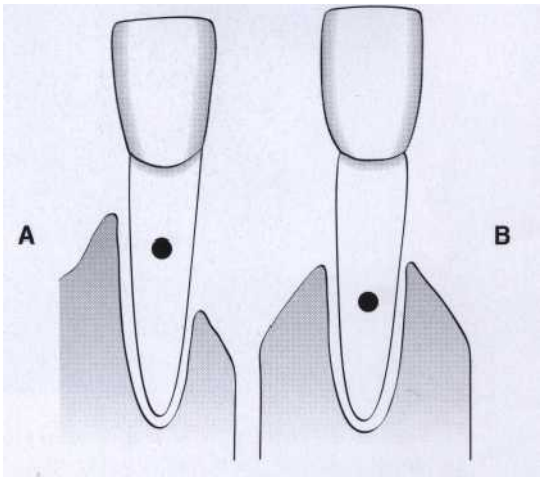

Fig. 33-3 The prognosis of tooth A is better than that for tooth B, despite the fact that there is less bone on one of the surfaces of A. Because the center of rotation of tooth A is closer to the crown, the distribution of occlusal forces to the periodontium is more favorable than in B.

should have a good prognosis. Similarly, in patients with other systemic disorders that could affect disease progression, prognosis improves with correction of the systemic problem.

The prognosis is questionable when surgical periodontal treatment is required but cannot be provided because of the patient's health (see Chapter 38). Incapacitating conditions that limit the patient's performance of oral procedures (e.g., Parkinson's disease) also adversely affect the prognosis. Newer "automated" oral hygiene devices such as electric toothbrushes may be helpful for these patients and improve their prognosis (see Chapter 49).

Genetic Factors. Periodontal diseases represent a complex interaction between a microbial challenge and the host's response to that challenge, both of which may be influenced by environmental factors such as smoking. In addition to these external factors, there also is evidence that genetic factors may play an important role in determining the nature of the host response." Evidence for this type of genetic influence exists for patients with both chronic and aggressive periodontitis. Genetic polymorphisms in the interleukin-1 (IL-1) genes, resulting in increased production of IL1-ß have been associated with a significant increase in risk for severe, generalized, chronic periodontitis.20.32 It has been demonstrated that knowledge of the patient's IL-1 genotype and smoking status can aid the clinician in assigning a prognosis.31 Genetic factors also appear to influence serum IgG2 antibody titers and the expression of Fc-yRII receptors on the neutrophil, both of which may be significant in aggressive periodontitis.15 Other genetic disorders such as leukocyte adhesion deficiency type I can influence neutrophil function, creating an additional risk factor for aggressive periodontitis.15 Finally, the familial aggregation that is characteristic of aggressive periodontitis indicates that additional, as yet unidentified, genetic factors may be important in susceptibility to this form of disease (see Chapter 28).

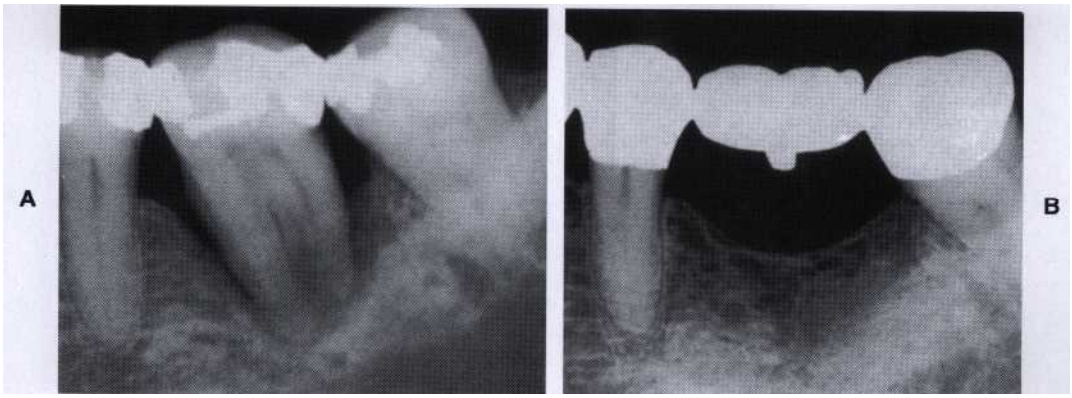

Fig. 33-4 Extraction of severely involved tooth to preserve bone on adjacent teeth. A, Extensive bone destruction around the mandibular first molar. B, Radiograph made 8.5 years after extraction of the first molar and replacement by a prosthesis. Note the excellent bone support.

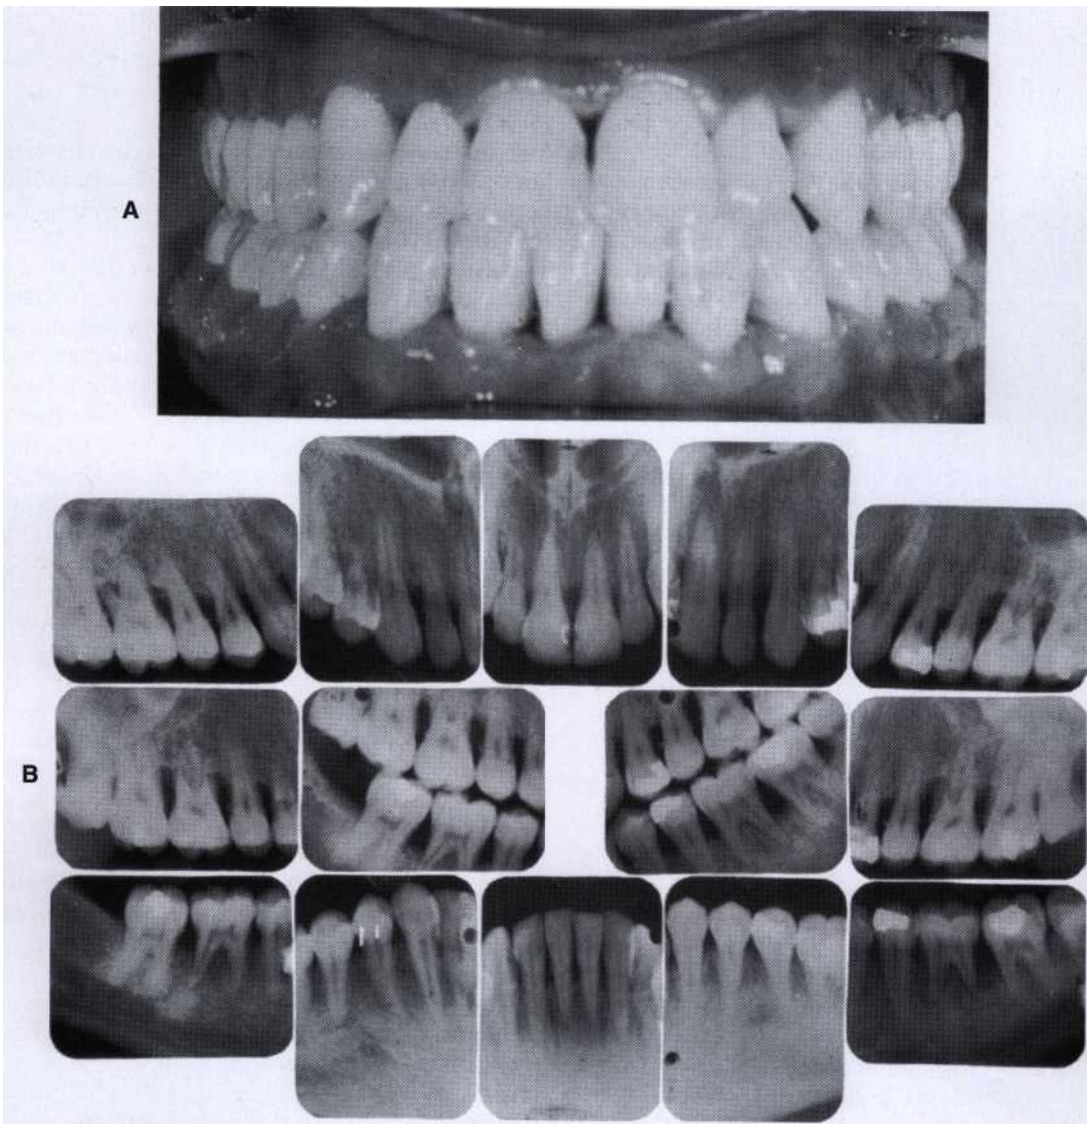

Fig. 33-5 Generalized aggressive periodontitis, poor crown-to-root ratio, overall prognosis poor. A, A 24-year-old patient with generalized periodontal attachment loss and pocket formation. B, Moderate to advanced bone destruction. The contrast between the well-formed crowns and the relatively short, tapered roots worsens the prognosis.

The influence of genetic factors on prognosis is not simple. Although microbial and environmental factors can be altered through conventional periodontal therapy and patient education, genetic factors currently cannot be altered. However, detection of genetic variations that are linked with periodontal disease can potentially influence the prognosis in several ways. First, early detection of patients at risk due to genetic factors can lead to early implementation of preventive and treatment measures for these patients. Second, identification of genetic risk factors later in the disease and/or during the course of treatment can influence treatment recommendations, such as the use of adjunctive antibiotic therapy or increased frequency of maintenance visits. Finally, identification of young individuals who have not been evaluated for periodontitis, but who are recognized as being at risk because of the familial aggregation seen in aggressive periodontitis, can lead to the development of early intervention strategies. In each of these cases, early diagnosis, intervention and/or alterations in the treatment regimen may lead to an improved prognosis for the patient.

Stress. Physical and emotional stress, as well as substance abuse, may alter the patient's ability to respond to the periodontal treatment performed (see Chapter 5). These factors have to be realistically faced in attempting to establish a prognosis.

Local Factors

Plaque/Calculus. The microbial challenge presented by bacterial plaque and calculus is the most important local factor in periodontal diseases. Therefore in most cases, having a good prognosis is dependent on the ability of the patient and the clinician to remove these etiologic factors (see Chapters 6 and 11).

Subgingival Restorations. Subgingival margins may contribute to increased plaque accumulation, increased inflammation and increased bone loss[2,35,43] when compared with supragingival margins. Furthermore, discrepancies in these margins (e.g., overhangs) can negatively impact the periodontium (see Chapter 11). The size of these discrepancies and amount of time they have been present are important factors in the amount of destruction that occurs. However, in general, a tooth with a discrepancy in its subgingival margins has a poorer prognosis than a tooth with well-contoured, supragingival margins.

Anatomic Factors. Anatomic factors that may predispose the periodontium to disease, and therefore affect the prognosis, include short, tapered roots with large crowns, cervical enamel projections (CEPS) and enamel pearls, intermediate bifurcation ridges, root concavities, and developmental grooves. The clinician must also consider root proximity and the location and anatomy of furcations when developing a prognosis.

Prognosis is poor for teeth with short, tapered roots and relatively large crowns (Fig. 33-5). Because of the disproportionate crown-to-root ratio and the reduced root surface available for periodontal support," the periodontium may be more susceptible to injury by occlusal forces.

CEPS are flat, ectopic extensions of enamel that extend beyond the normal contours of the cementoenamel junction.[27] They extend into the furcation of 28.6% of mandibular molars and 17% of maxillary molars.[27] They are most likely to be found on buccal surfaces of maxillary second molars.[13,45] Enamel pearls are larger, round deposits of enamel that can be located in furcations or other areas on the root surface.[34] Enamel pearls are less frequent (1.1% to 5.7% of permanent molars; 75% appearing in maxillary third molars[34]) than CEPS. An intermediate bifurcation ridge has been described in 73% of mandibular first molars, crossing from the mesial to the distal root at the midpoint of the furcation.[7] The presence of these enamel projections on the root surface interferes with the attachment apparatus and may prevent regenerative procedures from achieving their maximum potential. Therefore their presence may have a negative effect on the prognosis for an individual tooth.

Scaling with root planing is a fundamental procedure in periodontal therapy. Anatomic factors that decrease the efficiency of this procedure can have a negative impact on the prognosis. Therefore the morphology of the tooth root is an important consideration when discussing prognosis. Root concavities exposed through loss of attachment can vary from shallow flutings to deep depressions. They appear more marked on maxillary first premolars, the mesiobuccal root of the maxillary first molar, both roots of mandibular first molars, and the mandibular incisors[4,5] (Figs. 33-6 and 33-7). Any tooth, however, can have a proximal concavity.[10] Although

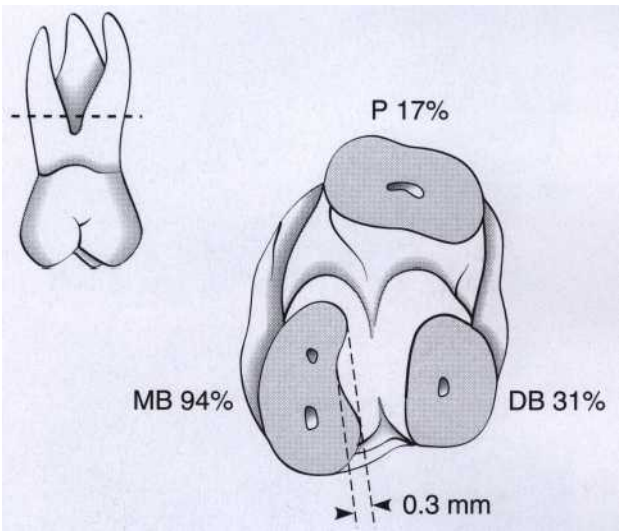

Fig. 33-6 Root concavities in maxillary first molars sectioned 2 mm apical to the furca. The furcal aspect of the root is concave in 94% of the mesiobuccal (MB) roots, 31% of the distobuccal (DB) roots, and 17% of the palatal (P) roots. The deepest concavity i5 found in the furcal aspects of the mesiobuccal root (mean concavity, 0.3 mm). The furcal aspect of the buccal roots diverges toward the palate in 97% of teeth (mean divergence: 22 degrees). (Redrawn from Bower RC: Furcation morphology relative to periodontal treatment-furcation root surface anatomy. J Periodontol 1979; 50:366.)

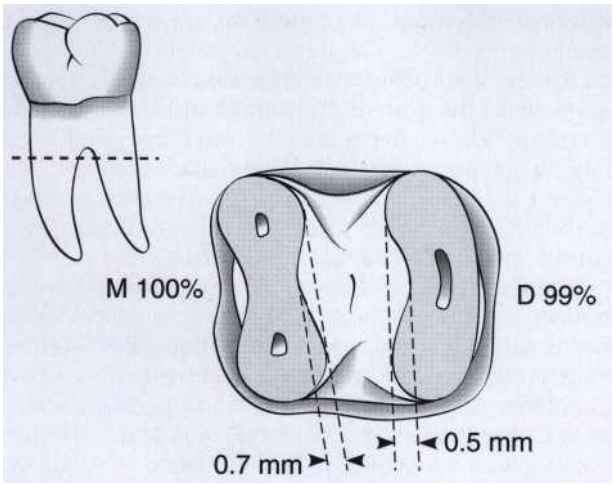

Fig. 33-7 Root concavities in mandibular first molars sectioned 2 mm apical to the furca. Concavity of the furcal aspect was found in 100% of mesial (M) roots and 99% of distal (D) roots. Deeper concavity was found in the mesial roots (mean concavity, 0.7 mm). (Redrawn from Bower RC: Furcation morphology relative to periodontal treatment-furcation root surface anatomy. J Periodontol 1979; 50:366.)

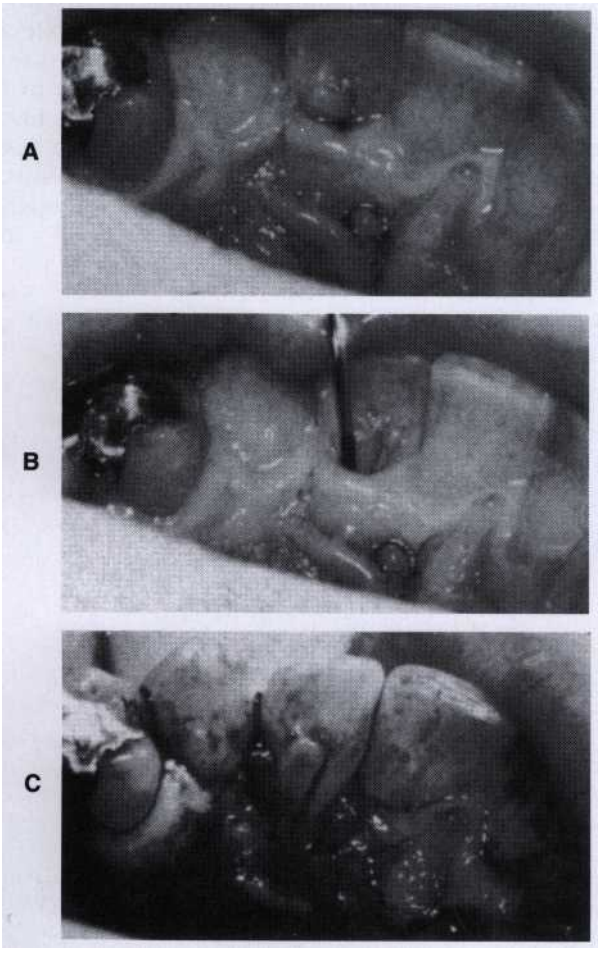

Fig. 33-8 Palatogingival groove. A, Gingival inflammation and exudate in an area palatal to the upper lateral incisor. B, Probing shows deep pocket. C, The area is flapped, and the presence of a palatogingival groove is confirmed. (Courtesy Dr. Robert Merin, Woodland Hills, Calif.)

these concavities increase the attachment area and produce a root shape that may be more resistant to torquing forces, they also create areas that can be difficult for both the dentist and the patient to clean.

Other anatomic considerations that present accessibility problems are developmental grooves, root proximity, and furcation involvements. The presence of any of these can worsen the prognosis. Developmental grooves, which sometimes appear in the maxillary lateral incisors (palatogingival groove)[46] (Fig. 33-8) or in the lower incisors, create an accessibility problem.[8,12] They initiate on enamel and can extend a significant distance on the root surface, providing a plaque-retentive area that is difficult to instrument. These palatogingival grooves are found on 5.6% of maxillary lateral incisors and 3.4% of maxillary central incisors.[19] Similarly, root proximity can result in interproximal areas that are difficult for the clinician and patient to access. Finally, access to the furcation area is usually difficult to obtain. In 58% of maxillary and mandibular first molars, the furcation entrance diameter is narrower than the width of conventional periodontal curettes.[5] (Fig. 33-9) Maxillary first premolars offer the greatest difficulties, and therefore their prognosis is usually unfavorable when the lesion reaches the mesial-distal furcation. Maxillary molars also offer some degree of difficulty; sometimes their prognosis can be improved by resecting one of the buccal roots (see Chapter 64), thereby improving access to the area. When mandibular first molars or buccal furcations of maxillary molars offer good access to the furcation area, their prognosis is usually better.

Tooth Mobility. The principal causes of tooth mobility are loss of alveolar bone, inflammatory changes in the periodontal ligament, and trauma from occlusion. Tooth mobility caused by inflammation and trauma from occlusion may be correctable.[33] However, tooth mobility resulting from loss of alveolar bone is not likely to be corrected. The likelihood of restoring tooth stability is inversely proportional to the extent to which mo-

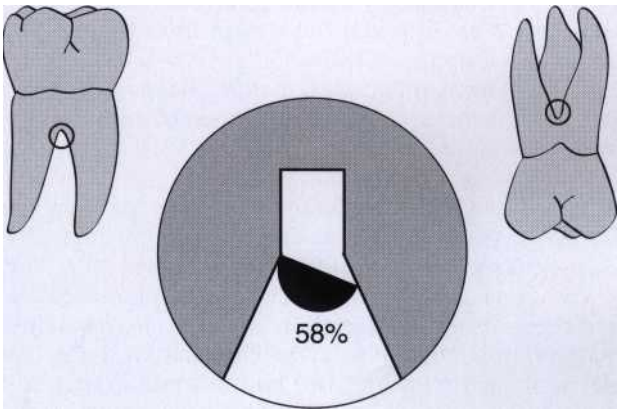

Fig. 33-9 The furcation entrance is narrower than a standard curette in 58% of first molars. (Redrawn from Bower RC: Furcation morphology relative to periodontal treatment-furcation root surface anatomy. J Periodontol 1979; 50:366.)

bility is caused by loss of supporting alveolar bone. A longitudinal study of the response to treatment of teeth with different degrees of mobility revealed that pockets on clinically mobile teeth do not respond as well to periodontal therapy as pockets on nonmobile teeth exhibiting the same initial disease severity.' Another study however, in which ideal plaque control was attained, found similar healing in both hypermobile and firm teeth.40 The stabilization of tooth mobility through the use of splinting may have a beneficial impact on the overall and individual tooth prognosis.

Prosthetic/ Restorative Factors

The overall prognosis requires a general consideration of bone levels (evaluated radiographically) and attachment levels (determined clinically) to establish whether enough teeth can be saved either to provide a functional and aesthetic dentition or to serve as abutments for a useful prosthetic replacement of the missing teeth.

At this point, the overall prognosis and the prognosis for individual teeth overlap because the prognosis for key individual teeth may affect the overall prognosis for prosthetic rehabilitation. For example, saving or losing a key tooth may determine whether other teeth are saved or extracted or whether the prosthesis used is fixed or removable (see Fig. 33-4). When few teeth remain, the prosthodontic needs become more important, and sometimes periodontally treatable teeth may have to be extracted if they are not compatible with the design of the prosthesis.

Teeth that serve as abutments are subjected to increased functional demands. More rigid standards are required when evaluating the prognosis of teeth adjacent to edentulous areas. A tooth that has undergone endodontic treatment that has a post is more likely to fracture when serving as a distal abutment supporting a distal removable partial denture. Additionally, special oral hygiene measures must be instituted in these areas.

Caries, Nonvital Teeth, and Root Resorption.

For teeth mutilated by extensive caries, the feasibility of adequate restoration and endodontic therapy should be considered before undertaking periodontal treatment. Extensive idiopathic root resorption or root resorption that has occurred as a result of orthodontic therapy, jeopardizes the stability of teeth and adversely affects the response to periodontal treatment. The periodontal prognosis of treated nonvital teeth is not different from that of vital teeth. New attachment can occur to the cementum of both nonvital and vital teeth.

RELATIONSHIP BETWEEN DIAGNOSIS AND PROGNOSIS

Many of the criteria used in the diagnosis and classification of the different forms of periodontal disease' (see Chapter 4) are also used in developing a prognosis (see Table 33-1). Factors such as patient age, severity of disease, genetic susceptibility, and presence of systemic disease are important criteria in the diagnosis of the condition. These are also important in developing a prognosis. These common factors suggest that for any given diagnosis, there should be an expected prognosis under ideal conditions. The following section discusses the potential prognoses of the various periodontal diseases outlined in Chapter 4.

Prognosis for Patients with Gingival Disease

Dental Plaque-Induced Gingival Diseases

GINGIVITIS ASSOCIATED WITH DENTAL PLAQUE ONLY. Plaque-induced gingivitis is a reversible disease that occurs when bacterial plaque accumulates at the gingival margin.[24,26] This disease can occur on a periodontium that has experienced no attachment loss, or on a periodontium with nonprogressing attachment loss (see Chapter 4). In either case, the prognosis for patients with gingivitis associated with dental plaque only is good, provided all local irritants are eliminated, other local factors contributing to plaque retention are eliminated, gingival contours conducive to the preservation of health are attained, and the patient cooperates by maintaining good oral hygiene.

PLAQUE-INDUCED GINGIVAL DISEASES MODIFIED BY SYSTEMIC FACTORS. The inflammatory response to bacterial plaque at the gingival margin can be influenced by systemic factors such as endocrine-related changes associated with puberty, menstruation, pregnancy, and diabetes, and the presence of blood dyscrasias. In many instances, the frank signs of gingival inflammation that occur in these patients are seen in the presence of relatively small amounts of bacterial plaque. Therefore the long-term prognosis for these patients depends not only on control of bacterial plaque, but also on control or correction of the systemic factor(s).

PLAQUE-INDUCED GINGIVAL DISEASES MODIFIED BY MEDICATIONS. Gingival diseases associated with medications include drug-influenced gingival enlargement, often seen with phenytoin, cyclosporin, nifedipine, and oral contraceptive-associated gingivitis. In drug-influenced gingival enlargement, it has been shown that reductions in dental plaque can limit the severity of the lesions. However, plaque control alone does not prevent development of the lesions, and surgical intervention is usually necessary to correct the alterations in gingival contour. Continued use of the drug usually results in recurrence of the enlargement, even following surgical intervention (see Chapter 18). Therefore the long-term prognosis is dependent on whether the patient's systemic problem can be treated with an alternative medication that does not have gingival enlargement as a side effect.

In oral contraceptive-associated gingivitis, frank signs of gingival inflammation can be seen in the presence of relatively little plaque. Therefore as seen in plaque-induced gingival diseases modified by systemic factors, the long-term prognosis in these patients is dependent on not only the control of bacterial plaque, but also on the likelihood of continued use of the oral contraceptive.

GINGIVAL DISEASES MODIFIED BY MALNUTRITION. Although malnutrition has been suspected to play a role in the development of gingival diseases, most clinical studies have not shown a relationship between the two. One possible exception is severe vitamin C

deficiency. In early experimental vitamin C deficiency, gingival inflammation and bleeding on probing were independent of plaque levels present. The prognosis in these cases may be dependent on the severity and duration of the deficiency and on the likelihood of reversing the deficiency through dietary supplementation.

Non-Plaque-Induced Gingival Lesions

Non-plaque-induced gingivitis can be seen in patients with a variety of bacterial, fungal, and viral infections." Since the gingivitis in these patients is not usually attributed to plaque accumulation, prognosis is dependent on elimination of the source of the infectious agent. Dermatologic disorders such as lichen planus, pemphigoid, pemphigus vulgaris, erythema multiforme, and lupus erythematosus also can manifest in the oral cavity as atypical gingivitis (see Chapter 21). Prognosis for these patients is linked to management of the associated dermatologic disorder. Finally, allergic, toxic, and foreign body reactions, as well as mechanical and thermal trauma can result in gingival lesions. Prognosis for these cases is dependent on elimination of the causative agent.

Prognosis for Patients with Periodontitis

Chronic Periodontitis. Chronic periodontitis is a slowly progressive disease associated with well-known local environmental factors .[22] It can present in a localized or generalized form (see Chapter 26). In cases where the clinical attachment loss and bone loss are not very advanced (slight-to-moderate periodontitis), the prognosis is generally good, provided the inflammation can be controlled through good oral hygiene and the removal of local plaque-retentive factors (see Fig. 33-1). In patients with more severe disease, as evidenced by furcation involvement and increasing clinical mobility, or in patients who are noncompliant with oral hygiene practices, the prognosis may be downgraded to fair to poor.

Aggressive Periodontitis. Aggressive periodontitis can present in a localized or a generalized form .21 Two common features of both forms are (1) rapid attachment loss and bone destruction in an otherwise clinically healthy patient and (2) a familial aggregation. These patients often present with limited microbial deposits that seem inconsistent with the severity of tissue destruction. However, the deposits that are present often have elevated levels of *Actinobacillus actinomycetemcomitans* or *Porphyromonas gingivalis*. These patients also may present with phagocyte abnormalities and a hyperresponsive monocyte/macrophage phenotype. These clinical, microbiologic and immunologic features would suggest that patients diagnosed with aggressive periodontitis would have a poor prognosis.

However, the clinician should consider additional specific features of the localized form of disease when determining the prognosis (see Fig. 33-2). Localized aggressive periodontitis usually occurs around the age of puberty and is localized to first molars and incisors. The patient often exhibits a strong serum antibody response to the infecting agents, which may contribute to localization of the lesions (see Chapter 27). When diagnosed early, these cases can be treated conservatively with oral hygiene instruction and systemic antibiotic therapy,[37] resulting in an excellent prognosis. When more advanced disease occurs, the prognosis can still be good if the lesions are treated with debridement, local and systemic antibiotics, and regenerative therapy.[25,47]

In contrast, although patients with generalized aggressive periodontitis also are young patients (usually under age 30), they present with generalized interproximal attachment loss and a poor antibody response to infecting agents (see Fig. 33-5). Secondary contributing factors such as cigarette smoking are often present. These factors, coupled with the alterations in host defense seen in many of these patients, may result in a case that does not respond well to conventional periodontal therapy (scaling with root planing, oral hygiene instruction, and surgical intervention). Therefore these patients often have a fair, poor, or questionable prognosis, and the use of systemic antibiotics should be considered to help control the disease (see Chapter 45).

PERIODONTITIS AS A MANIFESTATION OF SYSTEMIC DISEASES. Periodontitis as a manifestation of systemic diseases can be divided into two categories[18,23:(1)] those associated with hematologic disorders such as leukemia and acquired neutropenias and (2) those associated with genetic disorders such as familial and cyclic neutropenia, Down syndrome, Papillon-Lefevre syndrome, and hypophosphastasia. Although the primary etiologic factor in periodontal diseases is bacterial plaque, systemic diseases that alter the ability of the host to respond to the microbial challenge presented may affect the progression of disease and therefore the prognosis for the case. For example, decreased numbers of circulating neutrophils (as in acquired neutropenias) may contribute to widespread destruction of the periodontium. Unless the neutropenia can be corrected, these patients present with a fair-to-poor prognosis. Similarly, genetic disorders that alter the way the host responds to bacterial plaque (as in leukocyte adhesion deficiency syndrome) also can contribute to the development of periodontitis. Because these disorders generally manifest early in life, the impact on the periodontium may be clinically similar to generalized aggressive periodontitis. The prognosis in these cases will be fair to poor. Other genetic disorders exist that do not affect the host's ability to combat infections, but still have an affect on the development of periodontitis. Examples include hypophosphatasia, where patients have decreased levels of circulating alkaline phosphatase, severe alveolar bone loss, premature loss of deciduous and permanent teeth, and the connective tissue disorder, Ehlers-Danlos syndrome, where patients may present with the clinical characteristics of aggressive periodontitis. In both of these examples, the prognosis will be fair to poor.

Necrotizing Periodontal Diseases. Necrotizing periodontal disease can be divided into necrotic diseases that affect the gingival tissues exclusively (necrotizing ulcerative gingivitis [NUG]) and necrotic diseases that affect deeper tissues of the periodontium, resulting in loss of connective tissue attachment and alveolar bone

(necrotizing ulcerative periodontitis [NUP]).[3641] In NUG, the primary predisposing factor is bacterial plaque. However, this disease is usually complicated by the presence of secondary factors such as acute psychologic stress, tobacco smoking, and poor nutrition, all of which can contribute to immunosuppression. Therefore superimposition of these secondary factors on a preexisting gingivitis can result in the painful, necrotic lesions characteristic of NUG. With control of both the bacterial plaque and the secondary factors, the prognosis for a patient with NUG is good. However, the tissue destruction in these cases is not reversible, and poor control of the secondary factors may make these patients susceptible to recurrence of the disease. With repeated episodes of NUG, the prognosis may be downgraded to fair.

The clinical presentation of NUP is similar to that of NUG, except the necrosis extends from the gingiva into the periodontal ligament and alveolar bone. In systemically healthy patients, this progression may have resulted from multiple episodes of NUG or the necrotizing disease may occur at a site previously affected with periodontitis. In these cases the prognosis is dependent on alleviating the plaque and secondary factors associated with NUG. However, many patients presenting with NUP are immunocompromised through systemic conditions, such as HIV infection. In these cases, the prognosis is dependent on not only reducing local and secondary factors, but also on dealing with the systemic problem (see Chapter 40).

REEVALUATION OF PROGNOSIS AFTER PHASE I THERAPY

A frank reduction in pocket depth and inflammation after phase I therapy points to a favorable response to treatment and may suggest a better prognosis than previously assumed. If the inflammatory changes present cannot be controlled or reduced by phase I therapy, the overall prognosis may be unfavorable. In these cases, the prognosis can be directly related to the severity of inflammation. Given two patients with comparable bone destruction, the prognosis may be better for the patient with the greater degree of inflammation, since a larger component of that patient's bone destruction may be attributable to local irritants. In addition, phase I therapy allows the clinician an opportunity to work with the patient and the patients' physician to control systemic/environmental factors such as diabetes and smoking, which may have a positive effect on prognosis if adequately controlled.

It should be noted that the progression of periodontitis generally occurs in an episodic manner, alternating periods of quiescence with shorter destructive stages (see Chapter 22). There are no methods available at present to accurately determine whether a given lesion is in a stage of remission or exacerbation. Advanced lesions, if active, may progress rapidly to a hopeless stage, whereas similar lesions in a quiescent stage may be maintainable for long periods. Phase I therapy will, at least temporarily, transform an active advanced lesion's prognosis so that it should be reanalyzed after completion of Phase I therapy.

- **Tissue Breakdown Products**

LIMITATIONS OF CONVENTIONAL PERIODONTAL DIAGNOSIS

Periodontal diseases are prevalent human diseases defined by the signs and symptoms of gingival inflammation and/or periodontal tissue destruction. These diseases are conventionally diagnosed by clinical evaluation of the signs of inflammation in the gingiva without periodontal tissue destruction (gingivitis) or by the presence of both inflammation and tissue destruction (periodontitis). A clinical diagnosis of *periodontitis is* made by measuring the loss of connective tissue attachment to the root surface (clinical attachment loss) and loss of alveolar bone (radiographic bone loss) (Fig. 34-1). This information provides evidence of past periodontal destruction, as well as its extent and severity. However this approach does not provide any information on the cause of the condition, on the patient's susceptibility to disease, whether the disease is progressing, whether it is in remission or whether the response to therapy will be positive or negative.

The current view of the natural history of destructive periodontal disease is that disease susceptibility is subject related. This means that a person's susceptibility and host defense mechanisms are generalized. However, the disease process itself is considered to be site specific and has a multifactorial origin where periodontal pathogens, host response, genetic, systemic, and behavioral risk factors interplay to develop the disease process. In light of this information, consideration should be given to including microbiologic, immunologic, systemic, genetic, and behavioral factors, in addition to the traditional clinical and radiographic parameters, when assessing patient status. Considerable advances have been made51 in the use of these parameters and these advances will be systematically reviewed.

ADVANCES IN CLINICAL DIAGNOSIS

Gingival Bleeding

Clinical evaluation of the degree of gingival inflammation includes assessment of the redness and swelling of

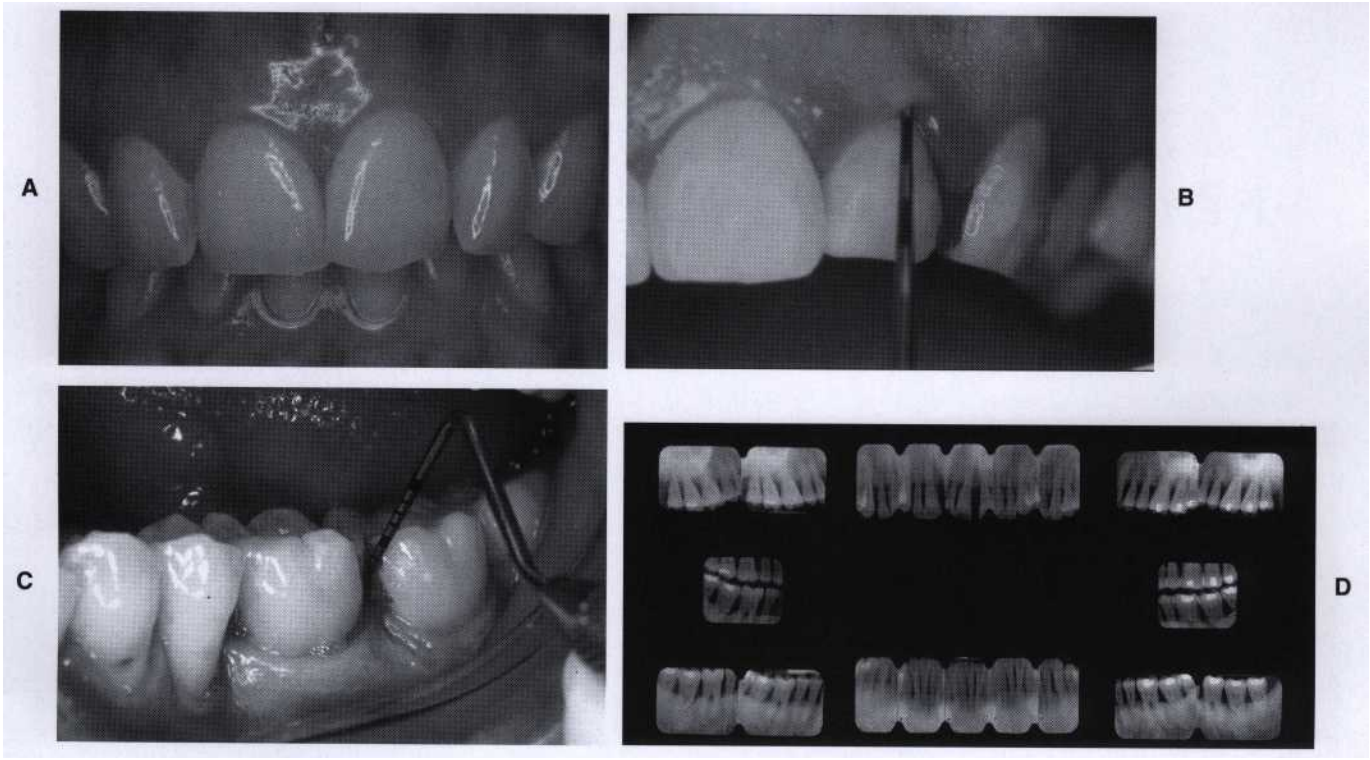

Fig. 34-1 Conventional clinical diagnostic tools. A, Visual diagnosis. Changes in color and contour of the gingival tissues are indicative of pathologic changes within the gingiva. B, Periodontal probing is used to determine pocket depth and clinical attachment levels. C, Bleeding on probing is indicative of periodontal inflammation. An absence of bleeding is associated with a healthy, stable periodontium. D, Periapical radiographs. A full mouth series of intraoral periapical radiographs is essential for the diagnosis of changes in the alveolar bone in response to periodontal disease.

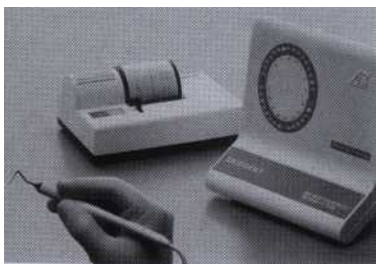

Fig. 34-2 Thermal periodontal probe system. Temperature changes detected within periodontal pockets are associated with inflammation and may be a predictor of future attachment loss. (Courtesy Abiomed, Inc., Danvers, MA.)

the gingiva along with assessment of gingival bleeding. Although the earliest clinical signs of gingivitis consist of color and texture changes, there may be underlying structural alterations without corresponding clinical signs (Fig. 34-1, A). Several studies have shown that gingival bleeding is a sensitive clinical indicator of early gingival inflammation.[62] Moreover, the use of gingival bleeding as an indicator of inflammation has the clinical advantage of being more objective, since color changes require a subjective estimation. It has also been shown that gingival bleeding is a good indicator of the presence of an inflammatory lesion in the connective tissue at the base of the sulcus and that the severity of bleeding increases with an increase in size of the inflammatory infiltrate.[26] Therefore there is a tendency to evaluate gingivitis by gingival bleeding alone, either with the use of a periodontal probe or a wooden interdental cleaner, instead of using visual signs of both inflammation and bleedingz (Fig. 34-1, C). Gingival bleeding has universally been considered an indicator of gingival inflammation and, by some investigators, an indicator of disease activity[73]; *however, its relationship to disease progression is unclear.*

Lang et a1,[49] in a retrospective study, reported that sites that bled on probing at several visits had a higher probability of losing attachment than those that bled at one visit or did not bleed. However, well-controlled longitudinal studies[7,31] investigated the predictive values of such clinical signs, trying to correlate them with attachment loss, but failed to demonstrate a significant correlation between bleeding on probing and other clinical signs and subsequent loss of attachment. A further limitation of the use of bleeding as an inflammatory parameter is the possibility that healthy sites may bleed on probing. Lang et al[50] demonstrated that any force greater than 0.25 N may evoke bleeding in healthy sites with an intact periodontium.

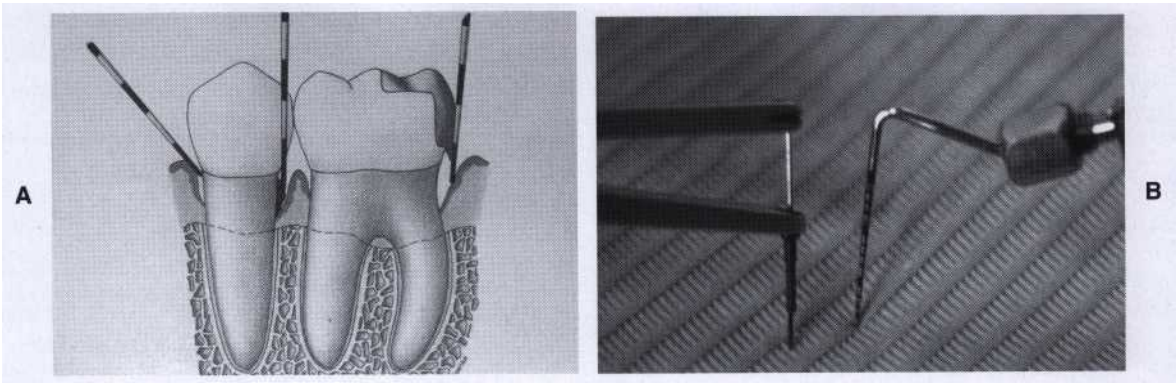

Fig. 34-3 Limitations in periodontal probing. A, Probing measurements can be affected by the incorrect angulation of the probe, by interference from calculus on the tooth or root surface, and by the presence of overhanging restorations. B, Probing measurements can be affected by the amount of pressure applied to the probe. Probes that provide a standardized force may be used to overcome this variable. (A, Courtesy Dr. J. Frontan.)

Gingival Temperature

Instruments that measure the temperature in the gingival tissues have been developed; Kung et all' claim that these thermal probes are sensitive diagnostic devices for measuring early inflammatory changes in the gingival tissues. Studies demonstrate that suspected active periodontitis lesions can create measurable elevations in sulcular temperature. One commercially available system, the PerioTemp® probe (Abiodent, Inc., Danvers, Mass.) (Fig. 34-2), detects pocket temperature differences of 0.1° C from a referenced subgingival temperature. A naturally occurring temperature gradient exists between maxillary and mandibular teeth and between posterior and anterior teeth. Individual temperature differences are compared with those expected for each tooth, and higher-temperature pockets are signalled with a red-emitting diode. Haffajee et a1[33] used this probe to assess its predictability in identifying loss of attachment, concluding that sites with a red (higher) temperature indication had more than twice the risk for future attachment loss than did those with a green indication. However, the influence of pocket depth on temperature is still not clear, and further studies are needed to demonstrate the accuracy of this device and its utility in clinical diagnosis.

Periodontal Probing

The most widely used diagnostic tool for the clinical assessment of connective tissue destruction in periodontitis is the periodontal probe. Increased probing depth and loss of clinical attachment are pathogneumonic for periodontitis. Therefore pocket probing is a crucial and mandatory procedure in diagnosing periodontitis and evaluating periodontal therapy (see Chapter 30). Reduction of pocket depth and gain of clinical attachment are the major clinical outcome measurements used to determine success of treatment (Fig. 34-1, B).

However, use of the periodontal probe presents many problems in terms of sensitivity and reproducibility of the measurements. Readings of clinical pocket depth obtained with the periodontal probe do not normally coincide with the histologic pocket depth, since the probe normally penetrates the coronal level of the junctional epithelium,[14] and the precise location of the probe tip depends on the degree of inflammation of the underlying connective tissues. If the tissue is inflamed, it offers less resistance to probe penetration, and the probe tip either coincides with or is apical to the coronal level of connective tissue attachment.[54] Conversely, healed gingiva following subgingival instrumentation demonstrates an increased resistance to periodontal probing.[59]

The disparity between measurements also depends on the probing technique, probing force, size of the probe, angle of insertion of the probe, and precision of the probe calibration[14] (Fig. 34-3, A). All of these variables contribute to the large standard deviations (0.5 to 1.3 mm) in clinical probing results, which make detection of small changes difficult.[30]

Since the mid-1980s, different probe prototypes have been developed and tested to overcome these limitations.[86] One of the main problems in reproducibility has been the variation in probing force. Different studies have shown that the penetration of the probe was positively correlated with probing force.[62] This has been solved with the development of pressure-sensitive probes, which have a standardized controlled insertion pressures (Fig. 34-3, B). These studies have shown that with forces of up to 30 g, the tip of the probe seems to remain within the junctional epithelium,[4] and forces of up to 50 g are necessary to diagnose periodontal osseous defects.[43] Standardization of probe tips (less than 1 mm) and use of registration stents to maintain reproducible probing angulation have also been used to overcome sources of error.[6] However, fabrication of stents is time consuming and impractical for clinical diagnosis. In addition, current techniques for data readout and storage are inaccurate and time consuming. This has resulted in the development of new periodontal probing systems.

TABLE 34-1

Criteria Defined by the National Institute of Craniofacial Research (NIDCR) for Overcoming the Limitations of Conventional Periodontal Probing

Limitation	Conventional Probing	NIDCR-Criteria
Precision	1 mm	0.1 mm
Range	12 mm	10 mm
Probing force	Nonstandardized	Constant and standardized
Applicability	Noninvasive and easy to use	Noninvasive, light-weight, and easy to use
Reach	Easy to access any location around all teeth	Easy to access any location around all teeth
Angulation	Subjective	A guidance system to ensure proper angulation
Security	Easily sterilized	Complete sterilization of all portions entering the mouth
	Simple stainless steel instrument	No biohazard from material or electric shock
Readout	Depending on voice dictation and recording in writing	Direct electronic reading and digital output

After a National Institute of Craniofacial Research (NIDCR) workshop on the quantitative evaluation of periodontal diseases by physical measurement techniques,[69] there was a proposal to develop and clinically evaluate an improved periodontal pocket depth-attachment level measurement system that would meet the nine criteria shown in Table 34-1.

Following these criteria, the Florida Probe System was developed.[24] This automated probe system consists of a probe hand-piece, digital readout, foot switch, computer interface, and computer (Fig. 34-4). The end of the probe tip is 0.4 mm in diameter. This probe tip reciprocates through a sleeve, and the edge of the sleeve provides a reference by which measurements are made. These measurements are made electronically and transferred automatically to the computer when the foot switch is pressed. Constant probing force is provided by coil springs inside the probe hand-piece and digital readout. This probing method combines the advantages of constant probing force with precise electronic measurement and computer storage of data, thus eliminating the potential errors associated with visual reading and also eliminates the need for an assistant to record the measurements. These automated probes offer many solutions to the problems of conventional probing but also introduce problems of their own. The probing elements lack tactile sensitivity, mostly because of their independent movement, which forces the operator to predetermine an insertion point and angle. In addition, the use of a fixed-force setting throughout the mouth, regardless of the site or inflammatory status, may generate inaccurate measurements or patient discomfort. One common problem reported in different studies where the Florida Probe System has been compared with conventional probing is the underestimation of deep probing depths by the automated probe[70]. In fact, several studies have suggested that the use of this automated probing system does not offer any advantage over conventional probing, rendering a similar level of reproducibility. However, other studies have clearly shown that with the use of trained operators and performing the "double pass" method the measurements taken with the Florida Probe System are significantly less variable (lower standard deviation) than those obtained with a conventional probe.[76,89] Magnusson et al[15,17,58] obtained mean standard deviations (reproducibility) for clinical attachment level measurements of about 0.3 mm, which is clearly superior to an average of 0.82 mm, with a range of 0.52 to 1.30 mm reported by Haffajee et al using manual probing.[32]

Electronic probing systems, such as the Interprobe System© or the Periprobe System®, are also commercially available. They provide constant probing force, computer storage of data, and precise electronic management of the resulting inflammation. However, clinical evaluations of these systems have reported only slightly improved reproducibility when compared with conventional probing, although not clinically significant.[75,85] Other electronic probing systems have been reported in the literature, although they have never been released for general use. One of these systems is the electronic probe described by Jeffcoat et al[39,40] (the Foster-Miller probe), capable of coupling pocket depth measurement with the detection of the cemento-enamel junction from which the clinical attachment level is automatically detected. Researchers at the University of Toronto have also described a probe (the Toronto Automated probe) that, like the Florida probe, uses the occlusal-incisal surface to measure relative clinical attachment levels.[61] The sulcus is probed with a 0.5-mm nickel-titanium wire that is extended under air pressure. It controls angular discrepancies by means of a mercury tilt sensor that limits angulation within ±30 degrees, but it requires reproducible positioning of the patient's head and cannot easily measure second or third molars.

The measurement of clinical attachment levels has traditionally been used in the diagnosis of periodontitis; however, this measurement only reflects the history of past disease and does not assess current or future disease

Fig. 34-4 Automated periodontal probes. Probing systems have been developed that allow the integration of direct electronic measurements at a constant probing force with computer storage and on-line data readout. The figure shows the Florida Probe System'.

activity. The most practical method of determining that disease is progressing (active) is the demonstration that a significant loss of attachment has occurred over time. To detect progression of periodontal disease over a short period, the clinician must overcome sources of error introduced by a lack of probing reproducibility. Various methods have been used to overcome these errors; these include regression analysis of measurements over time, running medians, the tolerance method, end-point analysis, and the cumulative sum method .[3,24,42] The development of electronic and automated probes (described in the preceding section) will probably allow more sensitive clinical assessments of disease progression in the near future.

ADVANCES IN RADIOGRAPHIC ASSESSMENT

Dental radiographs are the traditional method used to assess the destruction of alveolar bone associated with periodontitis. Although radiographs cannot accurately reflect the bone morphology buccally and lingually, they provide useful information on interproximal bone levels. Moreover, they provide information on the periodontium that cannot be obtained by any other noninvasive methods (e.g., root length, root proximity, and presence of periapical lesions and estimates of remaining alveolar bone) (Fig. 34-1, D). However, it is well known that substantial volumes of alveolar bone must be destroyed before the loss is detectable in radiographs[25]; specifically, more than 30% of the bone mass at the alveolar crest must be lost for a change in bone height to be recognized on radiographs.[66] *Therefore conventional radiographs are very specific, but lack sensitivity*. (See Chapters 32 and 33.)

Numerous cross-sectional and longitudinal epidemiologic studies have used radiographs as the principal method of determining the presence or absence of periodontal destruction. The primary criterion for bone loss in these studies was the distance from the cementoenamel junction (CEJ) to the alveolar crest as measured from bite-wing radiographs. The threshold distance of *bone loss* has varied from 1 mm to 3 mm, although most of the studies have used >2 mm as the criterion for bone loss.' This low degree of sensitivity is mainly due to the subjectivity of radiographic assessment and to the inherent sources of variability affecting the conventional radiographic technique, such as (1) variations in projection geometry; (2) variations in contrast and density due to differences in film processing, voltage and exposure time; and (3) masking of osseous changes by other anatomic structures (Fig. 34-5). The variations in projection geometry can be reduced by the use of well-standardized long cone parallel radiographic techniques (Fig. 34-6). To standardize the radiographic assessment, radiographs should be obtained in a constant and reproducible plane, using film holders with a template containing some kind of impression material, which is placed in a constant position on a group of teeth, and an extension arm that can be precisely attached to both the film holder and the x-ray tube[78] (Fig. 34-7). The use of a parallel radiographic technique should be standard to all radiographic assessments for periodontal diagnosis. The use of individualized film holders has been shown to be valid in evaluating bone changes in longitudinal studies and clinical trials .[44]

Digital Radiography

The variations in image quality due to the variables inherent to conventional radiography can be reduced with the use of digital intraoral radiography. Digital radiography enables the use of computerized images, which can be stored, manipulated, and corrected for under- and overexposures. Digital radiography may yield almost equal image properties compared with conventional radiographs, but through digital storage and processing, diagnostic information can be enhanced .[38] Moreover, there is an important dose reduction obtained with this technique (between 1/3 to 1/2 of dose reduction compared with conventional radiographs).

Two digital radiography systems rely on the sensor- the *direct* and *indirect* methods. The direct method uses a charge coupled device (CCD) sensor linked with a fiber optic or other wire to the computer system. This direct digital radiography obtains *real-time* imaging, offering both the clinician and the patient an improved visualization of the periodontium by image manipulation and comparison with previously stored images. The main disadvantage of this technique is the limited sensor area, which is only large enough to depict one or two teeth. In addition, the sensor rigidity attached to a wire, which besides sterility issues, makes ideal image projection by using film holders very difficult.

The indirect method (Digora System) uses a phosphor luminescence plate, which is a flexible filmlike radiation energy sensor placed intraorally and exposed to conventional x-ray tubes. A laser scanner (Fig. 34-8) reads the exposed plates offline and reveals digital image data, which can be enhanced, stored, and compared with previous images. The real advantage of this indirect

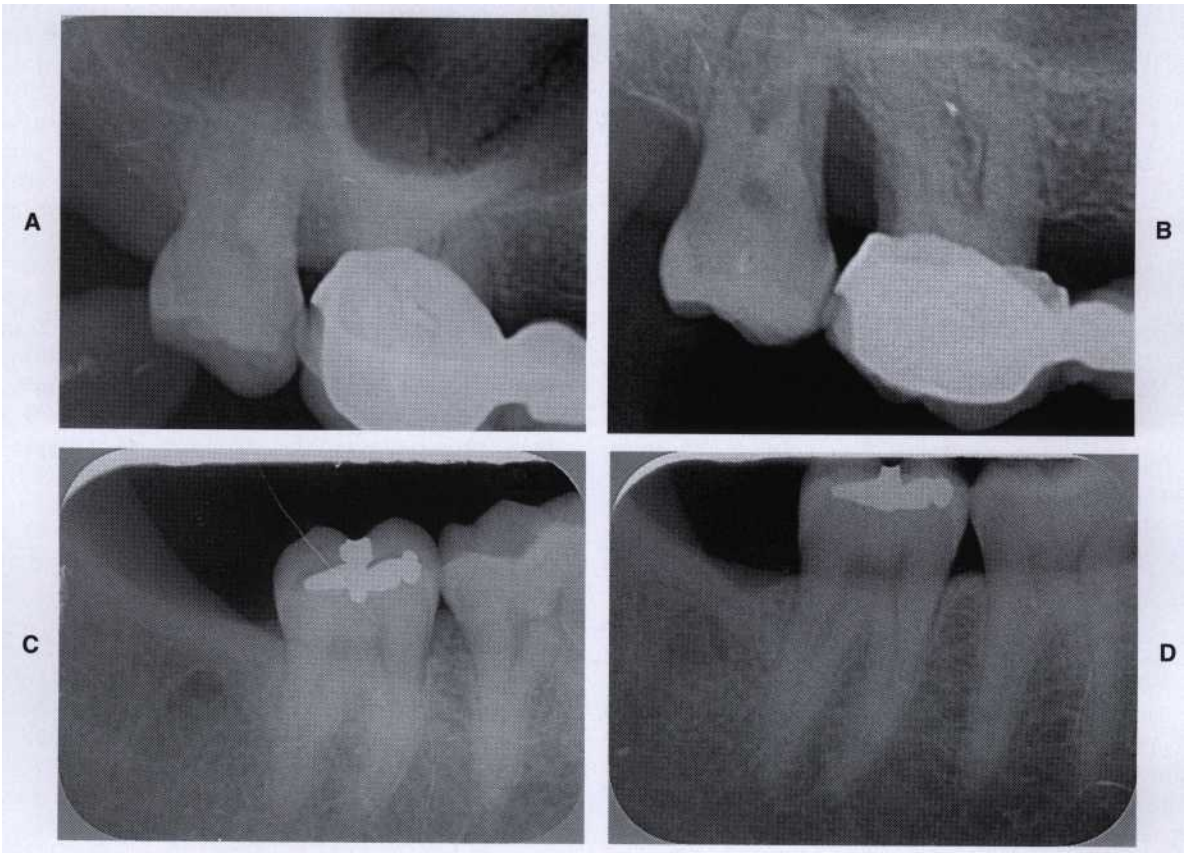

Fig. 34-5 Limitations in conventional periapical radiography. Examples of the importance of image projection in the diagnostic utility of oral periapical raciography. A, Radiograph taken without a paralleling technique showing a clear distortion of the root length relative to the crown. The alveolar bone height is and fills the interproximal space. B, Image of the same tooth with a proper image projection showing the real alveolar bone height demonstrating severe bone loss in the distal of the upper first molar. C, Radiograph taken without a paralleling technique showing a clear distortion of the root length relative to the crown. The alveolar bone height is and fills the interproximal space. D, Image of the same tooth with a proper image projection showing the real alveolar bone height and the open interproximal space. (Courtesy Dr. Fredrico Herrero.)

method is due to the plate size and flexibility, which is almost identical to conventional x-ray films. Therefore a paralleling technique with the use of film holders can be easily applied.

Digital intraoral radiography is in a state of rapid development. Sensors, as well as computer hardware and software, are continually modified and improved. Due to the clear advantage of *real or almost real images* that can be improved and to the important educational component of online images presented to the patient, it is expected that digital radiography will soon replace conventional radiography in modern daily practice. However, certain improvements should be expected in order to overcome some of the current limitations.

Subtraction Radiography

Subtraction radiography, a well-established technique in medicine, has been introduced as a technique in periodontal diagnosis.[27] This technique relies on the conversion of serial radiographs into digital images. The serially obtained digital images can then be superimposed and the resultant composite viewed on a video screen. Changes in the density and/or volume of bone can be detected as lighter areas (bone gain) or dark areas (bone loss). Quantitative changes in comparison with the baseline images can be detected using an algorithm for gray-scale levels. This is accomplished by means of a computer (computer-assisted subtraction radiography) (Fig. *34-9).* This technique requires a parallelization technique to obtain a standardized geometry and accurate superimposable radiographs. Radiographs taken with identical exposure geometry can then be scanned using a microphotometer that determines a gray-scale value for each picture point. After superimposition of two subsequent radiographs, this technique can show differences in relative densities. Studies using this technique have shown (1) a high degree of correlation

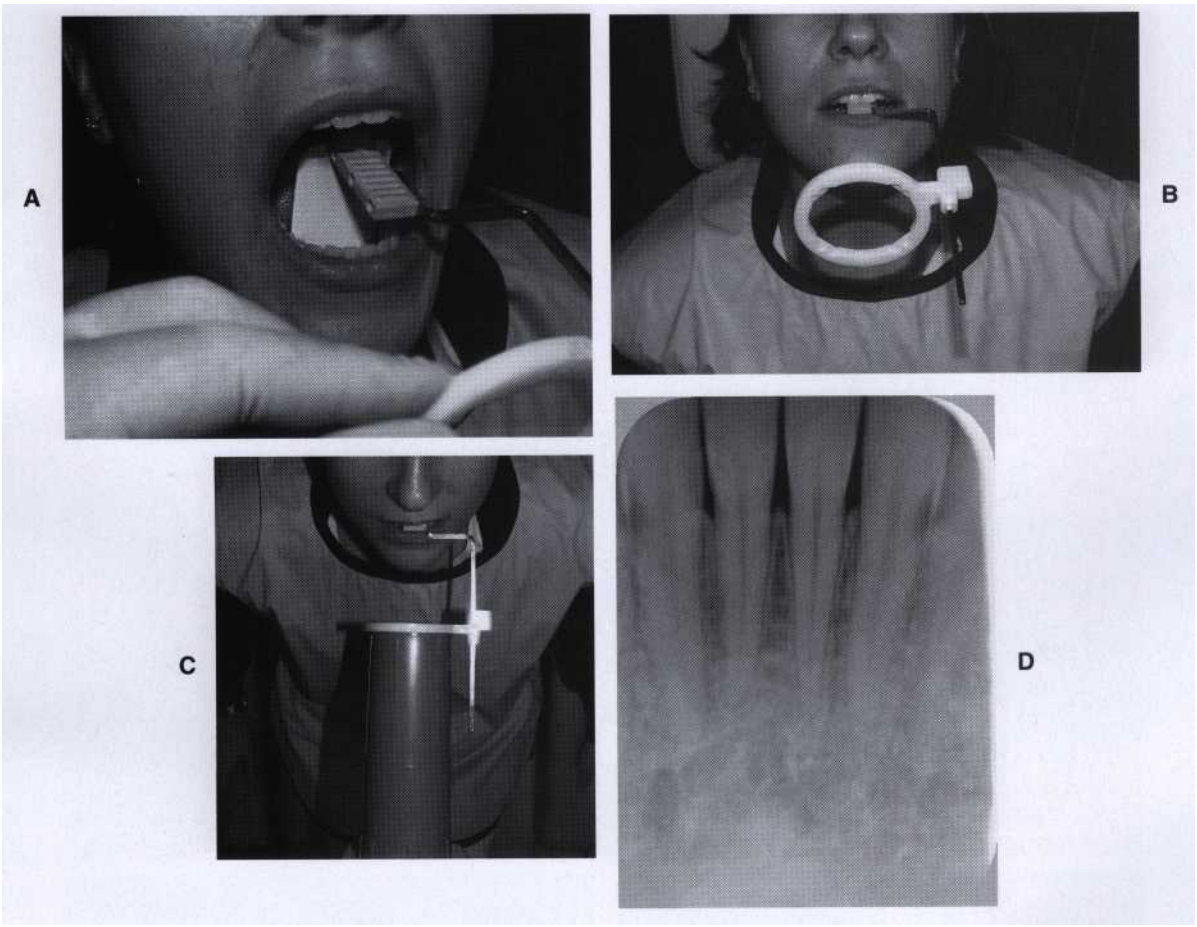

Fig. 34-6 Radiographic paralleling technique. A, Position of the film holder relative to the teeth. B, Position of the film holder relative to the paralleling device. C, Position of the paralleling device to the radiograph long cone tube. D, Obtained x-ray with proper image projection. (Courtesy Dr. Fredrico Herrero.)

between changes in alveolar bone determined by subtraction radiography and attachment level changes in periodontal patients after therapy[35] and (2) increased detectability of small osseous lesions compared with the conventional radiographs from which the subtraction images are produced." Grondahl et al," using subtraction analysis, showed nearly perfect accuracy at a lesion depth corresponding to *0.49* mm of compact bone, whereas a lesion must be at least three times larger to be detectable with a conventional radiology technique. Subtraction radiography has also shown a degree of sensitivity similar to that for I^{125} absorptiometry.[36] It can detect a change in bone mass of as little as 5%.[66]

Subtraction radiography has been applied to longitudinal clinical studies. Hausmann et al detected significant differences in crestal bone height of 0.87 mm,[37] and Jeffcoat et al[14] showed a strong relationship between probing attachment loss detected using sequential measurements made with an automated periodontal probe and bone loss detected with digital subtraction radiography. Subtraction radiography is a technique that facilitates both qualitative and quantitative visualization of even minor density changes in bone by removing the unchanged anatomic structures from the image. This enhances the detection of bone structures with true density change and significantly improved the sensitivity and accuracy of the evaluation. The main disadvantage of digital subtraction radiography techniques is the need to be close to identical projection alignment during the exposure of the sequential radiographs, which makes this method very impractical in a clinical setting. Recently, new image subtraction methods (diagnostic subtraction radiography [DSR®]) have been introduced combining the use of a positioning device during film exposure with specialized software designed for digital image subtraction using conventional personal computers in dental offices (see Fig. *34-9).* This image analysis software system applies an algorithm that corrects for the effects of angular alignment discrepancies and provides some degree of flexibility in the imaging procedure. Recently, the use of the DSR technique has been compared with the conventional subtraction radiography technique and with the conventional intraoral radiography technique yielding statistically significant gains in diagnostic accuracy over conventional radiographs and no differences against the classical subtraction radiography technique .[64]

C, Individualized paralleling technique in place intraorally. D and E, Two radiographs obtained 6 months apart demonstrating identical projection geometry. (Courtesy Dr. Fredrico Herrero.)

This method has great diagnostic potential, especially in clinical practice, because of the development of personal computers with capability for digitizing and image processing.

Computer-Assisted Densitometric Image Analysis System (CADIA)

Another technique that has been introduced is the video-based computer-assisted densitometric image analysis system (CADIA).[11] In this system, a video camera measures the light transmitted through a radiograph, and the signals from the camera are converted into gray-scale images. The camera is interfaced with an image processor and a computer that allow the storage and mathematical manipulation of the images. This system appears to offer an objective method for following alveolar bone density changes quantitatively over time, and, when compared with *IIIs* absorptiometry and digital subtraction analysis, it has shown a higher sensitivity and a high degree of reproducibility and accuracy.

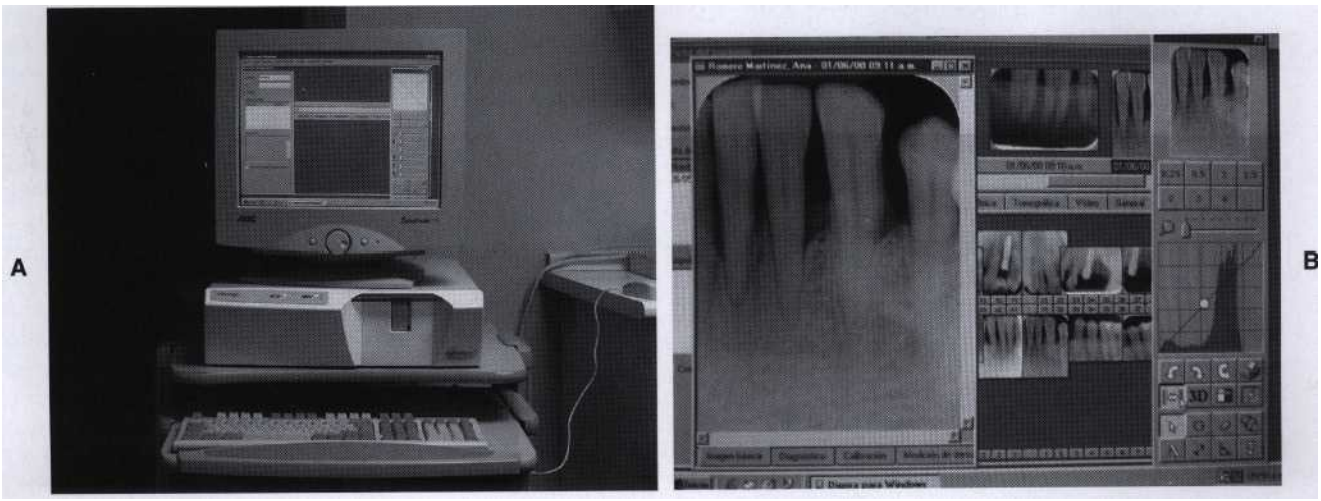

Fig. 34-8 Digital Radiographic System-Digora®. Digitized radiographs can be used for patient education and for demonstrating the effects of therapy.

This technique has also been applied to longitudinal clinical studies. Deas et al," using replicate measurements of clinical attachment levels and CADIA, demonstrated that the prevalence of progressing lesions in periodontitis (38% of sites per patient), as detected by this radiographic method, may be much higher than previously thought.

ADVANCES IN MICROBIOLOGIC ANALYSIS

Since subgingival oral bacteria are the main initiating agents in the development of periodontal disease, it makes sense to look for specific bacteria in the subgingival microflora of patients with disease.[34,81] These microbiologic tests have the potential to support the diagnosis of the various forms of periodontal disease, to serve as indicators of disease initiation and progression (i.e., disease activity), and to determine which periodontal sites are at higher risk for active destruction. Microbial tests can also be used to monitor periodontal therapy directed at the suppression or eradication of periodontopathic microorganisms."

Several methods have been employed for the detection of putative periodontal pathogens in subgingival samples. Some of these methods have been strictly used for research purposes, whereas others have been adapted or modified for clinical use. All of these methods share the common need for an appropriate subgingival plaque sample. Selecting the proper specimen site and collecting an adequate sample are essential elements in periodontal microbiology. These samples may be difficult to obtain in patients infected by organisms that are unevenly distributed in the dentition, Mombelli et a1[63] have shown that four individual subgingival specimens, each from the deepest periodontal pocket in each quadrant, should be pooled to be able to detect *Porphyromonas gingivalis.* If a microbial culture is contemplated, the sample must be collected and transported in an anaerobic environment and minimal transport time should be assured to reach the laboratory and to maintain the growth of the microorganisms sampled. Fig. 34-10 shows the standard subgingival sampling technique by means of sterile paper-points inserted into the deepest area of the selected periodontal pocket.

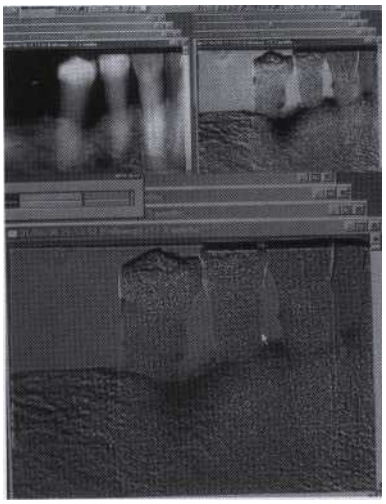

Fig. 34-9 Digital Subtraction Analysis (DSR®). Digital subtraction analysis can be used to evaluate the effects of therapy on bone density and morphology. The effects of surgical therapy on an angular defect are seen, with the new bone formation represented by the dark area.

Bacterial Culturing

Historically, culture methods have been widely used in studies aimed at characterizing the composition of the subgingival microflora and are still considered the reference method (gold standard) when determining the

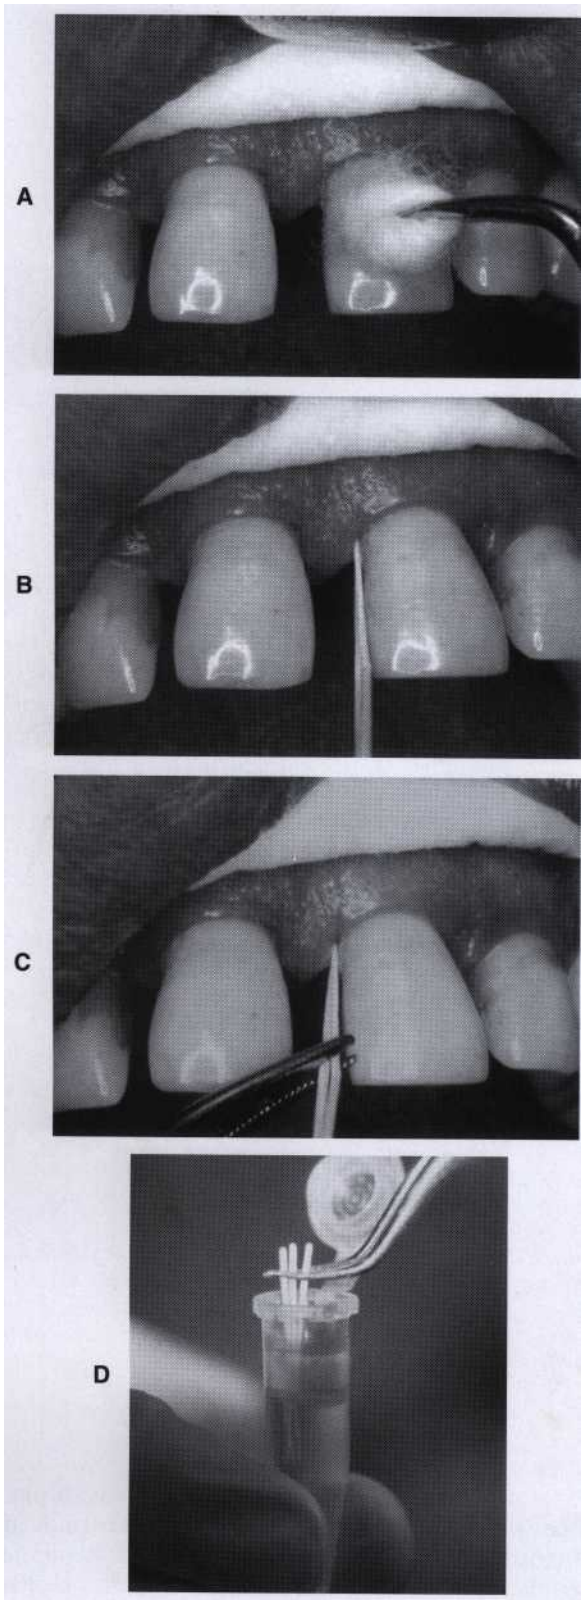

Fig. 34-10 Microbial sampling of the subgingival microflora. A and B, The tooth is dried and supragingival plaque is removed from the sampling site. C, Three sterile endodontic paper points are placed subgingivally to the base of the pocket. D, The paper points are removed and placed in a vial of anaerobic transport media for immediate transport to the laboratory for analysis.

performance of new microbial diagnostic methods. Generally, plaque samples are cultivated anaerobically and by using selective and nonselective media, together with several biochemical and physical tests, the different putative pathogens can be identified. The main advantage of this method is one can obtain relative and absolute counts of the cultured species. Moreover, it is the only in vitro method able to assess for antibiotic susceptibility of the microbes. However, culture techniques have important shortcomings. Culture methods can only grow live bacteria, therefore strict sampling and transport conditions are essential. Moreover, some of the putative pathogens, such as *Treponemas sp.* and *Bacteroides forsythus* are fastidious and difficult to culture. The sensitivity of culture methods is rather low, since the detection limits for selective and nonselective media average 10^3 to 10^4 bacteria and hence low numbers of a specific pathogen in a pocket are undetected. However, the most important drawback is that culture requires sophisticated equipment and experienced personnel and is relatively time-consuming and expensive. Clinicians, when using this method, must be confident that the laboratory has the appropriate technology and expertise in periodontal microbiology to communicate diagnostically and therapeutically useful information to them.

Direct Microscopy

Darkfield or phase contrast microscopy has been suggested as an alternative to culture methods[53] on the basis of its ability to directly and rapidly assess the morphology and motility of bacteria in a plaque sample. It has been used to indicate periodontal disease status and to structure maintenance programs. However, most of the main putative periodontopathogens, including *Actinobacillus actinomycetemcomitans, P. gingivalis, B. forsythus, Eikenella corrodens,* and *Eubacterium* species, are nonmotile, and therefore this technique is unable to identify these species. It is also unable to differentiate among the various species of *Treponema.* Therefore darkfield microscopy seems an unlikely candidate as a diagnostic test of destructive periodontal diseases.[55]

Immunodiagnostic Methods

Immunologic assays employ antibodies that recognize specific bacterial antigens to detect target microorganisms. This reaction can be revealed using a variety of procedures, including direct and indirect immunofluorescent microscopy assays (IFA), flow cytometry, enzyme-linked immunoabsorbent assay (ELISA), membrane assay, and latex agglutination.

Direct IFA employs both monoclonal and polyclonal antibodies conjugated to a fluorescein marker that binds with the bacterial antigen to form a fluorescent immune-complex detectable under a microscope. Indirect IFA employs a secondary fluorescein-conjugated antibody that reacts with the primary antigen-antibody complex. Both direct and indirect immunofluorescence assays are able to identify the pathogen and quantify the percentage of the pathogen directly using a plaque smear. IFA has

been used mainly to detect A. *actinomycetemcomitans* and *P. gingivalis.* Zambon et al[90] showed that this technique is comparable to bacterial culture in its ability to identify these pathogens in subgingival dental plaque samples. In fact, immune-fluorescence microscopy may be even more likely to detect them in clinical samples because it does not require viable bacterial cells. Comparative studies indicate that the sensitivity of these assays ranges from 82% to 100% for detection of A. *actinomycetemcomitans* and from 91% to 100% for detection of P. *gingivalis,* with specificity values of 88% to 92% and 87% to 89%, respectively.91

Cytofluorography or flow cytometry for the rapid identification of oral bacteria involves labelling bacterial cells from a patient plaque sample with both species-specific antibody and a second fluorescein-conjugated antibody. The suspension is then introduced into the flow cytometer, which separates the bacterial cells into an almost single-cell suspension by means of a laminar flow through a narrow tube. The sophistication and cost involved in this procedure precludes its wide usage.

ELISA is similar in principle to other radioimmunoassays, but an enzymatically derived color reaction is substituted as the label in place of the radioisotope. The intensity of the color depends on the concentration of the antigen and is usually read photometrically for optimal quantitation. ELISA has been used primarily to detect serum antibodies to periodontopathogens; however it has also been used in research studies to quantify specific pathogens in subgingival samples using specific monoclonal antibodies.[91]

Latex agglutination is a very simple immunological assay based on the binding of protein to latex. Latex beads are coated with the species-specific antibody, and when these beads come in contact with the microbial cell surface antigens or antigen extracts, cross-linking occurs; its agglutination or clumping is then visible usually in 2 to 5 minutes. Because of their simplicity and rapidity, these assays have great potential for chairside detection of periodontal pathogens. There are two types of latex agglutination tests-the indirect assay and inhibition assay. The indirect assay is the most common latex agglutination test for bacteria. The antibody is bound to latex. When a suspension of the plaque sample is mixed with the sensitized latex and gently agitated for 3 to 5 minutes, resulting agglutination or clumping is indicative of a positive result for the bacteria being tested. The inhibition assay is based on the principle of inhibiting the expected agglutination reaction between known antigen and known antibody as a result of competition.

A membrane immunoassay has been recently marketed (Evalusite°). It involves linkage between the antigen and a membrane-bound antibody to form an immunocomplex that is later revealed through a colorimetric reaction. Evalusite has been designed to detect A. *actinomycetemcomitans, P. gingivalis,* and P. *intermedia.*[91] Immunological assays for oral bacteria, although extensively used for research purposes, lack the clinical validation since most of them have never been available commercially. Cross reactivity leading to detection of false positives may represent a major problem, mostly when polyclonal antibodies are used. On the other hand the use of monoclonal antibodies may cause the occurrence of false negatives when compared with culture, due to their high specificity. Immunological assays can identify dead target cells, thus not requiring stringent sampling and transport methodology. However, they cannot be used to determine antibiotic susceptibility. Most of these assays provide a quantitative or semiquantitative estimate of target microorganisms; however, these methods generally show poorer detection limits than nucleic acid probes of PCR assays. Snyder et all° tested the sensitivity of the Evalusite test, demonstrating a detection limit of 10^5 for A. *actinomycetemcomitans* and 10^6 for P. *gingivalis.*

Enzymatic Methods of Bacterial Identification

B. forsythus, P. gingivalis, the small spirochete *Treponema denticola,* and *Capnocytophaga* species share a common enzymatic profile, since all have in common a trypsin-like enzyme. The activity of this enzyme can be measured with the hydrolysis of the colorless substrate N-benzoyl-dl-arginine-2-naphthylamide (BANA). When the hydrolysis takes place, it releases the chromophore ß-naphthylamide, which turns orange red when a drop of fast garnet is added to the solution. Diagnostic kits has been developed using this reaction for the identification of this bacteria profile in plaque isolates (Perioscan°). Loesche et all' proposed the use of this BANA reaction in subgingival plaque samples to detect the presence of any of these periodontal pathogens and thus serve as a marker of disease activity. Using probing depths as a measure of periodontal morbidity, Loesche et al[56] showed that shallow pockets exhibited only 10% positive BANA reactions, whereas deep pockets (7 mm) exhibited 80% to 90% positive BANA reactions. Beck et all used the BANA test as a risk indicator for periodontal attachment loss. Taken collectively, results using this diagnostic method suggest that positive BANA findings are a good indication that T. *denticola, P. gingivalis,* or both are present at sampled sites. One of the potential difficulties of this test is that it may be positive at clinically healthy sites and remains to be proven whether this test can detect sites undergoing periodontal destruction. Besides, since it only detects a very limited number of pathogens, its negative result does not rule out the presence of other important periodontal pathogens.

Deoxyribonucleic Acid Probe Technology

Nucleic Acid Probes. Deoxyribonucleic acid (DNA) probes entail segments of single-stranded nucleic acid, labelled with an enzyme or radioisotope, that can locate and bind to their complementary nucleic acid sequences with low cross-reactivity to nontarget organisms. DNA probe may target whole genomic DNA or individual genes. Whole genomic probes are more likely to cross-react with nontarget microorganisms due to the presence of homologous sequences between different bacterial species. However, specific genes, such as 16S rRNA (ribonucleic acid) genes, contain signature sequences limited to organisms of the same species. These oligonu-

cleotide probes display limited or no cross-reactivity with nontarget microorganisms.[14] To prepare the probe, specific pathogens used as marker organisms are lysed to remove their DNA. Their double helix is denatured, creating single strands that are individually labeled with a radioactive isotope. Subsequently, when a plaque sample is sent for analysis, it undergoes lysis and denaturation. Single strands are chemically treated, attached to a special filter paper, and then exposed to the DNA library. If complementary base pairs hybridize (cross-link), the radiolabeled strands will also be fixed to the filter paper. After the filter is washed to remove any unhybridized strands, it is covered with a radiographic plate. The radioactive labels create spots on the film, which are read with a densitometer. The darkness and size of the spots indicate the concentration of the organisms present in the given plaque sample. The assay can rapidly test for multiple bacteria, including A. actinomycetemcomitans, P. gingivalis, B. intennedius, C. rectus, *E.* corrodens, Fusobacterium nucleatum, and T. denticola in multiple clinical plaque samples. The probes are able to detect as few as 101 to 10⁴ bacteria, and the sensitivity and specificity are not affected by the presence of unrelated bacteria in mixed culture samples.[18,68]

Restriction Endonuclease Analysis. Restriction endonucleases recognize and cleave double-stranded DNA at specific base pair sequences. The DNA fragments generated are separated by electrophoresis, stained with ethidium bromide, and visualized with ultraviolet light. The genetic heterogeneity and homogeneity of strains can then be evaluated by comparing the number and size (electrophoretic pattern) of the DNA fragments obtained. These DNA fragment patterns constitute a specific "fingerprint" to characterize each strain. Restriction endonuclease analysis is thus a powerful tool for determining the distribution of a specific pathogenic strain throughout a population.22 This technology has also been applied to the molecular genetic analysis of the natural diversity of such oral bacteria as A. actinomycetemcomitans, P. gingivalis, P. intermedia, *E.* corrodens, F. nucleatum, and T. denticola and has been very useful in studying the transmission patterns of putative periodontal pathogens among family members.72

Polymerase Chain Reaction. Polymerase chain reaction (PCR) involves a reiterate amplification of a region of DNA flanked by a selected primer specific for the target species. The presence of the specific amplification product indicates the presence of the target microorganism. Among the different nucleic acid assays, PCR demonstrates the best detection limits, as few as five to ten cells and shows no cross-reactivity under optimized amplification conditions. Different bacterial species may be detected simultaneously by multiplex PCR in which several distinct primer pairs, each specific for a given target microorganism are employed in a single-tube amplification process.[l°,11,88] Most PCR assays have the drawback that relatively small aliquots are used for the amplification process. If this small quantity of the plaque sample does not contain the targeted microorganism, the assay will not detect it. Moreover, subgingival plaque may contain enzymes that can alter the amplification process. Until recently, PCR assays were able just to assess the presence of the target microorganism. Fujise et all' have developed a quantitative PCR method. PCR assays have the potential for being an ideal detection method of periodontal microorganisms. It is relatively easy to perform and demonstrates excellent detection limits and little cross-reactivity under optimal conditions.

ADVANCES IN CHARACTERIZING THE HOST RESPONSE

Our understanding of the initiation and progression of periodontal disease and the pathogenic processes involved has expanded enormously in light of advances in clinical and basic science research. Diagnostic tests have been developed that add measures of the inflammatory process to conventional clinical measures. These tests may provide information on the destructive process itself, current activity of the disease, rate of disease progression, patterns of destruction, extent and severity of future breakdown, and likely response to therapy. With this information the clinician would be able to better individualize his therapeutic approach, thus customizing the recommended treatment. Assessment of the host response refers to the study of mediators, by immunologic or biochemical methods, that are recognized as part of the individual's response to the periodontal infection. These mediators are either specifically identified with the infection, such as antibody to a putative pathogen, or represent a less specific reaction like the local release of inflammatory mediators, host-derived enzymes, or tissue breakdown products. The host response in periodontal disease involves aspects of acute and chronic inflammation, humoral and cellular immune responses. Mediators representing each of these systems have been evaluated as diagnostic tests in clinical periodontics from samples that usually involve non-invasive or minimally invasive techniques .[48]

Source of Samples

Potential sample sources include saliva, gingival crevicular fluid (GCF), gingival crevicular cells, blood serum, blood cells, and urine. However, analysis of urine shows little promise except for its use in the differential diagnosis of tooth loss related to hypophosphatasia in young children, in whom the presence of phosphoethanolamine in urine is diagnostic of the disease. Most efforts to date have been based on the use of components of GCF and, to a lesser extent, saliva and blood.67 Different studies have demonstrated a high correlation between clinical and histologic signs of gingivitis and increased amounts of gingival fluid flow." In addition, more than 40 components of GCF have been studied. They can be divided into three main groups: host-derived enzymes, tissue breakdown products, and inflammatory mediators. For the collection of gingival crevicular fluid (GCF) a number of approaches have been used, which range from the use of paper strips, to microcapillary tubes and micropipettes, to micro-syringes and plastic strips. The method most widely used is the use of paper strips.

These strips are placed in the gingival sulcus for a standard period of time until the filter paper is saturated (Fig. 34-11). The fluid volume collected on the strips can be then quantified in a number of ways. At present the most popular way is using the Periotron® (Fig. 34-11, B). This electronic device measures the change in capacitance across the wetted strip, and this change is converted to a digital readout, which can be correlated to the volume of gingival crevicular fluid. Researchers have established that the Periotron 6000 achieves the easiest and quickest measurement and shows high correlation with other clinical gingival indices.[84] Research on GCF has focused on the search for biochemical markers of the progression of periodontitis many of which are discussed below.

Saliva is another fluid that can be easily collected and may contain both locally and systemically derived markers of periodontal disease, which can be evaluated for diagnostic purposes. Saliva can be collected from the parotid, submandibular, or sublingual glands or as "whole saliva" consisting of a mixture of oral fluids, including secretions from the major and minor salivary glands, in addition to constituents of nonsalivary origin (GCF, bacteria and bacterial products, desquamated cells, expectorated bronchial secretions, and so on). In addition, saliva samples can be collected with or without stimulation. The use of saliva for periodontal diagnosis has been the subject of considerable research activity, although no saliva-based diagnostic tests are available to be used in clinical practice. Proposed diagnostic markers in saliva include proteins and enzymes of host origin, phenotypic markers, host cells, hormones (cortisol), bacteria and bacterial products, volatile compounds, and ions.[4a]

Inflammatory Mediators and Products

Cytokines are potent local mediators of inflammation that are produced by a variety of cells. Cytokines that are present in GCF and have been investigated as potential diagnostic markers include tumor necrosis factor alpha (TNF-a),[79] interleukin-1 alpha (IL-la), interleukin-1 beta (IL-1ß),[83] interleukin-6 (IL-6), and interleukin 8 (IL-8). IL-1, IL-6, and TNF-a are cytokines produced by a variety of cells at inflamed sites. They are potent immunoregulatory molecules with a variety of biologic effects, including metalloproteinase stimulation and bone resorption; therefore they seem good candidates for markers of disease progression (see Chapter 7). Cross-sectional studies have shown good correlation with disease status and severity,[83] but not disease progression. Prostaglandin E2 is a product of the cyclooxygenase pathway of the metabolism of arachidonic acid. It is a potent mediator of inflammation and induces bone resorption. In cases of untreated periodontitis, the concentration of prostaglandin E2 found in GCF increased during active phases of periodontal destruction.[65]

Host-Derived Enzymes

Various enzymes are released from host cells during the initiation and progression of periodontal disease.[10,45] The enzymes that have received the most attention as possible markers of active periodontal destruction are aspartate aminotransferase (AST), akaline phosphatase, ß-glucuronidase, elastase, cathepsins, and matrix metalloproteinases. Some of these enzymes are released from dead and dying cells of the periodontium; some come from polymorphonuclear neutrophils; and others are produced by inflammatory, epithelial, and connective tissue cells at affected sites.

AST is an enzyme released from dead cells from a variety of tissues throughout the body, including the heart (after myocardial infarction) and the liver (during hepatitis). Several studies evaluating the association be-

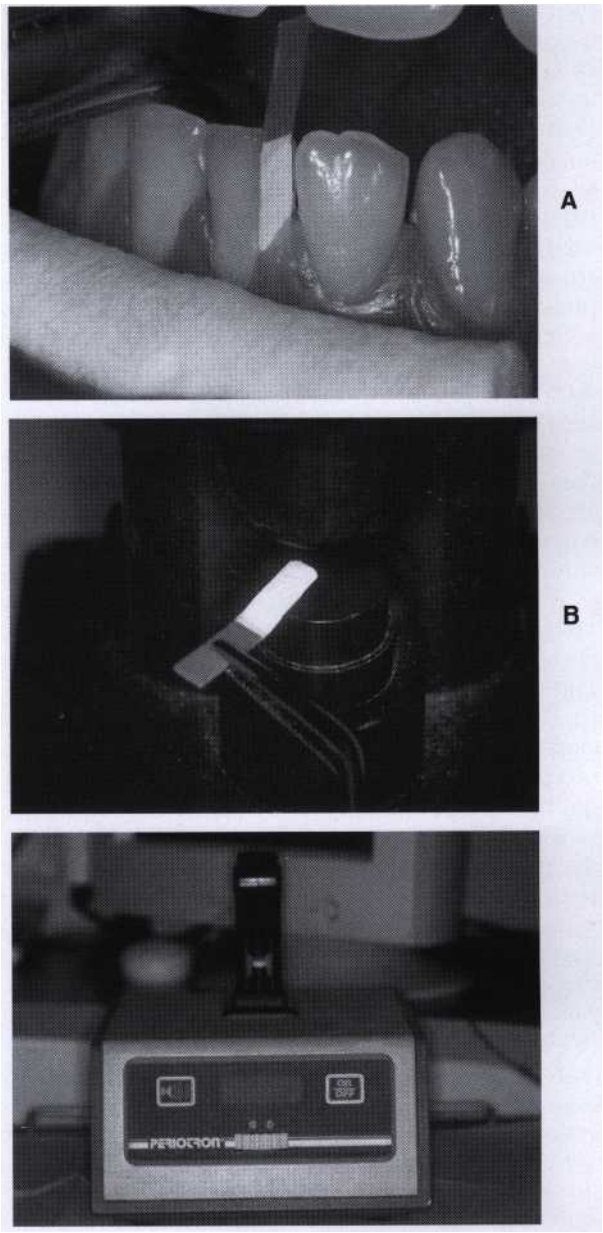

Fig. 34-11 Sampling method for crevicular fluid analysis (Periotron System). A, Saliva is removed from the tooth surface with cotton wool prior to placement of a periopaper strip into the pocket to collect GCF. B, The moist paper strip is removed and placed between the jaws of the Periotron for the assessment of fluid content.

tween elevated AST levels in GCF and periodontal disease have demonstrated a marked elevation in AST levels in GCF samples from sites with severe gingival inflammation[12] and sites with a recent history of progressive attachment loss. A rapid chairside test kit or AST has been developed (Periogard®). The test involves collection of GCF with a filter paper strip, which is then placed in tromethamine hydrochloride buffer. A substrate reaction mixture containing L-aspartic and a-ketoglutaric acids are added and allowed to react for 10 minutes. In the presence of AST, the aspartate and a-glutarate are catalyzed to oxalacetate and glutamate. The addition of a dye, such as fast red, results in a color product, the intensity of which is proportional to the AST activity in the GCF sample. A potential problem with the AST test is its inability to discriminate between sites with severe inflammation but with no attachment loss from sites that are losing attachment. It remains to be demonstrated whether this test offers some advantage over existing clinical measures of disease.[60,71]

Alkaline phosphatase (ALP) is an enzyme found in many cells of the periodontium, including osteoblasts, fibroblasts, and neutrophils. Cross-sectional studies show that concentrations of this enzyme in GCF from diseased sites are significantly higher than from healthy sites. Only one longitudinal study has associated whole mouth ALP levels with the progression of periodontitis,[9] but this study has not been reproduced.

ß-glucuronidase (ßG) is a lysosomal enzyme found in the primary (azurophilic) granules of neutrophils. Cross-sectional data clearly show elevated ßG activity in sites with more severe periodontal disease. Two longitudinal studies from the same research group have shown that the concentration of this enzyme may have predictive value in identifying patients at higher risk for losing attachment." Elastase is a serine protease also stored in the primary granules of neutrophils. Cross-sectional studies clearly indicate that GCF samples taken from sites with periodontitis have significantly higher elastase activity than GCF from healthy or gingivitis sites.[29] A rapid chairside test kit (Periocheck®) has been developed to detect neutral proteases in GCF. A limited number of longitudinal studies have evaluated its value as marker of periodontal disease progression.' They have shown some predictive value for disease progression in a short-term evaluation of an untreated population, but it remains unclear if its validity can be applied to a treated population in a maintenance program. Similar results have been obtained studying cathepsins. These enzymes are a group of acidic lysosomal enzymes that play an important role in intracellular protein degradation. Although they have shown correlation with disease severity and significant decrease after periodontal therapy, they have not been evaluated longitudinally as markers of disease progression."

Matrix metalloproteinases (MMP') are members of a large subfamily of zinc- and calcium-dependent proteolytic enzymes (proteinases) responsible for remodeling and degradation of extracellular matrix components. The homeostasis of extracellular matrices is regulated by the release of MMP' by different cells such as fibroblasts and macrophages and the presence of tissue inhibitors of MMP' that are widely distributed in tissues and fluids. Different cross-sectional studies have shown that high MMP levels are associated with periodontitis, as are low levels of tissue inhibitors. Recently Sorsa et al[28] suggested that MMP' be used as a method for detecting destructive periodontitis, especially MMP-8. However, no rapid chairside test kit has been developed for clinical use.

Tissue Breakdown Products

One of the major features of periodontitis is the destruction of collagen and extracellular matrices. Analysis of GCF obtained from sites with periodontitis clearly shows elevated levels of hydroxyproline from collagen breakdown and glycosaminoglycans from matrix degradation." Other bone and connective tissue proteins, including osteocalcin and type 1 collagen peptides, have been correlated with the progression of alveolar bone loss induced in beagle dogs.[23] Both markers gave high positive predictive values and now need to be extended to longitudinal studies in humans.

In conclusion, although there are many potential markers for periodontal disease activity and progression, still numerous features hamper the ability to use them as diagnostic tests of proven utility. There is still a lack of a proven gold standard of disease progression and thus the correlation of these potential markers with proven clinical attachment loss may be a potential confounder in any proposed test. After all these years of intensive research we still lack a proven diagnostic test that has demonstrated high predictive value for disease progression, has a proven impact on disease incidence and prevalence and is simple, safe and cost effective.[54]

The Treatment Plan

Fermin A. Carranza and Henry H. Takei

CHAPTER OUTLINE

THE MASTER PLAN FOR TOTAL TREATMENT
Extracting or Preserving a Tooth
THERAPEUTIC PROCEDURES
EXPLAINING THE TREATMENT PLAN TO THE PATIENT

After the diagnosis and prognosis have been established, the treatment is planned. *The treatment plan is the blueprint for case management.* It includes all procedures required for the establishment and maintenance of oral health, such as the following decisions:

- Teeth to be retained or extracted
- Pocket therapy, by means of surgical or nonsurgical methods, and the techniques to be used
- The need for occlusal correction, prior, during, or after pocket therapy
- The use of implant therapy
- The need for temporary restorations
- Final restorations that will be needed after therapy and which teeth will be abutments if fixed prosthesis is used
- The need for orthodontic consultation
- Endodontic therapy
- Regarding esthetic considerations in periodontal therapy
- On sequence of therapy

Unforeseen developments during treatment may necessitate modification of the initial treatment plan. However, except for emergencies, no treatment should be started until the treatment plan has been established.

THE MASTER PLAN FOR TOTAL TREATMENT

The aim of the treatment plan is total treatment-that is, the coordination of all treatment procedures for the purpose of creating a well-functioning dentition in a healthy periodontal environment. The master plan of periodontal treatment encompasses different areas of therapeutic objectives for each patient according to his or her needs. It is based on the diagnosis, disease severity, and other factors outlined in previous chapters and should include a reasoned decision on the possible and desirable therapeutic endpoints and the techniques to be used to reach this objective.

The primary goal is elimination of gingival inflammation and correction of the conditions that cause and/or perpetuate it. This includes not only elimination of root irritants, but also pocket eradication/reduction, establishment of gingival contours and mucogingival relationships conducive to the preservation of periodontal health, restoration of carious areas, and correction of existing restorations.

Extracting or Preserving a Tooth

Periodontal treatment requires long-range planning. Its value to the patient is measured in years of healthy functioning of the entire dentition, not by the number of teeth retained at the time of treatment. It is directed

to establishing and maintaining the health of the periodontium throughout the mouth rather than to spectacular efforts to "tighten loose teeth."

The welfare of the dentition should not be jeopardized by a heroic attempt to retain questionable teeth. The periodontal condition of the teeth to be retained is more important than the number of such teeth. Teeth that can be retained with minimal doubt and a maximal margin of safety provide the basis for the total treatment plan. Teeth on the borderline of hopelessness do not contribute to the overall usefulness of the dentition, even if they can be saved in a somewhat precarious state. Such teeth become sources of recurrent annoyance to the patient and detract from the value of the greater service rendered by the establishment of periodontal health in the remainder of the oral cavity.

Removal, retention or temporary (interim) retention of one or more teeth is a very important part of the overall treatment plan.

A tooth should be extracted when any of the following occurs:

- It is so mobile that function becomes painful.
- It can cause acute abscesses during therapy.
- There is no use for it in the overall treatment plan.

A tooth can be retained temporarily, postponing the decision to extract it until after treatment, when any of the following occurs:

- It maintains posterior stops; it can be removed after treatment when it can be replaced by a prosthesis.
- It maintains posterior stops and may be functional after implant placement in adjacent areas. When implant is exposed these teeth can be extracted.
- In anterior esthetic areas, a tooth can be retained during periodontal therapy and removed when treatment is completed and a permanent restorative procedure can be performed. This will replace wearing temporary appliances. This can be considered when retention of this tooth will not jeopardize adjacent teeth.
- Removal of hopeless teeth can also be performed during periodontal surgery of neighboring teeth. This would reduce surgical appointments for surgery in the same area.

Teeth will be retained when their prognosis is good to excellent (see Chapter 33).

In the formulation of the treatment plan, in addition to proper function of the dentition, *esthetic considerations* play an increasingly important role in many cases. Different patients value esthetics differently according to their age, gender, profession, social status, and other reasons, and the clinician should carefully evaluate and consider a final outcome of treatment that will be acceptable to the patient without jeopardizing the basic consideration of attaining health.

With the predictable use of implants, questionable teeth should be carefully evaluated as to whether their removal and replacement with an implant may be a better and more satisfactory course of therapy.

In complex cases, the interdisciplinary consultation with other specialty areas is necessary before a final plan can be made. The opinion of orthodontists and prosthodontists is especially important for the final decision in these cases.

Consideration of occlusal relationships may be in order and may necessitate occlusal adjustment, restorative, prosthetic and orthodontic procedures, splinting, and correction of bruxism and clamping and clenching habits.

Systemic conditions should be carefully evaluated, as they may require special precautions during the course of periodontal treatment and may also affect the tissue response to treatment procedures or threaten the preservation of periodontal health after treatment is completed. Such situations should be taken in conjunction with the patient's physician.

Supportive periodontal care is also of paramount importance for case maintenance. Such care entails all procedures for maintaining periodontal health after it has been attained. It consists of instruction in oral hygiene and checkups at regular intervals according to the patient's needs to examine the condition of the periodontium and the status of the restoration as it affects the periodontium.

THERAPEUTIC PROCEDURES

Periodontal therapy is an inseparable part of dental therapy. The list of procedures presented here includes periodontal procedures (in italics) and other procedures not considered to be within the province of the periodontist. They are listed together to emphasize the close relationship of periodontal therapy with other phases of therapy performed by general dentists or other specialists (Box 35-1).

The sequence in which the above phases of therapy are performed may vary to some extent in response to the requirements of the case. However, the preferred sequence, which covers the vast majority of cases, is shown in Box 35-2.

Although the phases of treatment have even been numbered, as mentioned above, their recommended sequence does not follow their numbers. The etiotropic phase, even when successfully performed, stops the progression of dental and periodontal disease. Immediately after completion of Phase I therapy, the patient should be placed on the Maintenance Phase (Phase IV) to preserve the results obtained and prevent any further deterioration and recurrence of disease. While the patient is on the Maintenance Phase, with its periodic checkups and controls, he/she enters into the surgical and reparative phases of treatment (Phases III and IV). This includes periodontal surgery to repair and improve the condition of the periodontal and surrounding tissues and esthetics, rebuild lost structures, place implants, and construct the necessary restorative work.

EXPLAINING THE TREATMENT PLAN TO THE PATIENT

The following discussion includes suggestions for explaining the treatment plan to the patient.

BOX 35-1

Phases of Periodontal Therapy

Preliminary Phase
Treatment of emergencies:

- Dental or periapical
- *Periodontal*
- Other

Extraction of hopeless teeth and provisional replacement if needed (may be postponed to a more convenient time)

Etiotropic Phase (Phase I Therapy)
Plaque control and patient education

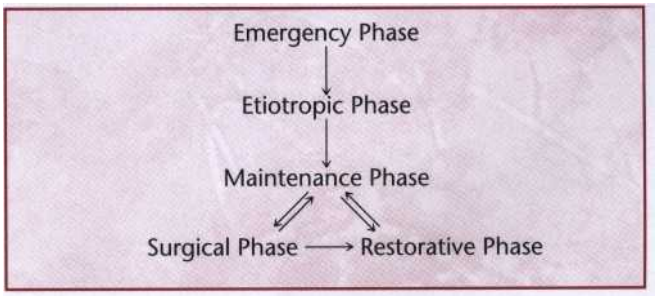
- Diet control (in patients with rampant caries)
- *Removal of calculus and root planing*
- *Correction of restorative and prosthetic irritational factors*
- Excavation of caries and restoration (temporary or final, depending on whether a definitive prognosis for the tooth has been arrived at and on the location of caries)
- *Antimicrobial therapy (local or systemic)*
- *Occlusal therapy*
- *Minor orthodontic movement*
- *Provisional splinting and prosthesis*

Evaluation of Response to Etiotropic Phase
Rechecking:

- *Pocket depth and gingival inflammation*
- *Plaque and calculus, caries*

Surgical Phase (Phase II Therapy)
Periodontal therapy, including placement of implants
Endodontic therapy

Restorative Phase (Phase III Therapy)
Final restorations
Fixed and/or removable prosthodontics



Evaluation of Response to Restorative Procedures
Periodontal examination

Maintenance Phase (Phase IV Therapy)
Periodic rechecking:

- *Plaque and calculus*
- *Gingival condition (pockets, inflammation)*
- *Occlusion, tooth mobility*
- Other pathologic changes

BOX 35-2

Preferred Sequence of Periodontal Therapy

Be specific. Tell your patient: "You have gingivitis," or "You have periodontitis." Then explain exactly what these conditions are, how they are treated, and prognosis for the patient after treatment. *Avoid vague statements* such as: "You have trouble with your gums," or "Something should be done about your gums." Patients do not understand the significance of such statements and disregard them.

Begin your discussion on a positive note. Talk about the teeth that can be retained and **the long-term service they can be expected** to render. Do not begin your discussion with the statement: "The following teeth have to **be extracted." This creates a negative impression, which adds to the erroneous attitude of** hopelessness the patient already may have regarding his or her mouth. Make it clear that every effort will be made to retain as many teeth as possible, *but do not dwell on the patient's loose teeth.* Emphasize that the important purpose of the treatment is to prevent the other teeth from becoming as severely diseased as the loose teeth.

Present the entire treatment plan as a unit. Avoid creating the impression that treatment consists of separate procedures, some or all of which may be selected by the patient. *Make it clear that dental restorations and prostheses contribute as much to the health of the gums as does the elimination of inflammation and periodontal pockets.* Do not speak in terms of "having the gums treated and then taking care of the necessary restorations later" as if these were unrelated treatments.

Patients often seek guidance from the dentist with such questions as: "Are my teeth worth treating?" "Would you have them treated if you were me?" or "Why don't I just go along the way I am until the teeth really bother me and then have them all extracted?"

Explain that "doing nothing" or holding onto hopelessly diseased teeth as long as possible is inadvisable for the following reasons:

Periodontal disease is a microbial infection, and research has clearly shown it to be an important risk factor for severe life-threatening diseases such as stroke, cardiovascular disease, pulmonary disease, and diabetes as well as for premature low birth-weight babies in women of childbearing age. Correcting the periodontal condition eliminates a serious potential risk of systemic disease, which in some cases ranks as high in the danger list as smoking.

It is not feasible to place restorations or bridges on teeth with untreated periodontal disease because the usefulness of the restoration is limited by the uncertain condition of the supporting structures.

- Failure to eliminate periodontal disease not only results in the loss of teeth already severely involved but also shortens the life span of other teeth that, with proper treatment, could serve as the foundation for a healthy, functioning dentition.
- Therefore the dentist should make it clear to the patient that if the periodontal condition is treatable, the best results are obtained by prompt treatment. If the condition is not treatable, the teeth should also be promptly extracted.

It is the dentist's responsibility to advise the patient of the importance of periodontal treatment. However, if treatment is to be successful, the patient must be sufficiently interested in retaining the natural teeth to maintain the necessary oral hygiene. Individuals who are not particularly perturbed by the thought of losing their teeth are generally not good candidates for periodontal treatment.

Rationale for Periodontal Treatment

- **Systemic Factors**

HEALING AFTER PERIODONTAL THERAPY
- **Regeneration**
- **Repair**
- **New Attachment**

WHAT DOES PERIODONTAL THERAPY ACCOMPLISH?

The effectiveness of periodontal therapy is made possible by the remarkable healing capacity of the periodontal tissues (Fig. 36-1). Periodontal therapy can restore chronically inflamed gingiva so that from a clinical and structural point of view it is almost identical with gingiva that has never been exposed to excessive plaque accumulation" (see Chapter 77).

Properly performed, periodontal treatment can be relied on to accomplish the following: eliminate pain, eliminate gingival inflammation [25] and gingival bleeding, reduce periodontal pockets and eliminate infection, stop pus formation, arrest the destruction of soft tissue and bone,[16] reduce abnormal tooth mobility,[6] establish optimal occlusal function, restore tissue destroyed by disease in some instances, reestablish the physiologic gingival contour necessary for the preservation of periodontal health, prevent the recurrence of disease, and reduce tooth loss (Fig. 36-2).[22]

Local Therapy

The cause of periodontitis and gingivitis is bacterial plaque accumulation on the tooth surface in close proximity to the gingival tissue. The accumulation of plaque can be favored by a variety of local factors, such as calculus, overhanging margins of restorations, and food impaction. The removal of plaque and of all the factors that favor its accumulation is therefore the primary consideration in local therapy.

Abnormal forces on the tooth increase tooth mobility. The thorough elimination of plaque and the prevention of its new formation, by themselves, maintain periodontal health, even if traumatic forces are allowed to persist.[17,18] However, the elimination of trauma may increase the chances of bone regeneration and gain of attachment." Although this point is not widely accepted,[23] it appears that creating occlusal relations that are more tolerable to the periodontal tissues increases the margin of safety of the periodontium to minor buildup of plaque, in addition to reducing tooth mobility. It should be remembered that total plaque elimination as obtained in experimental studies may not be possible in all human subjects.

Systemic Therapy

Systemic therapy may be employed *as an adjunct to local measures and for specific purposes,* such as the control of systemic complications from acute infections, chemotherapy to prevent harmful effects of posttreatment bacteremia, supportive nutritional therapy, and the control of systemic diseases that aggravate the patient's periodontal

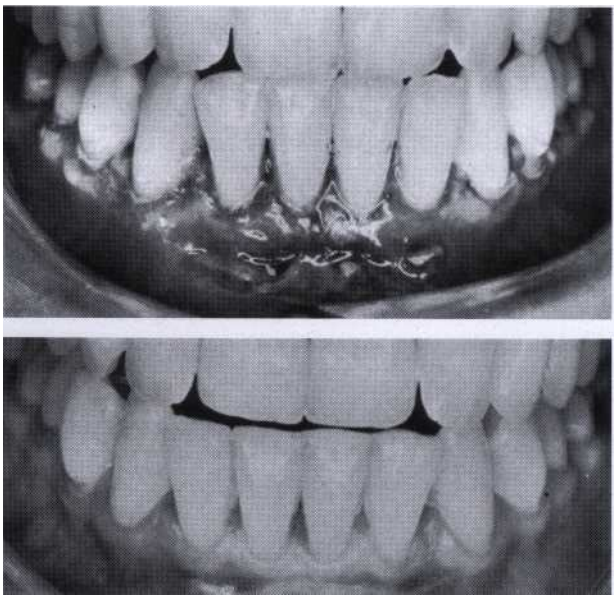

Fig. 36-1 Excellent healing capacity of the periodontium. *Above,* **One week following periodontal surgery, after removal of periodontal dressing.** *Below,* **After 7 months, showing healed tissues and restoration of physiologic gingival contour.**

condition or necessitate special precautions during treatment (see Chapter 38).

Systemic therapy *for treatment of the periodontal condition and in conjunction with local therapy is* indicated in localized and generalized aggressive periodontitis. In these diseases, systemic antibiotics are used to completely eliminate the bacteria that invade the gingival tissues and can repopulate the pocket after scaling and root planing (see Chapters 40 and 50).

In addition, *periodontal manifestations of systemic diseases* (see Chapter 12) are treated primarily by other than local measures. However, local therapy may still be indicated to reduce or prevent complications of gingival inflammation.

Evidence has been presented that some *nonsteroidal antiinflammatory drugs* such as flurbiprofen and ibuprofen can slow down the development of experimental gingivitis,$ as well as the loss of alveolar bone in periodontitis.[1o,31-33] These drugs are propionic acid derivatives and act by inhibiting the cyclooxygenase pathway of arachidonic acid metabolism, thereby reducing prostaglandin formation; they can be administered by mouth [12] or applied topically.[31] This type of therapy is still in experimental stages, and protocols for its clinical use have not been established. However, it shows that future treatment modalities may attempt not only to control the bacterial cause of the disease, but also to suppress the self-destructive components of the host inflammatory response. 10

Another drug that has a strong inhibitory effect on bone resorption is alendronate, a *bisphosphonate,* which is currently used to treat metabolic diseases in humans, such as Paget's disease or hypercalcemia of malignancy, which result in bone resorption. Experimental studies in monkeys have shown that the bisphosphonate alendronate reduced the bone loss associated with periodontitis.[3,30]

FACTORS THAT AFFECT HEALING

In the periodontium, as elsewhere in the body, healing is affected by local and systemic factors.

Local Factors

Systemic conditions that impair healing may reduce the effectiveness of local periodontal treatment and should be corrected before, or along with, local procedures. However, local factors, particularly plaque microorganisms are the most common deterrents to healing following periodontal treatment.

Healing is also delayed by excessive tissue manipulation during treatment, trauma to the tissues, the presence of foreign bodies, and repetitive treatment procedures that disrupt the orderly cellular activity in the healing process. An adequate blood supply is needed for the increased cellular activity during healing; if this is impaired or insufficient, areas of necrosis will develop and delay the healing process.

Healing is improved by debridement (the removal of degenerated and necrotic tissue), immobilization of the healing area, and pressure on the wound. The cellular activity in healing entails an increase in oxygen consumption, but healing of the gingiva is not accelerated by artificially increasing the oxygen supply beyond the normal requirements.'

Systemic Factors

The effects of systemic conditions on healing have been extensively documented in animal experiments but are less clearly defined in humans. Healing capacity diminishes with age,[4,9] probably due to atherosclerotic vascular changes, which are common in aging, and result in reduction in blood circulation. Healing is delayed in patients with generalized infections and in those with diabetes and other debilitating diseases.

Healing is retarded by insufficient food intake; bodily conditions that interfere with the use of nutrients; and deficiencies in vitamin [C,1,29] proteins,[28] and other nutrients. However, the nutrient requirements of the healing tissues in minor wounds, such as those created by periodontal surgical procedures, are ordinarily satisfied by a well-balanced diet.

Healing is also affected by hormones. Systemically administered glucocorticoids such as cortisone hinder repair by depressing the inflammatory reaction or by inhibiting the growth of fibroblasts, the production of collagen, and the formation of endothelial cells. Systemic stress,[27] thyroidectomy, testosterone, adrenocorticotropic hormone (ACTH), and large doses of estrogen suppress the formation of granulation tissue and retard healing.' Progesterone increases and accelerates the vascularization of immature granulation tissue[16] and appears to increase the susceptibility of the gingiva to mechanical injury by causing dilation of the marginal vessels.[11]

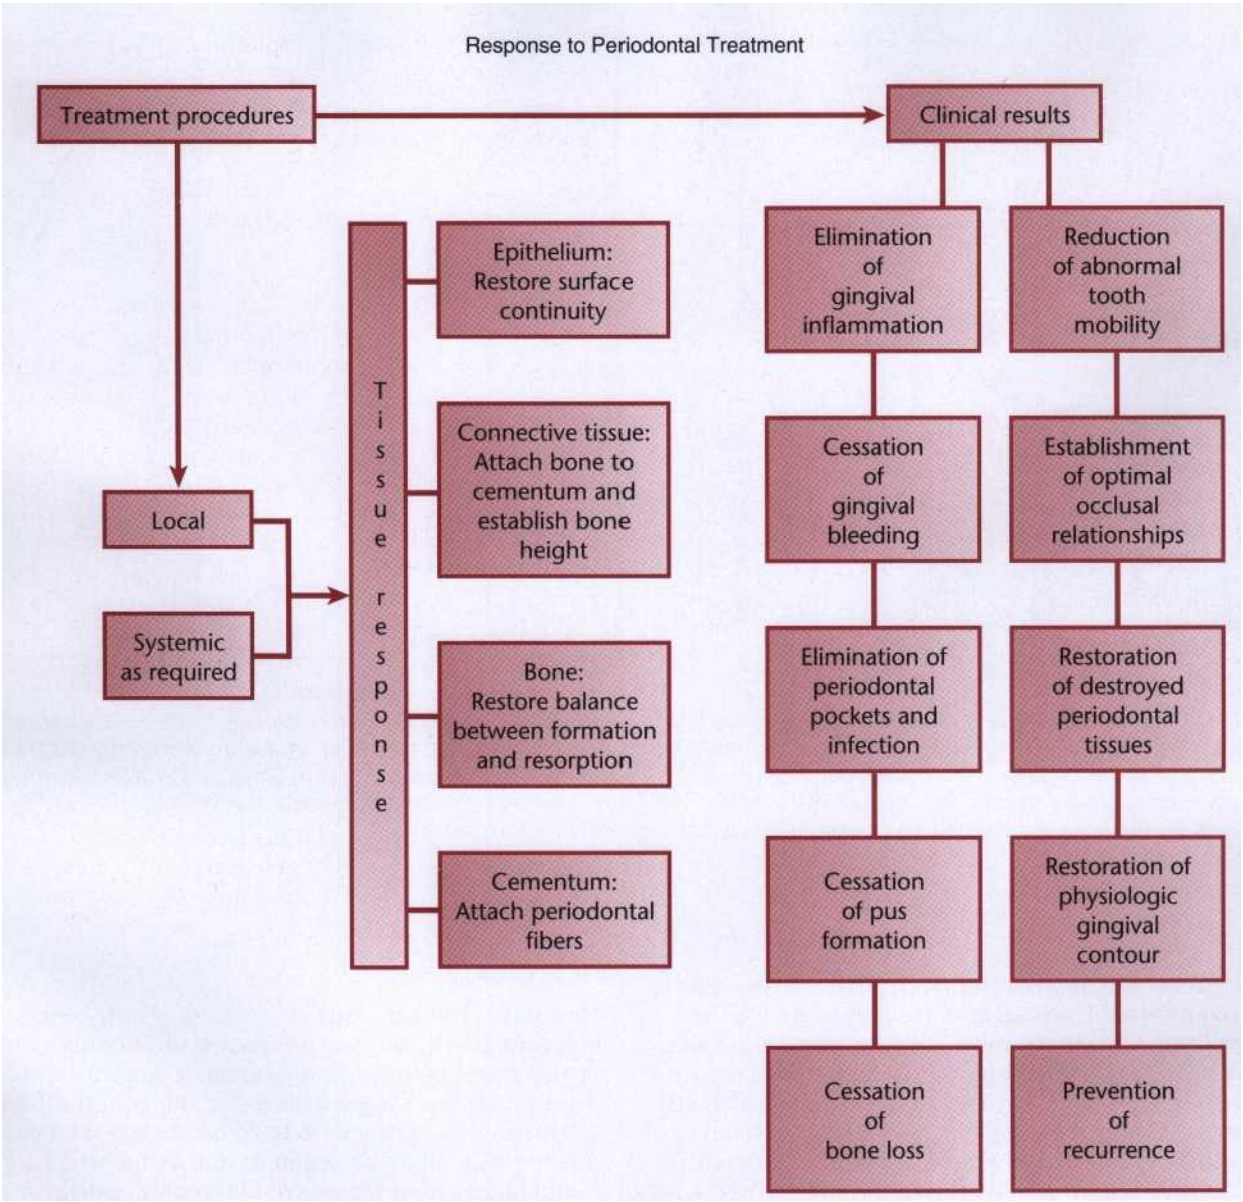

Fig. 36-2 Tissue response and clinical results after periodontal treatment.

HEALING AFTER PERIODONTAL THERAPY

The basic healing processes are the same following all forms of periodontal therapy. They consist of the removal of degenerated tissue debris and the replacement of tissues destroyed by disease. Regeneration, repair, and new attachment are aspects of periodontal healing that have a special bearing on the results obtainable by treatment.

Regeneration

Regeneration is the growth and differentiation of new cells and intercellular substances to form new tissues or parts. Regeneration takes place by growth from the same type of tissue that has been destroyed or from its precursor. In the periodontium, gingival epithelium is replaced by epithelium, and the underlying connective tissue and periodontal ligament are derived from connective tissue. Bone and cementum are not replaced by existing bone or cementum but by connective tissue, which is the precursor of both. Undifferentiated connective tissue cells develop into osteoblasts and cementoblasts, which form bone and cementum.

Regeneration of the periodontium is a continuous physiologic process. Under normal conditions new cells and tissues are constantly being formed to replace those that mature and die. This is termed *wear and tear repair."* It is manifested by mitotic activity in the epithelium of the gingiva and the connective tissue of the periodontal ligament, by the formation of new bone, and by the continuous deposition of cementum.

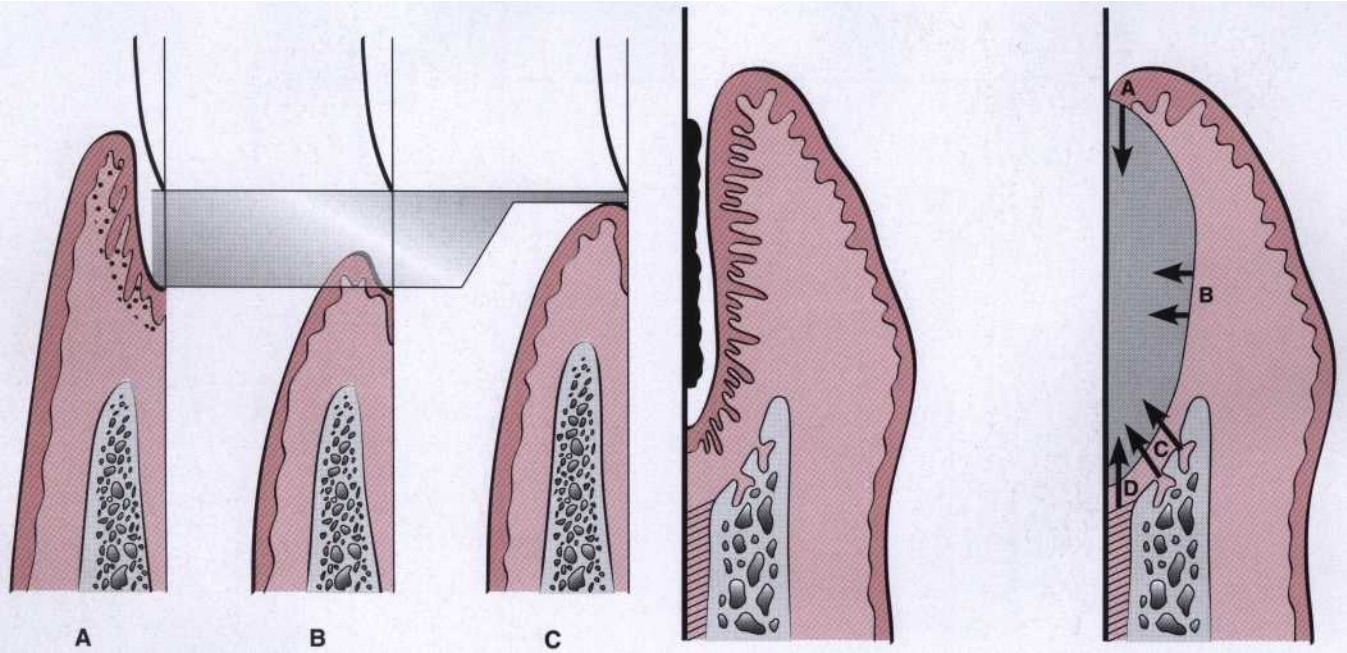

Fig. 36-3 Two possible outcomes of pocket elimination. A, Periodontal pocket before treatment. B, Normal sulcus reestablished at the level of the base of the pocket. C, Periodontium restored on the root surface previously denuded by disease. The latter is called *new attachment.* **Shaded areas show denudation caused by periodontal disease.**

Fig. 36-4 Sources of regenerating cells in the healing stages of a periodontal pocket. *Left,* **Intrabony pocket.** *Right* **After therapy, the clot formed is invaded by cells from A, the marginal epithelium; B, the gingival connective tissue; C, the bone marrow; and D, the periodontal ligament.**

Regeneration is also going on during destructive periodontal disease. Most gingival and periodontal diseases are chronic inflammatory processes and, as such, are healing lesions. Regeneration is part of the healing. However, bacteria and bacterial products that perpetuate the disease process and the inflammatory exudate they elicit are injurious to the regenerating cells and tissues and prevent the healing from proceeding to completion.

By removing bacterial plaque and creating the conditions to prevent its new formation, periodontal treatment removes the obstacles to regeneration and enables the patient to benefit from the inherent regenerative capacity of the tissues. There is a brief spurt in regenerative activity immediately following periodontal treatment, but there are no local treatment procedures that promote or accelerate regeneration.

Repair

Repair simply restores the continuity of the diseased marginal gingiva and reestablishes a normal gingival sulcus at the same level on the root as the base of the preexistent periodontal pocket (Fig. 36-3). This process, called *healing by scar,*[24] arrests bone destruction without necessarily increasing bone height. Restoration of the destroyed periodontium involves mobilization of epithelial and connective tissue cells into the damaged area and increased local mitotic divisions to provide sufficient number of cells (Fig. 36-4).

New Attachment

New attachment is the embedding of new periodontal ligament fibers into new cementum and the attachment of the gingival epithelium to a tooth surface previously denuded by disease (see Fig. 36-3). The critical phrase in this definition is "tooth surface previously denuded by disease" (Fig. 36-5). Attachment of the gingiva or the periodontal ligament to areas of the tooth from which they may be removed in the course of treatment or during the preparation of teeth for restorations represents *simple healing* or *reattachment* of the periodontium, not new attachment.[13] The term *reattachment* has been used in the past to refer to the restoration of the marginal periodontium, but because it is not the existing fibers that reattach but new fibers that are formed and attach to new cementum, the term has been replaced by the term *new attachment.* Reattachment is currently used only to refer to repair in areas of the root not previously exposed to the pocket, such as after surgical detachment of the tissues or following traumatic tears in the cementum, tooth fractures, or the treatment of periapical lesions.

Epithelial adaptation differs from new attachment in that it is the close apposition of the gingival epithelium to the tooth surface without complete obliteration of the pocket. The pocket space does not permit passage of a probe (Fig. 36-6). Studies have shown that these deep suld lined by long, thin epithelium may be as resistant to disease as true connective tissue attachments .2.[20] The absence of bleeding or secretion on probing, the absence of clinically visible inflammation, and

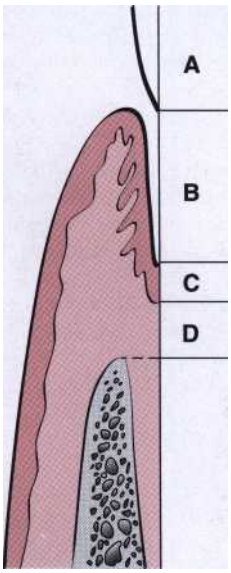

Fig. 36-5 A, Enamel surface. B, Area of cementum denuded by pocket formation. C, Area of cementum covered by junctional epithelium. D, Area of cementum apical to the junctional epithelium. The term *new attachment* refers to a new junctional epithelium and attached connective tissue fibers formed on zone B.

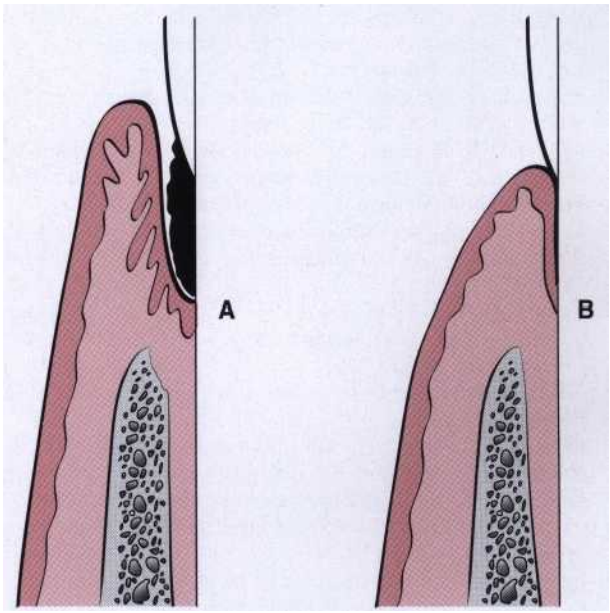

Fig. 36-6 Epithelial adaptation following periodontal treatment. A, Periodontal pocket. B, After treatment. The pocket epithelium is closely adapted to, but not attached to, the root.

the absence of stainable plaque on the root surface when the pocket wall is deflected from the tooth may indicate that the "deep sulcus" persists in an inactive state, causing no further loss of attachment.[5,34] A post-therapy depth of 4 or even 5 mm may therefore be acceptable in these cases.

New attachment and osseous regeneration have been a constant but elusive goal of periodontal therapy since beginning of this century. Since the 1970s, renewed laboratory and clinical research efforts have resulted in new concepts and techniques that have moved us much closer to attaining this ideal result of therapy. Chapter 63 presents the recommended methods of treatment and their indications and accomplishments.

Melcher pointed out that the regeneration of the periodontal ligament is the key to new attachment because it "provides continuity between the alveolar bone and the cementum and also because it contains cells that can synthesize and remodel the three connective tissues of the alveolar part of the periodontium."[21]

During the healing stages of a periodontal pocket, the area is invaded by cells from four different sources (see Fig. 36-4): oral epithelium, gingival connective tissue, bone, and periodontal ligament.

The final outcome of periodontal pocket healing depends on the sequence of events during the healing stages.[21] If the epithelium proliferates along the tooth surface before the other tissues reach the area, the result will be a long junctional epithelium. If the cells from the gingival **connective tissue are the first to populate the area, the result will** be fibers parallel to the tooth surface and remodeling of the alveolar bone with no attachment to the cementum. If bone cells arrive first, root resorption and ankylosis may occur. Finally, only when cells from the periodontal ligament proliferate coronally is there new formation of cementum and periodontal ligament.[21]

Several methods have been recommended to improve the likelihood of attaining new attachment. They are presented in Chapter 63.

CONCLUSION

Throughout a woman's life cycle, hormonal influences affect therapeutic decision making in periodontics. Historically, therapies have been gender biased. However, the advent of new research has provided keener appreciation of the unique systemic influences on oral, periodontal, and implant tissues. Oral health care professionals have greater awareness and capabilities of dealing with hormonal influences associated with the reproductive process. Periodontal and oral tissue responses may be altered, creating diagnostic and therapeutic dilemmas. Therefore it is imperative that the clinician recognize, customize, and appropriately alter periodontal therapy according to the individual woman's needs based on the stage of her life cycle.

This chapter reviews phases of the female life cycle from puberty through menopause. Periodontal manifestations, systemic effects, and clinical management are presented.

PUBERTY

Puberty occurs between the average ages of 11 to 14 in most women. An increase in the production of sex hormones (estrogen and progesterone) occurs, which then remains relatively constant during the remainder of the reproductive phase.

Also, the prevalence of gingivitis increases without an increase in the amount of plaque. Gram-negative anaerobes, especially *Prevotella intennedia,* have been implicated in association with puberty gingivitis. Kornman and Loesche postulated that this anaerobic organism may use ovarian hormone as a substitute for vitamin K growth factor .[41] Delaney and Kornman suggest levels of black pigmented *Bacteroides,* especially P. *intertnedia* (formerly known as *Bacteroides interrnedius),* increase with increased levels of gonadotrophic hormones in puberty. *Capnocytophaga* species also increase in incidence as well as in proportion. These organisms have been implicated in the increased bleeding tendency observed during puberty.[32] Recent studies associated with puberty gingivitis indicate proportionately elevated motile rods, spirochetes, and P. *intermedia.*[55] Statistically significant increases in gingival inflammation and in the proportions of P. *intermedia* and *Prevotella nigrescens* were seen in puberty gingivitis.[58]

During puberty, periodontal tissues may have an exaggerated response to local factors. A hyperplastic reaction of the gingiva may occur in areas where food debris,

materia alba, plaque, and calculus are deposited. The inflamed tissues become erythematous, lobulated, and retractable. Bleeding may occur easily with mechanical debridement of the gingival tissues. Histologically, the appearance is consistent with inflammatory hyperplasia.

During the reproductive years, women tend to have a more vigorous immune response including higher immunoglobulin concentrations, stronger primary and secondary responses, increased resistance to the induction of immunologic tolerance, and a greater ability to reject tumors and homografts.[81] Allergy sensitivity and asthma is higher in young men, but after puberty, women become more susceptible than their male counterparts.

Management

During puberty, education of the parent or caregiver is part of successful periodontal therapy. Preventive care, including a vigorous program of oral hygiene, is also vital. Milder gingivitis cases respond well to scaling and root planing with frequent oral hygiene reinforcement.[4] Severe cases of gingivitis may require microbial culturing, antimicrobial mouthwashes and local site delivery, or antibiotic therapy. Periodontal maintenance appointments may need to be more frequent when periodontal instability is noted.

The clinician should recognize the intraoral effects of chronic regurgitation of gastric contents on intraoral tissues because this age group also is susceptible to eating disorders, namely bulimia and anorexia nervosa. Perimylosis (smooth erosion of the enamel and dentin), typically on the lingual surfaces of maxillary anterior teeth, varies with the duration and frequency of the behavior."[] Also, enlargement of the parotid glands (occasionally sublingual glands) has been estimated to occur in 10% to 50% of patients who binge and purge.[52] Therefore a diminished salivary flow rate may also be present, which will increase oral mucous membrane sensitivity, gingival erythema, and caries susceptibility.

MENSES

Periodontal Manifestations

During the reproductive years, the ovarian cycle is controlled by the anterior pituitary gland. Gonadotrophins FSH (follicle stimulating hormone) and LH (luteinizing hormone) are produced from the anterior pituitary gland. The secretion of gonadotrophins is also dependent on the hypothalamus. Ongoing changes in the concentration of the gonadotrophins and ovarian hormones occur during the monthly menstrual cycle (Fig. 37-1). Under the influence of FSH and LH, estrogen and progesterone are steroid hormones produced by the ovaries during the menstrual cycle. During the reproductive cycle, the purpose of estrogen and progesterone is to prepare the uterus for implantation of the egg.

The monthly reproductive cycle has two phases. The first phase is referred to as the *follicular phase.* Levels of FSH are elevated, and estradiol (E2), the major form of estrogen, is synthesized by the developing follicle and peaks approximately 2 days before ovulation. The effect of estrogen stimulates the egg to move down the fallopian tubules (ovulation) and stimulates proliferation of the stroma cells, blood vessels, and glands of the endometrium.

Phase 11 is called the *Weal phase.* The developing corpus luteum synthesizes both estradiol and progesterone. Note that estrogen peaks to 0.2 ng/ml and progesterone 10.0 ng/ml to complete the rebuilding of the endometrium for fertilized egg implantation. The corpus luteum involutes, ovarian hormone levels drops, and menstruation ensues.

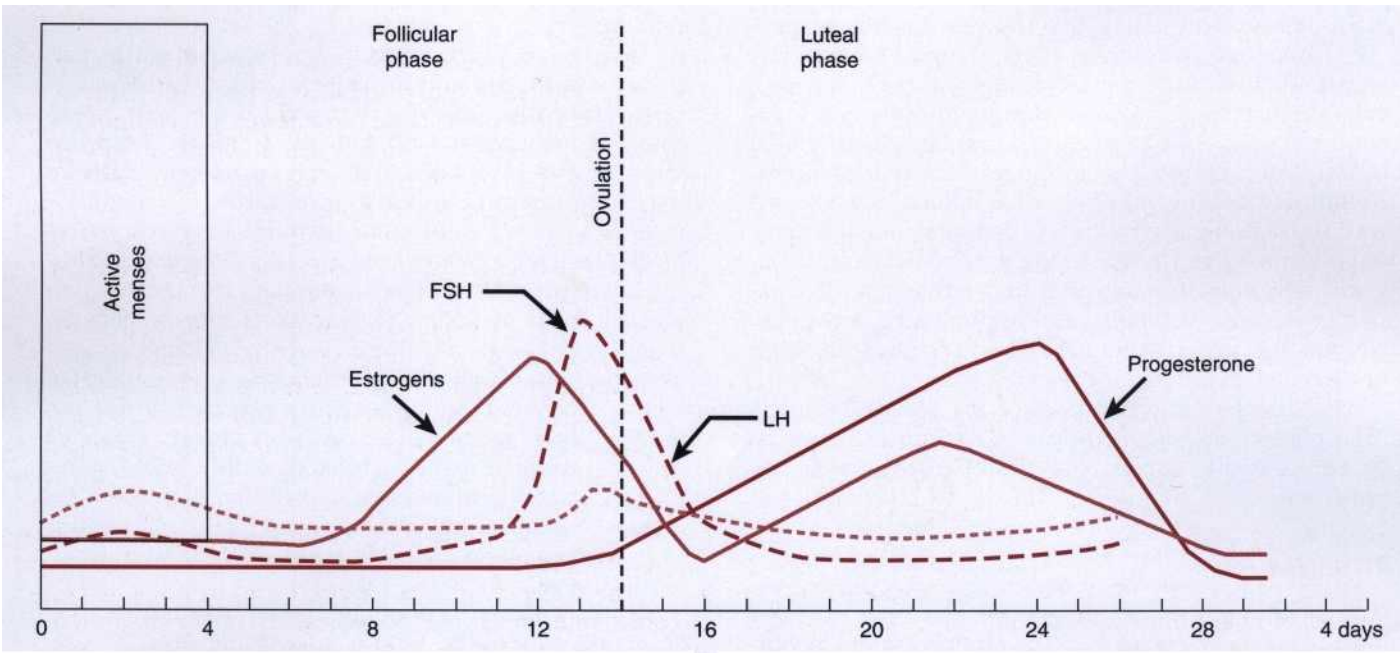

Fig. 37-1 Female reproductive cycle. Note the peak of progesterone and estrogen to FSH and LH.

The concept that ovarian hormones may increase inflammation in gingival tissues and exaggerate the response to local irritants has been postulated by several studies. Gingival inflammation seems to be aggravated by an imbalance and/or increase in sex hormones. Numerous studies have demonstrated in vitro and in vivo that sex hormones affect and modify the actions of cells of the immune system. In addition, evidence suggests that the interaction between estrogen and cells of the immune system can have nonimmune regulatory effects.[5,15]

Progesterone has been associated with increased permeability of the microvasculature, altering the rate and pattern of collagen production in the gingivas,[50] increasing folate metabolism,[66,87] and altering the immune response. During menses, progesterone increases from the second week, peaks at approximately 10 days, and dramatically drops before menstruation. (Note that this is based on a 28-day cycle; individual cycles are variable.) Progesterone plays a role in stimulating the production of prostaglandins that mediate the body's response to inflammation. Prostaglandin E_2 (PGE_2) is one of the major secretory products of monocytes and is higher in inflamed gingiva. Miyagi et al.[53] found that the chemotaxis of PMNs was enhanced by progesterone but reduced by estradiol. Testosterone did not have a measurable effect on PMN chemotaxis. The researchers suggested that the altered PMN chemotaxis associated with gingival inflammation may be due to the effects of sex hormones. Physiologic, experimental, and clinical data confirm differences in immune responses between the two sexes.[92]

Gingival tissues have been reported to be more edematous during menses and erythematous preceding the onset of menses in some individuals. In addition, an increase of gingival exudate has been observed during the menstrual period and is sometimes associated with a minor increase in tooth mobility.[30] The incidence of postextraction osteitis has also been reported to be higher during the initiation of menses. No significant hematologic laboratory findings accompany this, other than a slightly reduced platelet count and a slight increase in clotting time.

When progesterone is highest (during the luteal phase of the cycle), intraoral recurrent apthous ulcers,[24] herpes labialis lesions, and candida infections occur in some women as a cyclic pattern. Because the esophageal sphincter is relaxed by progesterone, women may be more susceptible to gastroesophageal reflux disease (GERD) during this time of the cycle as well. Symptoms of GERD include heartburn, regurgitation, and chest pain, and when reflux is severe, some people develop unexplained coughing, hoarseness, sore throat, gingivitis, or asthma.[79]

During the peak level of progesterone (about 7 to 10 days before menstruation), premenstrual syndrome (PMS) may also occur. There appears to be no significant difference in the estrogen and progesterone levels between women who suffer from PMS and those who do not. Yet women with PMS seem to have lower levels of certain neurotransmitters such as enkephalins, endorphins, gamma-aminobutyric acid (GABA), and serotonin. Depression, irritability, mood swings, and difficulty with memory and concentration may be symptoms of neurotransmitter reduction. Patients are more sensitive and less tolerant of procedures, have a heightened gag reflex, and may have an exaggerated response to pain.

Management

Increased gingival bleeding and tenderness associated with the menstrual cycle, requires closer periodontal monitoring. Periodontal maintenance should be titrated to the individual patient's need and, if problematic, 3- to 4-month intervals should be recommended. An antimicrobial mouthrinse before cyclic inflammation may be indicated. Emphasis should be placed on oral hygiene.

For the patient with a history of excessive postoperative hemorrhage or menstrual flow, scheduling surgical visits after cyclic menstruation is prudent. Anemia is common, and appropriate consultation with a physician and recent laboratory tests, where indicated, should be maintained.

During PMS, many women exhibit physical symptoms including fatigue, sweet and salty food cravings, abdominal bloating, swollen hands or feet, headaches, breast tenderness, nausea, and gastrointestinal upset.[92] GERD may make it more uncomfortable for the patient to lay fully supine, especially within hours immediately after consuming a meal, and there may be a more sensitive gag reflex. The clinician should be aware that nonsteroidal antiinflammatory medication, infection, and acidic foods exacerbate GERD. Patients taking over-the counter antacids, H_2-receptor antagonists (cimetidine, famotidine, nizatidine, and ranitidine), prokinetic agents (cisapride and metoclopramide), and proton-pump inhibitors (lansoprazole, omeprazole, pantoprazole, and abeprazole)" may be GERD patients. The aforementioned medications have interactions with some antibiotics and antifungal medications, thus review of their pharmacology is necessary. Fluoride rinses and/or trays, frequent periodontal debridement, and avoidance of high-alcohol-content mouthwashes may reduce the associated gingival and caries sequela.

PMS is often treated by antidepressants. Selective serotonin reuptake inhibitors (SSRIs) are generally the first-line choice because they have fewer side effects than other antidepressants, do not require blood monitoring, and are safe in overdoses. The SSRI fluoxetine reported a 70% response rate. It was ranked the 5th most dispensed prescription (new and refills) in the U.S. in 1998. (Sertraline was ranked 12th and is the drug of choice for treatment of PMS).[97] **The clinician should be aware that** patients on fluoxetine have increased side effects with highly protein-bound drugs (e.g., aspirin) and the half-life of diazepam and other CNS depressants is increased. Additional common selective serotonin reuptake inhibitors are fluvoxamine, paroxetine, and citalopram. Other antidepressants that may be prescribed are the selective serotonin and norepinephrine reuptake inhibitors (SNRIs), tricyclics, trazodone, mirtazapine, nefazodone, or maprotiline.

The PMS patient may be difficult to treat due to emotional and physiologic sensitivity. Treat the gingival and oral mucosal tissues gently. Moisten gauzes or cotton rolls with a lubricant, chlorhexidine rinse, or water

before placing them in the apthous prone patient. Careful retraction of the oral mucosa, cheeks, and lips is necessary in both the apthous and herpetic prone patient. Because the hypoglycemic threshold is elevated, advise the patient to have a light snack before her appointment. Note that 70% of menstruating women have PMS symptoms, but only 5% meet the strict diagnostic criteria.

PERIODONTAL MANIFESTATIONS OF PREGNANCY

The link between pregnancy and periodontal inflammation has been known for many years. In 1778, Vermeeren discussed "toothpains" in pregnancy. In 1818, Pitcarin described gingival hyperplasia in pregnancy.[71] Despite awareness regarding pregnancy and its effect on periodontal disease, only recently has evidence indicated an inverse relationship to systemic health. Current research implies periodontal disease may alter the systemic health of the patient and adversely affect the well-being of the fetus by elevating the risk for low-birth-weight, preterm infants.

Periodontal Diseases

In 1877, Pinard[70] recorded the first case of "pregnancy gingivitis." Only recently has periodontal research begun to focus on causative mechanisms. The occurrence of "pregnancy gingivitis" is extremely common, occurring in approximately 30% to 100% of all pregnant women.[33,44,48,80] It is characterized by erythema, edema, hyperplasia, and increased bleeding. Histologically, the description is the same as gingivitis. However, the etiologic factors are different despite clinical and histologic similarities. Cases range from mild to severe inflammation (Fig. 37-2). This can progress to severe hyperplasia, pain, and bleeding (Figs. 37-3 to 37-6). Other growths that resemble pregnancy granulomas must be ruled out, such as central giant cell granulomas or underlying systemic diseases. Periodontal status before pregnancy may influence the progression or severity as the circulating hormones fluctuate. The anterior region of the mouth is more commonly affected, and interproximal sites tend to be most involved.[19] Increased tissue edema may lead to increased pocket depths and relate to a transient tooth mobility.[73] Anterior site inflammation may be exacerbated by increased mouth breathing, primarily in the third trimester from pregnancy rhinitis. The gingiva is the most common site involved (approximately 70% of all cases), followed by the tongue and lips, buccal mucosa, and palate.'

Pyogenic granulomas, pregnancy tumors, or pregnancy epulides occur in 0.2% to 9.6% of pregnancies. They are clinically and histologically indistinguishable from pyogenic granulomas occurring in women who are not pregnant or in men. They appear most commonly during the second or third month of pregnancy. Clinically, they bleed easily and become hyperplastic and nodular. When excised, they do not usually leave a large defect. They may be sessile or pedunculated, ulcerated, and ranging in color from purplish red to deep blue, depending on the vascularity of the lesion and degree of venous stasis. The lesion classically occurs in an area of gingivitis and is associated with poor oral hygiene and calculus. Alveolar bone loss is not usually associated with pyogenic granulomas of pregnancy.

Role of Pregnancy Hormones

Subgingival Plaque Composition. Epidemiologic studies indicate a relationship between the level of home care and the severity of gingival inflammation. It appears that the relation between signs of gingival inflammation and the amount of plaque is closer after parturition than during pregnancy. An alteration in the compositions of subgingival plaque occurs during pregnancy. Kornman and Loesche found that during the second trimester, gingivitis and gingival bleeding increased without an increase in plaque levels.[42] Bacterial anaerobic to aerobic ratios increased in addition to *B. melaninogenicus* and P. *intermedia* proportions (2.2% to 10.1%). These authors suggested that estradiol or progesterone can substitute for menadione (vitamin K) as an essential growth factor for P. *intermedia* but not *Porphyromonas gingivalis* or *Bacteroides coherences.* There was also an increase in P. *gingivalis* during the 21St to 27th weeks of gestation, but this was not statistically significant. The relative increase in the numbers of P. *intennedia* may be a

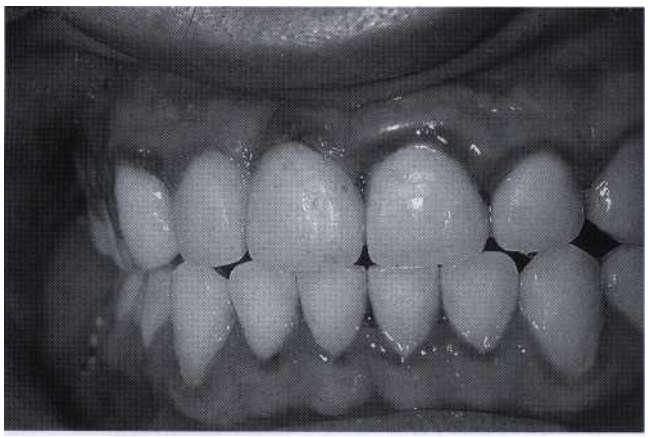

Fig. 37-2 Moderate pregnancy gingivitis.

Fig. 37-3 Pregnancy tumor.

more sensitive indicator of an altered systemic hormonal situation than clinical parameters of gingivitis.[83]

Periodontal Disease and Preterm, Low-Birth-Weight Births. Due to the pioneering research by Offenbacher, evidence exists that untreated periodontal disease in pregnant women may be a significant risk factor for preterm (<37 weeks' gestation), low-birth-weight (<2500 g) babies.[12] The relationship between genitourinary tract infection and preterm, low-birth-weight (PLBW) is well documented in human and animal studies. Periodontal researchers, suspecting periodontal disease as another source of infection, found that otherwise low-risk mothers of PLBW infants had significantly more periodontal attachment loss than control mothers having normal-weight infants at birth. The current opinion is that the correlation of periodontal disease to PLBW births occurs as a result of infection and is mediated indirectly, principally by the translocation of bacterial products such as endotoxin (lipopolysaccharide, LPS) and the action of maternally produced inflammatory mediators.[27] Biologically active molecules such as prostaglandin E2 (PGE2) and tumor necrosis factor-alpha (TNFa), which are normally involved in normal parturition, are raised to artificially high levels by the infection process, which may foster premature labor.[3] Gram-negative bacteria in periodontal diseases therefore may permit selective overgrowth or invasion of gram-negative bacteria within the genitourinary tract. Recently, gingival crevicular fluid levels of PGE2 were positively associated with intraamniotic PGE2 levels (P = 0.018), suggesting that gram-negative periodontal infection may present a systemic challenge sufficient to initiate the onset of premature labor as a source of LPS and/or through stimulation of secondary inflammatory mediators such as PGE2 and interleukin 1 beta (IL-1ß).[16] Ongoing research supports the association of periodontal disease and PLBW.[17,18] Offenbacher has recently published data suggesting a dose response relationship for increasing gingival crevicular fluid PGE2 as a marker of current periodontal disease activity and decreasing birth weight. Four organisms associated with mature plaque and progressing periodontitis (Bacteroides forsythus, P. gingivalis, Actinobacillus actinomycetemcomitans, and Treponema denticola) were detected at higher levels in PLBW mothers as compared with normal-birth-weight controls[61] (see also Chapter 13).

Maternal Immunoresponse

The maternal immune system is thought to be suppressed during pregnancy. This response may allow the fetus to survive as an allograft. Documentation of immunosuppressive factors in the sera of pregnant women can be noted by marked increase of monocytes (which in large numbers inhibit in vitro proliferative responses to mitogens, allogenic cells, and soluble antigen)," and

BOX 37-1

Etiology of Gingival Responses to Elevated Estrogen and Progesterone during Pregnancy

Subgingival Plaque Composition

Anaerobic to aerobic ratio increases
Higher concentrations of *Prevotella intermedia* (substitutes sex hormone for Vitamin K–growth factor)
Higher concentrations of *Bacteroides melaninogenicus*
Higher concentrations of *Porphyromonous gingivalis*

Maternal Immunoresponse

Depression of cell-mediated immunity
Decreased neutrophil chemotaxis
Depression of antibody and T cell responses
  Decrease in the ratio of peripheral T helper cells to T suppressor–cytotoxic cells (CD4/CD8 ratio)
Cytotoxicity directed against macrophages and B cells may result in diminished immunoresponsiveness
Decrease in absolute numbers or CD3, CD4, and CD19 positive cells in peripheral blood during pregnancy versus postpartum
Stimulation of the production of prostaglandin

Sex Hormone Concentration

Estrogen
  Increases cellular proliferation in blood vessels (known in the endometrium)
  Decreases keratinization, while increasing epithelial glycogen
  Specific receptors are found in gingival tissues
Progesterone
  Increases vascular dilation, thus increases permeability (result in edema and accumulation of inflammatory cells)
  Increases proliferation of newly formed capillaries in gingival tissues (increased bleeding tendency)
  Alters rate and pattern of collagen production
  Increased metabolic breakdown of folate (a deficiency can inhibit tissue repair)
  Specific receptors are found in gingival tissues
  Decreases plasminogen activator inhibitor factor type 2, thus increases tissue proteolysis
Estrogen and Progesterone
  Effect ground substance of connective tissue by increasing fluidity
  Concentrations increase in saliva and fluid with increased concentrations in serum

pregnancy-specific B-1-glycoproteins contribute to diminished lymphocyte responsiveness to mitogens and antigens.[9] In addition, a decrease in the ratio of peripheral T helper cells to T suppressor cells (CD4/CD8) ratio has been reported to occur throughout pregnancy.[11]

These changes in maternal immunoresponsiveness suggest an increased susceptibility to developing gingival inflammation. In one study, the gingival index was higher but percentages of T3, T4, and B cells appeared to decrease in peripheral blood and gingival tissues during pregnancy as compared with a control group.[1] Other studies report decreased neutrophil chemotaxis, depression of cell-mediated immunity, phagocytosis, and a decreased T cell response with elevated ovarian hormones levels, especially progesterone.[7,12] A decrease in in vitro responses of peripheral blood lymphocytes to several mitogens and a preparation of P. *intennedia* has been reported,[10,49,60] and evidence suggests a decrease in the absolute numbers of CD4 positive cells in peripheral blood during pregnancy as compared with the number of these cells postpartum.[7,14] Lapp et al suggests that high levels of progesterone during pregnancy affect the development of localized inflammation by down-regulation of IL-6 production, rendering the gingiva less efficient at resisting the inflammatory challenges produced by the bacteria.[43]

Also, ovarian hormone stimulates the production of prostaglandins, in particular PGE1 and PGE2, which are potent mediators of the inflammatory response. With the prostaglandin acting as an immunosuppressant, gingival inflammation may increase when the mediator level is high.[20,63] Kinnby et all' found that high progesterone levels during pregnancy influenced plasminogen activator inhibitor type 2 (PAI-2) and disturbed the balance of the fibrinolytic system. Because PAI-2 serves as an important inhibitor of tissue proteolysis, the research of Kinnby et al implies that components of the fibrinolytic system may be involved in the development of pregnancy gingivitis.

Sex Hormone Levels

During pregnancy, hormonal levels rise dramatically (Box 37-1). Progesterone reaches levels of 100 ng/mL, 10 times the peak luteal phase of menses. Estradiol in the plasma may reach 30 times higher levels than during the reproductive cycle. In early pregnancy and during the normal ovarian cycle, the corpus luteum is the major source of estrogen and progesterone. During pregnancy, the placenta begins to produce estrogens and progesterone.

Estrogen may regulate cellular proliferation, differentiation, and keratinization, whereas progesterone influences the permeability of the microvasculature,[45,46] alters the rate and pattern of collagen production, and increases the metabolic breakdown of folate (necessary for tissue maintenance).[95] High concentration of sex hormones in gingival tissues, saliva, serum, and crevicular fluid also may exaggerate the response.

Regulation via hormones of most cellular processes occurs by interaction of these products with intracellular receptors. The resulting effects are dependent on the concentration of unbound hormone diffused through the cell membrane. Vittek has demonstrated specific estrogen and progesterone receptors in gingival tissues.[90] This is direct biochemical evidence that this tissue may function as a target organ for sex hormones. Muramatsu and Takaesu found increasing concentration of sex hormones in saliva from the first month and peaking in the ninth month of gestation, along with increasing percentages of P. *intertnedia.* Probing depths, increasing numbers of gingival sites with bleeding, and redness increased un-

til 1 month postpartum.[56] Also, evidence of sex hormone concentration in crevicular fluid exists, providing a growth media for periodontal pathogens.

Other Oral Manifestations of Pregnancy

Perimylolysis or acid erosion of teeth may occur if "morning sickness" or esophageal reflux is severe and involves repeated vomiting of the gastric contents. Note that severe reflux may cause scarring of the esophageal sphincter and the patient may become a more likely candidate for GERD later in life.

Xerostomia is a frequent complaint among pregnant women. One study found this persistent dryness in 44% of pregnant participants.[22]

A rare finding in pregnancy is ptyalism or sialorrhea. This excessive secretion of saliva usually begins at 2 to 3 weeks of gestation and may abate at the end of the first trimester. The etiology of ptyalism has not been identified, but it may occur because of the inability of nauseated gravid women to swallow normal amounts of saliva rather than from a true increase in the production of saliva.[14]

Because pregnancy places the woman in an immunocompromised state, the clinician must be aware of the total health of the patient. Gestational diabetes, leukemia, and other medical conditions may appear during pregnancy.

Clinical Management

A thorough medical history is an imperative component of the periodontal examination, especially in the pregnant patient. Due to immunologic alterations, increase in blood volume (ruling out mitral valve prolapse and heart murmurs), and fetal interactions, the clinician must diligently and consistently monitor the patient's medical and periodontal stability. Medical history dialogue should include pregnancy complications, previous miscarriages, recent history of cramping, spotting, or pernicious vomiting. Next, the patient's obstetrician should be contacted to discuss her medical status, periodontal or dental needs, and the proposed treatment plan.

Establishment of a healthy oral environment and optimal oral hygiene levels are primary objectives in the pregnant patient. A preventive periodontal program consisting of nutritional counseling and rigorous plaque control measures in the dental office and at home should be reinforced.

Plaque Control. The heightened tendency for gingival inflammation should be clearly explained to the patient so that acceptable oral hygiene techniques may be taught, reinforced, and monitored throughout pregnancy. Scaling, polishing, and root planing may be performed whenever necessary throughout the pregnancy. Some practitioners avoid the use of high-alcohol-content antimicrobial mouthrinses in pregnant women and prefer to use those that are non-alcohol based.

Prenatal Fluoride. The prescribing of prenatal fluoride supplements has been an area of controversy for quite some time. Although two studies have claimed beneficial results,[28,29] others suggest that the clinical efficacy of prenatal fluoride supplements is uncertain and the mechanism by which prenatal fluorides might impart cariostasis is unclear.[69]

The American Dental Association does not recommend the use of prenatal fluoride because its efficacy has not been demonstrated. The American Academy of Pediatric Dentistry supports this position as well. The American Academy of Pediatrics has no stated position on prescribing prenatal fluorides.

Treatment

Elective Dental Treatment. Other than good plaque control, it is prudent to avoid elective dental care if possible during **the first trimester and the last half of the** third trimester. The first trimester is the period of organogenesis when the fetus is highly susceptible to environmental influences. In the last half of the third trimester, a hazard of premature delivery exists because the uterus is very sensitive to external stimuli. Prolonged chair time may need to be avoided because the woman is most uncomfortable at this time. Further, supine hypotensive syndrome may possibly occur. In a semi-reclining or supine position, the great vessels, particularly the inferior vena cava, are compressed by the gravid uterus. By interfering with venous return, this compression will cause maternal hypotension, decreased cardiac output, and eventual loss of consciousness. Supine hypotensive syndrome can usually be reversed by turning the patient on her left side, thereby removing pressure on the vena cava and allowing blood to return from the lower extremities and pelvic area. A preventive 6-inch soft wedge (rolled towel) should be placed on the patient's right side when she is reclined for clinical treatment.

The second trimester is the safest period for providing routine dental care. The emphasis at this time is on controlling active disease and eliminating potential problems that could arise in late pregnancy. Major oral or periodontal surgery should be postponed until after delivery. Pregnancy tumors that are painful, interfere with mastication, or continue to bleed or suppurate after mechanical debridement may require excision and biopsy before delivery.

Dental Radiographs. The safety of dental radiography has been well established, provided features such as high-speed film, filtration, collimation, and lead aprons are used. However, it is most desirable not to have any irradiation during pregnancy, especially during the first trimester, because the developing fetus is particularly susceptible to radiation damage.[47] When radiographs are needed for diagnosis, the most important aid for the patient is the protective lead apron. Studies have shown that when an apron is used during contemporary dental radiography, gonadal and fetal radiation is virtually immeasurable.'

Even in light of the obvious safety of dental radiography, radiographs should be used selectively during pregnancy and only when necessary and appropriate to aid in diagnosis and treatment. In most instances, only

BOX 37-2

FDA Classification System

The following table represents the five category systems used by the FDA to classify drugs based on their potential for causing birth defects.

A Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.

B Either animal-reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).

C Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal, or other) and there are not controlled studies in women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.

D There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).

X Studies in animals or human beings have demonstrated fetal abnormalities, or there is evidence of fetal risk based on human experience, or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug contraindicated in women who are or may become pregnant.

bitewing, panoramic, or selected periapical films are indicated.

Medications. Drug therapy in the pregnant patient is controversial because drugs can affect the fetus by diffusion across the placenta. Prescriptions should be only the duration absolutely essential for the pregnant patient's well-being and only after careful consideration of potential side effects. The classification system established by the FDA in 1979 to rate fetal risk levels associated with many prescription drugs provides safety guidelines (Box 37-2). The prudent practitioner should consult references such as Briggs, *Drugs in Pregnancy and Lactation"* or Olin's *Drug Facts and Comparisons64* for information on the FDA pregnancy risk factor associated with prescription drugs. Ideally, no drug should be administered during pregnancy, especially the first trimester .[47] However, it is sometimes impossible to adhere to this rule. It is therefore fortunate that most commonly used drugs in dental practice can be given during pregnancy with relative safety, although there are a few important exceptions (see Tables 37-1 to 37-3). The table of drugs presented is considered a general guideline." Refer to the tables regarding local anesthetic, antibiotic, and analgesic prescriptions. In particular, antibiotics are often needed in periodontal therapy. Note that the effect of a particular medication on the fetus depends on the type of antimicrobial, dosage, trimester, and duration of the course of therapy. [65] Research regarding subgingival irrigation and local site delivery in relation to the developing fetus is inadequate at this date.

Breast Feeding. Usually, there is a risk that the drug can enter breast milk and be transferred to the nursing infant, in whom exposure could have adverse effects (see Tables 37-4 and 37-5). Unfortunately, there is little conclusive information about drug dosage and effects via breast milk; however, retrospective clinical studies and empiric observations coupled with known pharmacologic pathways allow recommendations to be made .[47] The amount of drug excreted in breast milk is usually not more than 1% to 2% of the maternal dose; therefore it is highly unlikely that most drugs have any pharmacologic significance for the infant .[85,94]

The mother should take prescribed drugs just after breastfeeding and then avoid nursing for 4 hours or more, if possible,[47,85] to markedly decrease the drug concentration in breast milk.

ΩRAL CONTRACEPTIVES

Oral contraceptives (OC) may have similar responses to those witnessed in pregnant patients. An exaggerated response to local irritants occurs in gingival tissues. Inflammation ranges from mild edema and erythema to severe inflammation with hemorrhagic or hyperplasic gingival tissues. It has been reported more exudate is present in inflamed gingival tissues of OC users versus that of pregnancy.[82,11]

Investigators have reported several mechanisms for the heightened response in gingival tissues. Kalkwarf reported the response may be due to alteration of the microvasculature, increased gingival permeability, and increasing synthesis of prostaglandin .[38] Prostaglandin E appears to rise significantly with increasing sex hormones. Prostaglandin E is a potent mediator of inflammation.[23] Jensen et al found dramatic microbial changes in pregnant and OC groups as compared with a nonpregnant group.[37] A 16-fold increase in *Bacteroides* species was noted in the OC group versus the nonpregnant group, despite no statistically significant clinical differences in gingival index or crevicular fluid flow. Jensen et al stated that the increased female sex hormones substituting for the napthaquinone requirement of certain *Bacteroides* species were most likely responsible for this increase.

TABLE 37-1

Local Anesthetic/Analgesic Administration during Pregnancy

Drug	FDA Category (Prescription Drug)	During Pregnancy
*Local Anesthetics**		
Lidocaine	B	Yes
Mepivacaine	C	Use with caution; consult physician
Prilocaine	B	Yes
Bupivacaine	C	Use with caution; consult physician
Etidocaine	B	Yes
Procaine	C	Use with caution; consult physician
Analgesics		
Aspirin	C/D, 3rd trimester	Caution; avoid in 3'd trimester
Acetaminophen	B	Yes
Ibuprofen	B/D, 3rd trimester	Caution; avoid in 3rd trimester
Codeine**	C	Use with caution; consult physician
Hydrocodone**	B	Use with caution; consult physician
Oxycodone**	B	Use with caution; consult physician
Propoxyphene	C	Use with caution; consult physician

* Can use vasoconstrictors if necessary

** Avoid prolonged use

The OC-associated gingival inflammation may become chronic (versus that of acute inflammation of pregnancy) due to the extended periods of time that women are exposed to elevated levels of estrogen and progesterone .[40,68] Some have reported that the inflammation increases with prolonged use of OCs. Kalkawarf did not find that duration of use made a significant difference; however, the brand used had different responses. It is apparent that further studies need to be performed in relation to dosage, duration, and type of OC used in association with the periodontium. The concentration of female sex hormones in today's OC is significantly less than that of the 1970s with the same level of contraceptive efficacy.

Salivary composition has a noted change in patients taking OCs in studies conducted in the 1970s. A decrease concentration of protein, sialic, acid, hexosamine fucose, hydrogen ions, and total electrolytes has been reported. Salivary flow rates have been reported to be increased in one report[51] and decreased in 30% of subjects in another report .[21]

The dental literature reports that women taking OCs experience a twofold to threefold increase in the incidence of localized osteitis following extraction of mandibular third molars.[86] The higher incidence of osteitis is these patients may be attributed to the effects of OCs (estrogens) on clotting factors. However, a number of studies refute these finding. [13] Evidence to this date is inconclusive with regard to osteitis following third molar extractions and use of OCs.

Also, it has been reported in the medical literature that a spotty melanotic pigmentation of the skin may occur with use of oral contraceptives. This suggests a relationship between the use of OCs and the occurrence of gingival melanosis,[34] especially in fair-skinned individuals.

Management

Medical histories should include OCs under the heading of "Medications," and an oral dialogue should include questions regarding OCs in women of childbearing age. The patient should be informed of the oral and periodontal side effects of OCs and the need for meticulous home care and compliance with periodontal maintenance. Treatment of gingival inflammation exaggerated by OCs should include establishing an oral hygiene program and eliminating local predisposing factors. Periodontal surgery may be indicated if resolution after initial therapy (scaling and root planing) is inadequate. It may be advisable to perform extraction of teeth (especially of third molars) on nonestrogenic days (days 23 to 28) of the OC cycle to reduce the risk of a postoperative localized osteitis,[25] but note that

evidence of this association is inconclusive and warrants further investigation.

Although the results from animal studies have demonstrated antibiotic interference adversely affecting contraceptive sex hormone levels, several studies involving human subjects have failed to support such an interaction.[6,26,57,59] This issue is controversial, and antibiotics possibly could render OCs ineffective in preventing pregnancies. In 1991 an ADA Health Foundation Report stated that all women of childbearing age should be informed of possible reduced efficacy of steroid OCs during antibiotic therapy and advised to use additional forms of contraception during short-term antibiotic therapy. During long-term antibiotic therapy, they should consult their physician about using high-dose OC preparations.' Although research regarding oral manifestations attributed to OCs has been reported in the literature, it can be presumed that the same effects could occur with the use of contraceptive implants. Along the same lines, the remote possibility of reduced efficacy of the contraceptive implant with concurrent antibiotic administration also exists and the same precautions can be adhered to as with OCs.

MENOPAUSE

Female life expectancy is 80+ years, therefore many women will live 40% of their lives in menopause. This cohort represents a large number of the patients that present in clinical practices. Therefore we must be aware of the implications that reduced hormones have on the periodontal tissues as well as the systemic changes that may manifest.

Throughout a woman's lifetime, the number of oocytes steadily diminishes. Menopause is associated with symptoms of estrogen deficiency. Estradiol levels fall gradually in the years before menopause. Levels of the gonadotophins FSH and LH begin to rise, and levels of sex hormones begin to fluctuate. This stage of "perimenopause" is characterized by increasing ovarian unresponsiveness, therefore sporadic ovulation ensues. Anovulatory cycles indicate low estradiol and progesterone because of absent corpus luteum function.

Oral Changes

Important to the clinician is recognition of the effect of hormonal alterations on the oral cavity as well as systemic and psychologic changes. Oral changes in menopause include thinning of the oral mucosa, oral discomfort ("burning mouth"), gingival recession, xerostomia, altered taste sensation, alveolar bone loss, and alveolar ridge resorption.

Fluctuations of sex hormones during menopause have been implicated as factors in inflammatory changes in the human gingiva, hypertrophy, or atrophy. Estrogen affects cellular proliferation, differentiation, and keratinization of the gingival epithelium. Hormone receptors have been identified in basal and spinous layers of the epithelium and connective tissue,' implicating gingiva and other oral tissues as targets to manifest hormone deficiencies. Sex steroids are known to have a direct effect on connective tissue, with estrogens increasing the intracellular fluid content. Estrogen deficiency can lead to a reduction in collagen formation in connective tissues, resulting in a decrease in skin thickness.93 Alterations in collagen affect tissues such as joints, hair, nails, and glands. In 1996, Mohammed et al noted significant increased recession in postmenopausal patients with low bone density.[54]

Osteopenia and osteoporosis have been associated with the menopausal patient. Osteopenia is a reduction in bone mass due to an imbalance between bone resorption and formation, favoring resorption and resulting in demineralization and osteoporosis. Osteoporosis is a disease characterized by low bone mass and fragility and a consequent increase in fracture risk.[91] In most women, peak bone mass occurs between 20 to 30 years of age and declines from this point. Menopause accelerates declining bone mass .[89] It is estimated that 25 million Americans are affected with osteoporosis, of whom 80% are female. Ongoing studies are examining the association of postmenopausal primary osteoporosis with mandibular/maxillary bone mineral density, tooth loss, alveolar ridge atrophy, and clinical periodontal attachment loss. The effects of hormone replacement therapy (HRT) or estrogen replacement therapy (ERT) on the oral bone and tooth loss is under investigation. Much of the latest evidence points to an probable association between osteoporosis and tooth loss as well as alveolar bone loss .[36,67,76,77]

Clinical Management

It is the clinician's responsibility to review the patient's medical history and keep information up to date. Due to possible alterations in oral soft and osseous tissues during perimenopause and postmenopause, appropriate questioning regarding hormone changes should be performed and documented. A myriad of therapies for HRT/ERT are available, from prescriptions to holistic approaches that need to be followed. Many medications may alter clotting times, prolong other medications, and interfere with absorption or effectiveness of prescription medications.

If gingival and mucosal tissue thinning occurs, soft tissue augmentation may be performed. Brushing with an extra-soft toothbrush using the toe or heal of the brush may prevent "scrubbing" the thinning gingiva. Dentifrices with minimal abrasive particles should be used. Rinses should have low alcohol concentrations. During periodontal maintenance, root surfaces should be debrided gently with minimal soft tissue trauma. Oral pain may be from thinning tissues, xerostomia, inadequate nutritional intake, or hormone depletion. It has been noted that when patients with oral symptoms were placed on HRT, symptoms were significantly reduced.

If the patient is osteoporosis susceptible (menopausal, female, Caucasian or Asian, smoker, minimal physical activity, low calcium intake, thin build or low body weight <58 kg, systemic disease associated with predisposition, and genetic history),[35] consult the patient's physician as to the risks versus benefits of HRT/ERT and calcium/vitamin D supplementation for the individual patient. Sodium fluoride, biphosphonates (alendronate),

BOX 37-3

National Institutes of Health (NIH) Consensus Conference Recommendations for Optimal Calcium Intake[31]

Premenopausal women (25–50 years old):	1000 mg/d
Postmenopausal women (estrogen therapy):	1000 mg/d
Postmenopausal women (no estrogen therapy):	1500 mg/d
Men (25–65 years old):	1000 mg/d
Women and men >65 years old:	1500 mg/d

selective estrogen receptor modulators, and parathyroid hormone may be other possible therapies for the osteoporotic patient. Close monitoring of the periodontal stability of the patient, performing titrated periodontal maintenance, informing the patient regarding potential risks of hormone depletion on the oral tissues, and consulting the treating physician is advised. The 1994 NIH Conference on Optimal Calcium Intake recommends 1000 mg of calcium per day for premenopausal women and 1500 mg per day for postmenopausal women (Box 37-3). To date, no data are available regarding success or failure with periodontal regeneration procedures in osteoporotic versus nonosteoporotic individuals. Also, no scientific data are available to contraindicate the use of osseointegrated implants in osteoporotic patients, despite articles stating osteoporosis as a risk factor. Much research is needed to address the increasing number of patients who may present to our periodontal practices with osteoporosis or osteopenia, most of whom will be undiagnosed.

CONCLUSION

Clinical periodontal therapy includes an understanding of our role in the total health and well-being of our patients. We do not treat localized site infections without affecting other systemic systems (and the possible unborn fetus or breastfed infant). Therefore female patients may present with periodontal and systemic considerations that alter conventional therapy.

The cyclic nature of the female sex hormones often reflect in the gingival tissues as the initial signs and symptoms. Our medical histories and dialogues should include thoughtful investigation of the individual patient's problems and needs. Questioning should reflect hormonal stability and medications associated with regulation. Patients should be educated regarding the profound effects the sex hormones may play on periodontal and oral tissues as well as the consistent need for home and office removal of local irritants.

Research regarding female issues and medical/periodontal therapy is in process. In the near future, information regarding specific management and etiology of sex hormone-mediated infections will enhance our ability to provide quality care to our patients.

INFECTIOUS DISEASES
- **Hepatitis**
- **HIV and AIDS**
- **Tuberculosis**

Many patients seeking dental care have significant medical conditions that may alter both the course of their oral disease and the therapy provided. The older age of the average periodontal patient increases the likelihood of underlying disease. Therefore the therapeutic responsibility of the clinician includes identification of the patient's medical problems to formulate proper treatment plans. Thorough medical histories are paramount.[52] If significant findings are unveiled, consultation with or referral of the patient to an appropriate physician may be indicated. This ensures correct patient management and provides medicolegal coverage to the clinician.

This chapter covers common medical conditions and associated periodontal management. Review of each topic area is general, and the reader is encouraged to consult other references for more detailed coverage of specific disorders. Understanding these conditions will enable the clinician to treat the total patient, not merely the periodontal reflection of underlying disease.

CARDIOVASCULAR DISEASES

Cardiovascular diseases are the most prevalent category of systemic disease in the U.S. and many other countries, and they are more common with increasing age .[69] Health histories should be closely scrutinized for cardiovascular problems. These conditions include hypertension, angina pectoris, myocardial infarction, previous cardiac bypass surgery, previous cerebrovascular accident, congestive heart failure, presence of cardiac pacemakers or automatic defibrillators, and infective endocarditis.

In most cases the patient's physician should be consulted, especially if stressful or prolonged treatment is anticipated. Short appointments and a calm, relaxing

environment help minimize stress and maintain hemodynamic stability.

Hypertension

Hypertension, the most common cardiovascular disease, affects more than 20% of American adults, many of whom are undiagnosed.34 Hypertension is defined as a systolic blood pressure of 140 mm Hg or greater, or a diastolic blood pressure of 90 mm Hg or greater.[25,29,30,40] Hypertension is not diagnosed on a single elevated blood pressure recording. Rather, classification is based on the average value of three or more blood pressure readings taken at three or more appointments (Table 38-1). The higher value of either the systolic or diastolic blood pressure determines the patient's classification. Patients with hypertension enter the dental practice every day and are particularly common amongst the older population seen in most periodontal practices.

Hypertension is divided into primary and secondary types. Primary (essential) hypertension occurs when no underlying pathologic abnormality can be found to explain the disease. Approximately 95% of all hypertensive patients have primary hypertension. The remaining 5% have secondary hypertension, in which an underlying etiology can be found and often treated. Examples of the conditions responsible for secondary hypertension are renal disease, endocrinologic changes, and neurogenic disorders.

In early hypertension, the patient may be asymptomatic. If not identified and diagnosed, hypertension may persist and increase in severity, leading eventually to coronary artery disease, angina, myocardial infarction, congestive heart failure, cerebrovascular accident, or kidney failure.[35] The dental office can play a vital role in the detection of hypertension and maintenance care of the patient with hypertensive disease. The first dental office visit should include two blood pressure readings spaced at least 10 minutes apart, which are averaged and used as a baseline. Before the clinician refers a patient to a physician because of elevated blood pressure, readings should be taken at a minimum of two appointments, unless the measurements are extremely high (i.e., systolic pressure >180 mm Hg or diastolic pressure >100 mm Hg). The periodontal recall system is an ideal method for hypertension detection and monitoring. Nearly 3 of every 4 adult hypertension patients in the U.S. do not control their blood pressure well enough to attain the goal of systolic pressure <140 mm Hg and diastolic pressure <90 mm Hg.' Lack of compliance with antihypertensive therapy is the primary reason for this failure. Dentists can help achieve greater success in managing hypertension by taking blood pressure recordings at each periodontal recall visit.

Periodontal procedures should not be performed until accurate blood pressure measurements and histories have been taken to identify those patients with significant hypertensive disease. The time of day should be recorded along with the blood pressure reading because blood pressure varies significantly throughout the day.[48] Table 38-1 outlines appropriate medical referral or consultation and dental treatment modifications, depending on the patient's stage of hypertension.

Dental treatment for hypertensive patients is generally safe as long as stress is minimized.[35,40] If a patient is currently receiving antihypertensive therapy, consultation with the physician may be warranted regarding the current medical status, medications, periodontal treat-

TABLE 38-1

Classification of Adult Blood Pressure

Classification	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)	Dental Treatment Modifications
Normal	<130	<85	No changes in dental treatment.
High normal	130-139	85-89	No changes in dental treatment.
Hypertension			
Stage 1	140-159	90-99	• Inform patient of findings. • Routine medical consultation/referral. • No changes in dental treatment; minimize stress.
Stage 2	160-179	100-109	• Inform patient. • Routine medical referral. • Selective dental care (routine exam, prophylaxis, restorative, nonsurgical endodontics and periodontics); minimize stress.
Stage 3	>_180	>_110	• Inform patient. • Immediate medical consultation/referral. • Emergency dental care only (to alleviate pain, bleeding, infection)*; minimize stress.

* **Risk of providing emergency dental care must outweigh risk of possible hypertensive complications.**

See references 25, 29, and 30.

ment plan, and patient management. Many physicians are not knowledgeable about the nature of specific periodontal procedures. The dentist must inform the physician regarding the estimated degree of stress, length of the procedures, and complexity of the individualized treatment plan. Morning dental appointments were once suggested for hypertensive patients. However, recent evidence indicates that blood pressure generally increases around awakening and peaks at mid-morning.5,48,64 Lower blood pressures occur in the afternoon. Therefore afternoon dental appointments may be preferred.

No routine periodontal treatment should be given to a patient who is hypertensive and not under medical management. For patients with stage 3 hypertension, treatment should be limited to emergency care until hypertension is controlled. Analgesics are prescribed for pain and antibiotics for infection. Acute infections may require surgical incision and drainage, although the surgical field should be limited because excessive bleeding may be seen with elevated blood pressures.

When treating hypertensive patients, the clinician should not use a local anesthetic containing an epinephrine concentration greater than 1:100,000, nor should a vasopressor be used to control local bleeding. Local anesthesia without epinephrine may be used for short procedures (less than 30 minutes). In a patient with hypertensive disease, however, it is important to minimize pain by providing profound local anesthesia to avoid an increase in endogenous epinephrine secretion.[35,40] The benefits of the small doses of epinephrine used in dentistry far outweigh the potential for hemodynamic compromise. The smallest possible dose of epinephrine should be used, and aspiration before injection of local anesthetics is critical. Intraligamentary injection is generally contraindicated because hemodynamic changes are similar to intravascular injection.63

/3-adrenergic receptor antagonists or ß-blockers are commonly used to treat hypertension (Table 38-2). /3-blockers are either cardioselective, blocking only ß-1 cardiac receptors, or non-selective, blocking both ß-1 cardiac receptors and ß-2 peripheral receptors. Epinephrine, an a- and ß-adrenergic agonist, produces an increase in heart rate via direct stimulation of cardiac ß-1 receptors. Epinephrine also stimulates a-adrenergic receptors, producing vasoconstriction of arteries, as well as ß-2 receptors, causing vasodilation of skeletal muscle arterioles. Administration of local anesthetics containing epinephrine to patients taking nonselective ß-block-ers such as propanolol or nadolol may cause elevated blood pressure.[2] Epinephrine-induced a-adrenergic stimulation results in vasoconstriction and an increase in blood pressure. Because the patient's nonselective medication has blocked the ß-2 receptors, epinephrine will not stimulate the normal compensatory ß-2-in-duced vasodilation. This may result in dramatically increased blood pressure, which is then followed by a reflex bradycardia mediated by the vagus nerve and carotid baroreceptors. The end result is a patient with severe hypertension and bradycardia, resulting in a dangerous decrease in vascular perfusion and possible death. Because of this potential complication, epinephrine-containing local anesthetics should be used cautiously and only in very small amounts in patients taking nonselective /3-blockers, with careful monitoring of vital signs.[3-5,12]

The clinician should be aware of the many side effects of various antihypertensive medications. Postural hypotension is very common and can be minimized by slow positional changes in the dental chair.[25,35] Depression is a side effect of which many patients are unaware. Nausea, sedation, oral dryness, lichenoid drug reactions, and gingival overgrowth are associated with certain classes of antihypertensive agents.[25,40]

Ischemic Heart Diseases

Ischemic heart disease includes disorders such as angina pectoris and myocardial infarction (Fig. 38-1). Angina occurs when myocardial oxygen demand exceeds supply, resulting in temporary myocardial ischemia.[26] Patients with a history of unstable angina pectoris (angina that occurs irregularly or on multiple occasions without predisposing factors) should be treated for emergencies only and then in consultation with the patient's physician. Patients with stable angina (angina that occurs infrequently, is associated with exertion or stress, and is easily controlled with medication and rest) can undergo elective dental procedures. Because stress often induces an acute anginal attack, stress reduction is important. Profound local anesthesia is vital, and conscious sedation may be indicated for anxious patients. Supplemental oxygen delivered via nasal cannula may also help prevent intraoperative anginal attacks.

Patients who treat acute anginal attacks with nitroglycerine should be instructed to bring their medication to dental appointments. Nitroglycerine should also be kept in the office emergency medical kit. For particularly stressful procedures, the patient may take a nitroglycerine

TABLE 38-2

Nonselective and Selective ß-Adrenergic Receptor Antagonists ß-Blockers)

Generic Name	Trade Name
Nonselective	
Carteolol hydrochloride	Cartrol
Nadolol	Corgard
Penbutolol sulfate	Levatol
Pindolol	Visken
Propanolol hydrochloride	Inderal; Inderal LA
Timolol maleate	Blocadren
Selective	
Acebutolol hydrochloride	Sectral
Atenolol	Tenormin
Betaxolol hydrochloride	Kerlone
Bisoprolol fumarate	Zebeta
Metoprolol tartrate	Lopressor
Metoprolol succinate	Toprol-XL

tablet preoperatively to prevent angina, although this is generally not necessary. The patient's nitroglycerin should be readily accessible on the dental tray in case it is needed during treatment. As the shelf life of nitroglycerin is relatively short, the expiration date of the patient's nitroglycerin should be noted, as should the expiration date of the nitroglycerin in the office's emergency medical kit. Also, patients with angina may be taking longer-acting nitroglycerins (in tablet or patch form), ß-blockers, or calcium channel blockers (also used in the treatment of hypertension) for prevention of angina. Restrictions on use of local anesthetics containing epinephrine are similar to the patient with hypertension. In addition, intraosseous injection with epinephrine-containing local anesthetics using systems such as the Stabident system (Fairfax Dental Inc.) should be done cautiously in patients with ischemic heart disease, because it results in transient increases in heart rate and myocardial oxygen demand.so

If the patient becomes fatigued or uncomfortable or has a sudden change in heart rhythm or rate during a periodontal procedure, the procedure should be discontinued as soon as possible. A patient who has an anginal episode in the dental chair should receive the following emergency medical treatment:

1. Discontinue the periodontal procedure.
2. Administer one tablet (0.3 to 0.6 mg) of nitroglycerin sublingually.
3. Reassure the patient and loosen restrictive garments.
4. Administer oxygen with the patient in a reclined position.
5. If the signs and symptoms cease within 3 minutes, complete the periodontal procedure if possible, making sure that the patient is comfortable. Terminate the procedure at the earliest convenient time.
6. If the anginal signs and symptoms do not resolve with this treatment within 2 to 3 minutes, administer another dose of nitroglycerin, monitor the patient's vital signs, call his or her physician, and be ready to accompany the patient to the emergency department.
7. A third nitroglycerin tablet may be given 3 minutes after the second. Chest pain that is not relieved by 3 tablets of nitroglycerin indicates likely myocardial infarction. The patient should be transported to the nearest emergency medical facility immediately.

Myocardial infarction is the other category of ischemic heart disease frequently encountered in dental practice. Dental treatment is generally deferred for at least 6 months following a myocardial infarction because the peak mortality rate occurs during this time .z° After 6 months, myocardial infarction patients can usually be treated using techniques similar to the stable angina patient.

Cardiac (aortocoronary) bypass, femoral artery bypass, angioplasty, and endarterectomy have become common surgical procedures in patients with ischemic heart disease. The physician should be consulted before elective dental therapy if one of these procedures was performed recently to determine the degree of heart damage or arterial occlusive disease, the stability of the patient's condition, and the potential for infective endocarditis or graft rejection. Prophylactic antibiotics are not usually neces-

sary for cardiac bypass patients unless recommended by the cardiologist.

Congestive Heart Failure

Congestive heart failure (CHF) is a condition in which the pump function of the heart is unable to supply sufficient amounts of oxygenated blood to meet the body's needs .z° CHF usually begins with left ventricular failure caused by a disproportion between the hemodynamic load and the capacity to handle that load. It may be due to a chronic increase in workload (as in hypertension or aortic, mitral, pulmonary, or tricuspid valvular disease), direct damage to the myocardium (as in myocardial infarction or rheumatic fever), or an increase in the body's oxygen requirements (as in anemia, thyrotoxicosis, or pregnancy).

Patients with poorly controlled or untreated congestive heart failure are not candidates for elective dental procedures. These individuals are at risk for sudden death, usually from ventricular arrhythmias. For patients with treated congestive heart failure, the clinician should consult with the physician regarding the severity of CHF, underlying etiology, and current medical management. Medical management of CHF may include use of calcium channel blockers, direct vasodilators, diuretics, ACE inhibitors, a-receptor blockers, and cardiotonic agents such as digoxin.43 Each of these medications has potential side effects that may have an impact on periodontal therapy. Due to the presence of orthopnea (the inability to breathe unless in an upright position) in some CHF patients, the dental chair should be adjusted to a comfortable level for the patient rather than being placed in a supine position. Short appointments, stress reduction with profound local anesthesia and possibly conscious sedation, and use of supplemental oxygen should be considered.[20,35]

Cardiac Pacemakers and Automatic Defibrillators

Some cardiac arrhythmias are treated with implantable pacemakers or automatic defibrillators.[35] Pacemakers are usually implanted in the chest wall and enter the heart transvenously. Automatic defibrillators are more often implanted subcutaneously near the umbilicus and have electrodes passing into the heart transvenously or directly attached to the epicardium. Consultation with the patient's physician allows determination of the underlying cardiac status, the type of pacemaker or automatic defibrillator, and any precautionary measures to be taken. Older pacemakers were unipolar and could be disrupted by dental equipment that generates electromagnetic fields such as ultrasonic and electrocautery units. Newer units are bipolar and are generally not affected by dental equipment. Automatic defibrillators activate without warning when certain arrhythmias occur. This may endanger the patient during dental treatment because such activation often causes sudden patient movement. Stabilization of the operating field during periodontal treatment with bite blocks or other devices can prevent unexpected trauma.

Infective Endocarditis

Infective endocarditis (IE) is a disease in which microorganisms colonize the damaged endocardium or heart valves.22 Although the incidence of IE is low, it is a serious disease with a poor prognosis, despite modern therapy. The term *infective endocarditis is* preferred to the previous term *bacterial endocarditis* because the disease can also be caused by fungi and viruses. The organisms most commonly encountered in IE are a-hemolytic streptococci (e.g., *Streptococcus viridans).* However, nonstreptococcal organisms often found in the periodontal pocket have been increasingly implicated, including *Eikenella corrodens, Actinobacillus actinomycetemcomitans, Capnocytophaga,* and *Lactobacillus* species.'

IE has been divided into acute and subacute forms. The acute form involves virulent organisms, generally nonhemolytic streptococci and strains of staphylococci, which invade normal cardiac tissue, produce septic emboli, and cause infections that run a rapid, generally fatal course. The subacute form, on the other hand, occurs as a result of colony formation on damaged endocardium or heart valves by low-grade pathogenic organisms; the classic example is rheumatic carditis consequent to rheumatic fever.

The risk for IE varies with the underlying disorder *(Box 38-1).*[14,15] The high-risk category includes patients at high risk of developing IE after dental-induced bacteremia and those in whom the resultant IE is associated with high morbidity and mortality. The moderate-risk category includes patients at higher risk for IE than the general population.

The practice of periodontics is intimately concerned with the prevention of IE. Because dental procedures that involve bleeding may induce a transient bacteremia, the American Heart Association (AHA) recommends antibiotic prophylaxis before procedures "associated with significant bleeding from hard or soft tissues, periodontal surgery, scaling and professional teeth cleaning."" However, bacteremia may occur even in the absence of dental procedures, especially in individuals with poor oral hygiene and significant periodontal inflammation. Thus prevention of periodontal inflammation is paramount. The AHA states that patients who are at risk for IE should "establish and maintain the best possible oral health to reduce potential sources of bacterial seeding." To provide adequate preventive measures for IE, the clinician's major concern should be to reduce the microbial population in the oral cavity so as to minimize soft tissue inflammation and bacteremia.

Preventive measures to reduce the risk of IE should consist of the following:

1. *Define the susceptible patient.* A careful medical history will disclose the aforementioned susceptible patients. Health questioning should cover history of all potential categories of risk (see Box *38-1).* If any doubt exists, the patient's physician should be consulted.
2. *Provide oral hygiene instruction.* Oral hygiene should be practiced with methods that improve gingival health yet minimize bacteremia. In patients with significant gingival inflammation, oral hygiene should initially be limited to gentle procedures (i.e., oral rinses and

BOX 38-1

Heart Conditions Associated with Infective Endocarditis (IE)*

Endocarditis Prophylaxis Recommended

High-risk patients
- Previous history of IE
- Prosthetic heart valves
- Major congenital heart disease
  - Tetralogy of Fallot
  - Transposition of great arteries
  - Single ventricle states
  - Surgically constructed systemic pulmonary shunts, or conduits

Moderate-risk patients
- Acquired valvular dysfunction (e.g., rheumatic heart disease)
- Most other congenital heart malformations
- Hypertrophic cardiomyopathy
- Mitral valve prolapse with valvular regurgitation, thickened leaflets, or both

Endocarditis Prophylaxis* Not *Recommended (No Greater Risk than General Population)

Mitral valve prolapse without valvular regurgitation
Previous coronary artery bypass graft surgery
Physiologic, functional, or innocent heart murmurs
Previous rheumatic fever without valvular dysfunction
Cardiac pacemakers and implanted defibrillators
Isolated secundum atrial septal defect
Surgically repaired atrial septal defect, ventricular septal defect, or patent ductus arteriosus
Previous Kawasaki disease without valvular dysfunction

* **Recommendations by the American Heart Association .14,15**

gentle toothbrushing with a soft brush) to minimize bleeding. As gingival health improves, more aggressive oral hygiene may be initiated. Oral irrigators are generally not recommended because their use may induce bacteremia.44 Susceptible patients should be encouraged to maintain the highest level of oral hygiene once soft tissue inflammation is controlled.

3. *During periodontal treatment, currently recommended antibiotic prophylactic regimens should be practiced with all susceptible patients* (Table *38-3).* If any doubt regarding susceptibility exists, the patient's physician should be consulted. In patients who have been receiving continuous oral penicillin for secondary prevention of rheumatic fever, penicillin-resistant a-hemolytic streptococci are occasionally found in the oral cavity. It therefore is recommended that an alternate regimen be followed instead. Likewise, if the periodontal patient is taking a systemic antibiotic as part of periodontal therapy, changes in the IE prophylaxis regimen may be indicated. For example, a patient currently taking a penicillin agent after regenerative therapy may be placed on azithromycin before the next periodontal procedure. Patients with early onset forms of periodontitis often have high levels of *Actinobacillus actinomycetemcomitans* in the subgingival plaque. This organism has been associated with IE and is often resistant to penicillins. Therefore in patients with early onset periodontitis who are also at risk for IE, Slots and co-workers have suggested using tetracycline, *250* mg, four times daily for 14 days to eliminate or reduce A. *actinomycetemcomitans,* followed by the conventional prophylaxis protocol at the time of dental treatment .62

4. *Periodontal treatment should be designed for susceptible patients to accommodate their particular degree o f periodontal involvement.* The nature of periodontal therapy enhances the problems related to the prophylaxis of subacute IE. Patients are faced with long-term therapy, healing periods that extend beyond a 1-day antibiotic regimen, multiple visits, and procedures that easily elicit gingival bleeding. The following guidelines should aid in the development of periodontal treatment plans for patients susceptible to IE:
   - Periodontal disease is an infection with potentially wide-ranging systemic effects. In patients at risk for IE, every effort should be made to eliminate this infection. Teeth with severe periodontitis and a poor prognosis may require extraction. Teeth with less severe involvement in a motivated patient should be retained, treated, and maintained closely.
   - All periodontal treatment procedures (including probing) require antibiotic prophylaxis; gentle oral hygiene methods are excluded. Pretreatment chlorhexidine mouthrinses are recommended before all procedures, including periodontal probing, because they significantly reduce the presence of bacteria on mucosal surfaces.15
   - To reduce the number of visits required and thereby minimize the risk of developing resistant bacteria, numerous procedures may be accomplished at each appointment, depending on the patient's needs and ability to tolerate dental treatment .35
   - When possible, allow at least 7 days between appointments (preferably 10 to 14 days). If this is not possible, select an alternative antibiotic regimen for appointments within a 7-day time period.
   - Evidence does not support nor refute a need to place patients at risk for IE on extended antibiotic regimens after treatment.35 Therefore patients who have had periodontal surgery are not generally placed on antibiotics for the first week of healing (unless there are specific indications to do so). If patients are placed on **such regimens, the dosages are inadequate to prevent endocarditis** during ensuing appointments. Therefore the standard prophylactic antibiotic dose is still needed. For example, if a patient was placed on *250* mg of amoxicillin three times a day for 10 days after periodontal surgery and was returning to the office for more treatment on the seventh day, he or she would still require a full 2.0 g dose of amoxicillin before that treatment. Alternatively, clindamycin or azithromycin could be used at the second appointment.
   - The need for antibiotic prophylaxis before simple suture removal is controversial. Some authors

TABLE 38-3

Recommended Antibiotic Prophylaxis Regimens for Periodontal Procedures in Adults at Risk for Infective Endocarditis

Regimen	Antibiotic	Dosage
Standard oral regimen	Amoxicillin	2.0 g 1 hour before procedure
Alternate regimen for patients allergic to amoxicillin, penicillin, or both	Clindamycin	600 mg 1 hour before procedure
	OR	
	Azithromycin or clarithromycin	500 mg 1 hour before procedure
	OR	
	Cephalexin or cefadroxil*	2.0 g 1 hour before procedure
Patients unable to take oral medications	Ampicillin	2.0 g intramuscularly or intravenously within 30 minutes before procedure
Patients unable to take oral medications and allergic to penicillin	Clindamycin	600 mg intravenously within 30 minutes before procedure (must be diluted and injected slowly)
	OR	
	Cefazolin*	1.0 g intramuscularly or intravenously within 30 minutes before procedure

* Cephalosporins should *not* be used in patients with immediate-type hypersensitivity reactions to penicillins (e.g., urticaria, angioedema, anaphylaxis).

Note: Children's dosages are lower

See References 14 and 15.

suggest it is needed, whereas others suggest it is not. When possible, sutures that resorb in a short period of time, such as chromic gut, may be indicated for patients at risk of IE.

- Regular recall appointments, with an emphasis on oral hygiene reinforcement and maintenance of periodontal health, are extremely important in this population.

Cerebrovascular Accident

A cerebrovascular accident (CVA), or stroke, occurs as a result of ischemic changes (e.g., cerebral thrombosis owing to an embolus) or hemorrhagic phenomena. Hypertension and atherosclerosis are predisposing factors to a CVA and should alert the clinician to evaluate the patient's medical history carefully for the possibility of early cerebrovascular insufficiency and to be aware of symptoms of the disease. A physician's referral should precede periodontal therapy if the signs and symptoms of early cerebrovascular insufficiency are evident.

To prevent a repeat stroke, active infections should be treated aggressively because even minor infection may alter blood coagulation and trigger thrombus formation and ensuing cerebral infarction. The clinician should counsel the patient as to the importance of thorough oral hygiene. Post-stroke weakness of the facial area or paralysis of extremities may make oral hygiene procedures extremely difficult.42 The clinician may need to modify oral hygiene instruments for ease of use, perhaps in consultation with an occupational therapist. Long-term chlorhexidine rinses may greatly aid in plaque control.

Patients who are seen after a stroke should be treated following these guidelines:

1. No periodontal therapy (unless for an emergency) should be performed for 6 months because of the high risk of recurrence during this period.
2. After 6 months, periodontal therapy may be performed using short appointments with an emphasis on minimizing stress. Profound local anesthesia should be obtained using the minimal effective dose of local anesthetic agents. Concentrations of epinephrine greater than 1:100,000 are contraindicated.
3. Light conscious sedation (inhalation, oral or parenteral) may be used for very anxious patients. Supplemental oxygen is indicated to maintain thorough cerebral oxygenation.
4. Stroke patients are frequently placed on oral anticoagulants. For procedures that entail significant bleeding, such as periodontal surgery or tooth extraction, the anticoagulant regimen often needs adjustment in consultation with the physician.
5. Monitor blood pressure carefully. Recurrence rates for CVAs are high, as are rates of associated functional deficits.

ENDOCRINE DISORDERS

Diabetes

The diabetic patient requires special precautions before periodontal therapy. The two major types of diabetes are type 1 (formerly known as "insulin-dependent diabetes")

BOX 38-2

Diagnostic Criteria for Diabetes Mellitus

Diabetes mellitus may be diagnosed by any 1 of 3 different laboratory methods. Whatever method is used *must be confirmed on a subsequent day* by using any 1 of the 3 methods.

1. *Symptoms of diabetes plus casual (nonfasting) plasma glucose ≥200 mg/dl.* Casual glucose may be drawn at any time of day without regard to time since the last meal. Classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
2. *Fasting plasma glucose ≥126 mg/dl.* Fasting is defined as no caloric intake for at least 8 hours. (Normal fasting glucose is 70–100 mg/dl.)
3. *2 hour postprandial glucose ≥200 mg/dl during an oral glucose tolerance test.** The test should be performed using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water. (Normal 2 hour postprandial glucose is <140 mg/dl.)

* **The third method i5 not recommended for routine clinical use. See reference 3.**

BOX 38-3

Laboratory Evaluation of Diabetes Control (American Diabetes Association Guidelines)

Glycated Hemoglobin Assay (HbA1c)	
4% to 6%	Normal
<7%	Good diabetes control
7% to 8%	Moderate diabetes control
>8%	Action suggested to improve diabetes control

BOX 38-4

Signs and Symptoms of Hypoglycemia

- Shakiness or tremors
- Confusion
- Agitation and anxiety
- Sweating
- Tachycardia
- Dizziness
- Feeling of "impending doom"
- Unconsciousness
- Seizures

and type 2 (formerly called "non-insulin-dependent diabetes")." Over the last decade, the medical management of diabetes has changed significantly in an effort to minimize the debilitating complications associated with this disease. [17,68] Patients are more tightly managing their blood glucose levels (glycemia) through diet, oral agents, and insulin therapy. [16]

If the clinician detects intraoral signs of undiagnosed or poorly controlled diabetes, a thorough history is indicated. The classic signs of diabetes include polydipsia (excessive thirst), polyuria (excessive urination), and polyphagia (excessive hunger, often with unexplained concurrent weight loss). If the patient has any of these signs or symptoms, or if the clinician's index of suspicion is high, further investigation via laboratory studies and physician consultation is indicated. Periodontal therapy has limited success in the presence of undiagnosed or poorly controlled diabetes.

If a patient is suspected of having undiagnosed diabetes, the following procedures should be performed:

1. Consult the patient's physician.
2. Analyze laboratory tests (Box 38-2): fasting blood glucose, casual glucose, and postprandial blood glucose.'
3. Rule out acute orofacial infection or severe dental infection, and provide emergency care only until diagnosis is established.

If a patient is known to have diabetes, it is critical that the level of glycemic control be established before initiating periodontal treatment. The fasting glucose and casual glucose tests provide "snapshots" of the blood glucose concentration at the time the blood was drawn. They reveal nothing about long-term glycemic control. The primary test used to assess glycemic control in a known diabetic individual is the glycosylated or glycated hemoglobin assay (Box 38-3). Two different tests are available, the HbAl and the HbAlc test; the HbAlc is more commonly used .36 This assay reflects blood glucose concentrations over the preceding 6 to 8 weeks and may provide an indication of the potential response to periodontal therapy. Patients with relatively well-controlled diabetes (HbAlc < 8%) usually respond to therapy in a manner similar to nondiabetic individuals. [11,66,71] Poorly controlled patients (HbAlc > 10%) often have a poor response to treatment, with more postoperative complications and less favorable long-term results .37,66

As discussed in Chapter 13, periodontal infection may worsen glycemic control, and should be managed aggressively. Diabetic patients with periodontitis should received oral hygiene instructions, mechanical debridement to remove local factors, and regular maintenance. When possible, an HbAlc of <10% should be established before surgical treatment is performed. Systemic antibiotics are not needed routinely, although recent evidence indicates that tetracycline antibiotics in combination with scaling and root planing may positively influence glycemic control (see Chapter 13). If the patient has poor glycemic control and surgery is absolutely needed, prophylactic antibiotics may be given. Penicillins are most often used for this purpose. Frequent reevaluation

TABLE 38-4

Oral Agents Used in Management of Diabetes

Agent	Action	Risk of Hypoglycemia
Sulfonylureas (first generation) Chlorpropamide Tolbutamide Tolazamide	Stimulate pancreatic insulin secretion.	++
Sulfonylureas (second generation) Glyburide Glipizide	Stimulate pancreatic insulin secretion.	+++
Sulfonylureas (third generation) Glimepiride	Stimulates pancreatic insulin secretion.	+
Meglitinides: Repaglinide	Stimulates rapid pancreatic insulin secretion.	+
Phenylalanine derivatives: Nateglinide	Stimulates rapid pancreatic insulin secretion.	+
Biguanides Metformin	Blocks production of glucose by liver; improves tissue sensitivity to insulin.	–

a-Glucosidase inhibitors Acarbose Miglitol	Slows absorption of some carbohydrates from gut, decreasing postprandial peaks in glycemia.	–

after active therapy is needed to assess treatment response and prevent recurrence of periodontitis.

Many diabetic patients today use glucometers for immediate blood glucose self-monitoring. These devices use capillary blood from a simple finger stick to provide blood glucose readings in a matter of seconds to minutes. Diabetic patients should be asked whether they have glucometers and how often they use them. Because these devices provide an instantaneous assessment of blood glucose, they are highly beneficial in the dental office environment. The following guidelines should be observed:

1. Patients should be asked to bring their glucometer to the dental office at each appointment.
2. Patients should check their blood glucose before any long procedure to get a baseline level. Patients with blood glucose levels at or below the lower end of normal before the procedure may become hypoglycemic intraoperatively. It is advisable to have such a patient consume some carbohydrate before starting treatment. For example, if a 2-hour procedure is planned and the pretreatment glucose level is 70 mg/dl (the lower end of normal range), providing 4 oz of juice preoperatively may help prevent hypoglycemia during treatment. If pretreatment glucose levels are excessively high, the procedure may need to be postponed until better glycemic control is established.
3. After the procedure, the blood glucose can be checked again to assess fluctuations over time.
4. Any time the patient feels symptoms of hypoglycemic, the glucose should be checked immediately. This may prevent onset of severe hypoglycemia, a medical emergency.

The most common dental office complication seen in diabetic patients taking insulin is symptomatic low blood glucose or hypoglycemia (Box *38-4).* Hypoglycemia is also associated with the use of numerous oral agents (Table *38-4).* In patients receiving conscious sedation, the warning signs of an impending hypoglycemic episode may be masked, making the glucometer one of the best diagnostic aids. Hypoglycemia does not usually occur until blood glucose levels fall below 60 mg/dl. However, in patients with poor glycemic control who have prolonged hyperglycemia (high blood glucose levels), a rapid drop in glucose can precipitate signs and symptoms of hypoglycemia at levels well above 60 mg/dl.

As medical management of diabetes has intensified over the last decade, the incidence of severe hypoglycemia has risen." The clinician should question diabetic patients about past episodes of hypoglycemia. Hypoglycemia is more common in patients with better glycemic control. When planning dental treatment, it is best to schedule appointments before or after periods of peak insulin activity. This requires knowledge of the

TABLE 38-5

Types of Insulin

Insulin Type	Insulin Classification	Onset of Activity	Peak Activity	Duration of Activity
Lispro	Rapid acting	15 min	30 to 90 min	<5 hrs
Regular	Short acting	30 to 60 min	2 to 3 hrs	4 to 12 hrs
NPH	Intermediate acting	2 to 4 hrs	4 to 10 hrs	14 to 18 hrs
Lente	Intermediate acting	3 to 4 hrs	4 to 12 hrs	16 to 20 hrs
Ultralente	Long acting	6 to 10 hrs	12 to 16 hrs	20 to 30 hrs
Glargine	Long acting	6 to 8 hrs	No peak in activity	22 to 28 hrs

pharmacodynamics of the drugs being taken by the diabetic patient. Patients taking insulin are at greatest risk, followed by those on sulfonylurea agents. Metformin and thiazolidinediones generally do not cause hypoglycemia (see Table 38-4).

Insulins are classified as rapid-, short-, intermediate-, or long-acting (Table 38-5). The categories vary in their onset, peak, and duration of activity. It is important that the clinician establish exactly which insulins the diabetic patient takes, the amount, the number of times per day, and the time of the last dose. Periodontal treatment often can be timed to avoid peak insulin activity. Many diabetic patients take multiple injections each day, in which case it is difficult, if not impossible, to avoid peak insulin activity. Checking the pretreatment glucose with the patient's glucometer, checking again during long procedures, and again at the end of the procedure provides a better understanding of the patient's insulin pharmacodynamics and helps prevent hypoglycemia.

If hypoglycemia occurs during dental treatment, therapy should be immediately terminated. If a glucometer is available, the blood glucose level should be checked. Treatment guidelines include the following[36]:

1. Provide approximately 15 g of oral carbohydrate to the patient:
   - 4 to 6 oz of juice or soda
   - 3 or 4 tsp of table sugar
   - Hard candy with 15 g of sugar
2. If the patient is unable to take food or drink by mouth, or if the patient is sedated:
   - Give 25 ml to 30 ml of 50% dextrose intravenously, or
   - Give 1 mg of glucagon intravenously (glucagon results in rapid release of stored glucose from the liver), or
   - Give 1 mg of glucagon intramuscularly (if no IV access)

Emergencies due to hyperglycemia are rare in the dental office. They generally take days to weeks to develop. However, the glucometer may be used to rule out hyperglycemic emergencies such as diabetic ketoacidosis, a life-threatening event.

Because periodontal therapy may render the patient unable to eat for some time, adjustment in insulin or oral agent dosages may be required. It is absolutely critical that patients eat their normal meal before dental treatment. Taking insulin without eating is the primary cause of hypoglycemia. If the patient is restricted from eating before treatment (e.g., for conscious sedation), normal insulin doses will need to be reduced. As a general guideline, well-controlled diabetic patients having routine periodontal treatment may take their normal insulin doses as long as they also eat their normal meal. If the procedures are going to be particularly long, the insulin dose before treatment may need to be reduced. Likewise, if the patient will have dietary restrictions after treatment, insulin or sulfonylurea dosages may need to be reduced. Consultation with the patient's physician is prudent and allows both practitioners to review the proposed treatment plan and determine any modifications needed. When periodontal surgery is indicated, it is usually best to limit the size of the surgical fields so that the patient will be comfortable enough to resume a normal diet immediately.

Thyroid and Parathyroid Disorders

Periodontal therapy requires minimal alterations in the patient with adequately managed thyroid diseases$ Patients with thyrotoxicosis and those with inadequate medical management should not receive periodontal therapy until their conditions are stabilized. Patients with histories of hyperthyroidism should be carefully evaluated to determine the level of medical management, and they should be treated in a way that limits stress and infection. Hyperthyroidism may cause tachycardia and other arrhythmias, increased cardiac output, and myocardial ischemia. Medications such as epinephrine and other vasopressor amines should be given with caution in patients with treated hyperthyroidism, although the small amounts used in dental anesthetics rarely cause problems.[72] They should not be given to patients with thyrotoxicosis or poorly controlled thyroid disorders. Patients with hypothyroidism require careful administration of sedatives and narcotics due to the potential for excessive sedation.

Routine periodontal therapy may be provided to patients with parathyroid disease once that disorder has been identified and the proper medical treatment given.

BOX 38-5

Manifestations of Acute Adrenal Insufficiency

Mental confusion, fatigue, and weakness
Nausea, vomiting, or both
Hypertension
Syncope

Methylprednisolone	4
Triamcinolone	4
Dexamethasone	0.75
Betamethasone	0.6

However, patients who have not received medical care may have significant renal disease, uremia, and hypertension. Also, if hypercalcemia or hypocalcemia is present, the patient may be more prone to cardiac arrhythmias.

Adrenal Insufficiency

Acute adrenal insufficiency is associated with significant morbidity and mortality owing to peripheral vascular collapse and cardiac arrest. Therefore the periodontist should be aware of the clinical manifestations (Box 38-5) and ways of preventing acute adrenal insufficiency in patients with histories of primary adrenal insufficiency (Addison's disease) or secondary adrenal insufficiency (most often caused by use of exogenous glucocorticosteroids).

The use of systemic corticosteroids is common in allergic, endocrine, respiratory, joint, intestinal, neurologic, renal, liver, skin, and connective tissue disorders. Significant complications associated with corticosteroid use include alterations in glucose metabolism (steroid-induced diabetes), increased risk of infection, altered wound healing, osteoporosis, skin disorders, cataracts, glaucoma, and suppression of the hypothalamic-pituitary-adrenal (HPA) axis.[24,35] In the normal healthy patient, stress activates the HPA axis, stimulating increased endogenous cortisol production by the adrenal glands. Exogenous steroids may suppress the HPA axis and impair the patient's ability to respond to stress with increased endogenous cortisol production, leading to the potential for acute adrenal crisis (see Table 38-5). The degree of adrenal suppression depends on the drugs used, dose, duration of administration, length of time elapsed since steroid therapy was terminated, and route of administration.

It has been common practice in the past to administer prophylactic systemic steroids before dental treatment for patients who are taking or recently have taken exogenous steroids. A thorough review of the literature and recent clinical evidence suggests such steroid supplementation may not be required for many periodontal procedures.[24] Shapiro et al found that patients taking 5 to 20 mg/day prednisone maintained at least some adrenal reserve after immediate termination of steroid therapy.[57] Higher doses may suppress the adrenal glands to a greater degree. Although exogenous steroids may suppress normal adrenal cortisol secretion for an extended period of time, the ability of the adrenal gland to respond to stress may return quickly after termination of steroid therapy. However, the severe consequences of adrenal crisis suggest caution in patient management. Before treating a patient with a history of recent or current steroid use, physician consultation is indicated to determine whether the patient's periodontal needs and proposed treatment plan suggest a requirement for supplemental steroids. Use of a stress reduction protocol and profound local anesthesia may help minimize the physical and psychologic stress associated with therapy and reduce the risk of acute adrenal crisis. A rapid assay is available to determine the degree of adrenal reserve by measurement of serum cortisol levels 30 and 60 minutes after intravenous administration of synthetic corticotrophin.[57]

There is no set protocol for steroid prophylaxis. Topical corticosteroids generally have minimal to no HPA effect, and steroid supplementation generally is not required for these patients. For the patient currently receiving systemic steroid therapy, the need for corticosteroid prophylaxis depends on the drug used because of the variance in equivalent therapeutic doses (Table 38-6). Glucocorticosteroid coverage regimens vary, but most provide a 2- to 4-fold increase in coverage, depending on the stress produced by the procedure. For patients taking large doses of >20 mg cortisol-equivalent per day and requiring stressful periodontal procedures, doubling or tripling the normal steroid dose 1 hour before the procedure is often recommended. For those patients on low doses for short periods of time (i.e., less than 1 month), no supplementation is generally warranted. Again, in an emergency situation, increasing the steroid dose before the procedure may decrease the chances of acute adrenal crisis. If emergency treatment is not needed, consultation with the physician before treatment is best.

Management of the patient in an acute adrenal insufficiency crisis is as follows:

1. Terminate periodontal treatment.
2. Summon medical assistance.
3. Give oxygen.
4. Monitor vital signs.
5. Place the patient in a supine position.
6. Administer 100 mg of hydrocortisone sodium succinate (Solu-Cortef) intravenously for 30 seconds or intramuscularly.

RENAL DISEASES

The most common causes of renal failure are glomerulonephritis, pyelonephritis, kidney cystic disease, renovascular disease, drug nephropathy, obstructive uropathy, and hypertension.[31,74] Renal failure may result in severe electrolyte imbalances, cardiac arrhythmias, pulmonary congestion, congestive heart failure, and prolonged bleeding.[35] Because the dental management of patients with renal disease may need to be drastically altered, physician consultation is necessary to determine the stage of renal disease, regimen for medical management, and alterations in periodontal therapy. The patient in chronic renal failure has a progressive disease that ultimately may require kidney transplantation or dialysis. It is preferable to treat the patient before, rather than after, transplant or dialysis. The following treatment modifications should be used:

1. Consult the patient's physician.
2. Monitor blood pressure (patients in end-stage renal failure are usually hypertensive).
3. Check laboratory values: partial thromboplastin time, prothrombin time, bleeding time, and platelet count; hematocrit; blood urea nitrogen (do not treat if less than 60 mg/dl); and serum creatinine (do not treat if less than 1.5 mg/dl).
4. Eliminate areas of oral infection to prevent systemic infection.
   - Good oral hygiene should be established.
   - Periodontal treatment should aim at eliminating inflammation or infection and providing easy maintenance. Questionable teeth should be extracted if medical parameters permit.
   - Frequent recall appointments should be scheduled.
5. Drugs that are nephrotoxic or metabolized by the kidney should not be given (e.g., phenacetin, tetracycline, aminoglycoside antibiotics). Acetaminophen may be used for analgesia and diazepam may be used for sedation. Local anesthetics such as lidocaine are generally safe.[35,51]

The patient who is receiving dialysis requires treatment planning modifications.[31] The three modes of dialysis are intermittent peritoneal dialysis (IPD), chronic ambulatory peritoneal dialysis (CAPD), and hemodialysis. Only hemodialysis patients require special precautions. These patients have a high incidence of viral hepatitis, anemia, and prolonged hemorrhage. The risk for hemorrhage is related to anticoagulation during dialysis, platelet trauma from dialysis, and the uremia that develops with renal failure.[35] Hemodialysis patients have either an internal arteriovenous fistula or an external arteriovenous shunt. This shunt is often located in the arm and must be protected from trauma. Thus in addition to guidelines for patients with chronic renal disease, the following recommendation are made for those on hemodialysis:

1. Screen for hepatitis B and hepatitis C antigens and antibody before any treatment.
2. Provide antibiotic prophylaxis to prevent endarteritis of the arteriovenous fistula or shunt. (IPD and CAPD patients do not generally require prophylactic antibiotics).
3. Patients receive heparin anticoagulation on the day of hemodialysis. Therefore provide periodontal treatment on the day *after* dialysis, when the effects of heparinization have subsided. Hemodialysis treatments are generally performed 3 or 4 times a week. (IPD and CAPD patients are not systemically heparinized; therefore they usually do not have the potential bleeding problems associated with hemodialysis.)
4. Be careful to protect the hemodialysis shunt or fistula when the patient is in the dental chair. If the shunt or fistula is placed in the arm, do not cramp the limb; *blood pressure readings should be taken from the other arm*. Do not use the limb for the injection of medication. Patients with leg shunts should avoid sitting with the leg dependent for longer than 1 hour. If appointments last longer, allow the patient to walk about for a few minutes and then resume therapy.
5. Refer the patient to the physician if uremic problems develop, such as uremic stomatitis. Refer to the physician if oral infections do not resolve promptly to prevent systemic dissemination.

The renal transplant patient's greatest foe is infection. Transplant patients take immunosuppressive drugs that greatly reduce resistance to infection.[51] Excessive bleeding may occur during or after periodontal treatment due to drug-induced thrombocytopenia, anticoagulation, or both. A periodontal abscess is a potentially life-threatening situation. For this reason, a dental team approach should be used *before* transplantation to determine which teeth can be easily maintained. Many organ transplant centers now include dental examination in their standard pretransplant protocol. Teeth with severe bone and attachment loss, furcation invasion, periodontal abscesses, or extensive surgical requirements should be extracted, leaving an easily maintainable dentition. In addition to the recommendations for patients with chronic renal failure, the following should be considered for the renal transplant patient:

1. Hepatitis B and C screening.
2. Determination of level of immunocompromise derived from antirejection drug therapy.
3. Prophylactic antibiotics (using American Heart Association recommendations). Not all transplant patients require antibiotic coverage, and physician consultation is warranted before prescribing.

LIVER DISEASES

Liver diseases may range from mild to complete failure. Major causes of liver disease include drug toxicity, cirrhosis, viral infections (e.g., hepatitis B and C), neoplasms, and biliary tract disorders.[13] Because the liver is the site of production for most of the clotting factors, excessive bleeding during or after periodontal treatment may occur in patients with severe liver disease. Many drugs are metabolized in the liver; thus liver disease alters normal drug metabolism. Treatment recommendations for patients with liver disease include the following:

1. Consultation with the physician concerning current stage of disease, risk for bleeding, potential drugs to be prescribed during treatment, and required alterations to periodontal therapy.
2. Screening for hepatitis B and C.
3. Check laboratory values for prothrombin time and partial thromboplastin time.

PULMONARY DISEASES

The **periodontal treatment of a patient with** pulmonary disease may require alteration depending on the nature and the severity of the respiratory problem. Pulmonary diseases range from obstructive lung diseases (e.g., asthma, emphysema, bronchitis, and acute obstruction) to restrictive ventilatory disorders that are due to muscle weakness, scarring, obesity, or any condition that could interfere with effective lung ventilation.[47,13] Combined restrictive-obstructive lung disease may also develop.

The clinician should be aware of the signs and symptoms of pulmonary disease, such as increased respiratory rate, cyanosis, clubbing of the fingers, chronic cough, chest pain, hemoptysis, dyspnea or orthopnea, and wheezing. Patients with these problems should be referred for medical evaluation and treatment. Most patients with chronic lung disease may undergo routine periodontal therapy if they are receiving adequate medical management. Caution should be practiced in relation to any treatment that may depress respiratory function.

Acute respiratory distress may be caused by slight airway obstruction or depression of respiratory function. Because of their limited vital lung capacity, these patients also have decreased cough effectiveness.[56] They must continually deal with the mental anxiety caused by air hunger and alter their position in attempts to improve their ventilatory efficiency.

The following guidelines should be used during periodontal therapy:

1. Identify and refer patients with signs and symptoms of pulmonary disease to their physicians.
2. In patients with known pulmonary disease, consult with their physicians regarding medications (antibiotics, steroids, chemotherapeutic agents) and the degree and severity of pulmonary disease.
3. Avoid **elicitation** of respiratory depression or distress:
   - Minimize the stress of a periodontal appointment. The patient with emphysema should be treated in the afternoon, several hours after sleep, to allow for airway clearance.
   - Avoid medications that could cause respiratory depression (e.g., narcotics, sedatives, and general anesthetics).
   - Avoid bilateral mandibular block anesthesia, which could cause increased airway obstruction.
   - Position the patient to allow maximal ventilatory efficiency, be careful to prevent physical airway obstruction, keep the patient's throat clear, and avoid excess periodontal packing.
4. In a patient with a history of asthma, make sure the patient's medication (inhaler) is available.
5. Patients with active fungal or bacterial respiratory diseases should not be treated unless the periodontal procedure is an emergency.

IMMUNOSUPPRESSION AND CHEMOTHERAPY

Immunosuppressed patients have impaired host defenses as a result of an underlying immunodeficiency or drug administration (primarily related to organ transplantation or cancer chemotherapy).[38,55] Because chemotherapy is often cytotoxic to bone marrow, destruction of platelets and red and white blood cells results in thrombocytopenia, anemia, and leukopenia. Immunosuppressed individuals are at greatly increased risk for infection, and even minor periodontal infections can become life threatening if immune suppression is severe. Intraorally, bacterial, viral, and fungal infections may manifest. Patients receiving bone marrow transplantation require special attention because these patients receive very high-dose chemotherapy and are particularly susceptible to dissemination of oral infections.

Treatment in these patients should be directed toward the prevention of oral complications that could be life threatening. The greatest potential for infection occurs during periods of extreme immunosuppression; therefore treatment should be conservative and palliative. It is always preferable to evaluate the patient before initiation of chemotherapy.[38,11] Teeth having a poor prognosis should be extracted, with thorough debridement of remaining teeth to minimize the microbial load. The clinician must teach and emphasize the importance of good oral hygiene. Antimicrobial rinses such as chlorhexidine are recommended, especially for patients with chemotherapy-induced mucositis, to prevent secondary infection.

Chemotherapy is usually performed in cycles, with each cycle lasting several days followed by intervening periods of myelosuppression and recovery. If periodontal therapy is needed during chemotherapy, it is best done the day *before* chemotherapy is given, when white cell counts are relatively high. Coordination with the oncologist is **critical.** Dental treatment should be done when white cell counts are above 2000/mm^3, with an absolute granulocyte count of 1000 to 1500/mm^3.[35]

RADIATION THERAPY

The use of radiotherapy, alone or in conjunction with surgical resection, is common in the treatment of head and neck tumors. The side effects of ionizing radiation include dramatic perioral changes of significant concern

to dental health personnel.[39,14] The extent and severity of mucositis, dermatitis, xerostomia, dysphagia, gustatory alteration, radiation caries, vascular changes, trismus, temporomandibular joint degeneration, and periodontal change depend on a myriad of radiation factors: the type of radiation used, fields of irradiation, number of ports, types of tissues in the fields, and dosage."

Patients scheduled to receive head and neck radiation therapy require dental consultation *at the earliest possible time* to reduce the morbidity of the known perioral side effects. Preirradiation treatment depends on the patient's prognosis, compliance, and residual dentition in addition to the fields, ports, dose, and immediacy of radiotherapy. The initial visit should include panoramic and intraoral radiographs, a clinical dental examination, a periodontal evaluation, and a physician consultation. The physician should be asked about the amount of radiation to' be administered, extent and location of the lesion, nature of any surgical procedures already performed or to be performed, number of radiation ports, exact fields to be irradiated, mode of radiation therapy, and patient's prognosis (i.e., the likelihood of metastasis). Preirradiation treatment should commence immediately after the physician consultation. The first decision that should be made relates to possible extractions because radiation can cause side effects that interfere with healing.

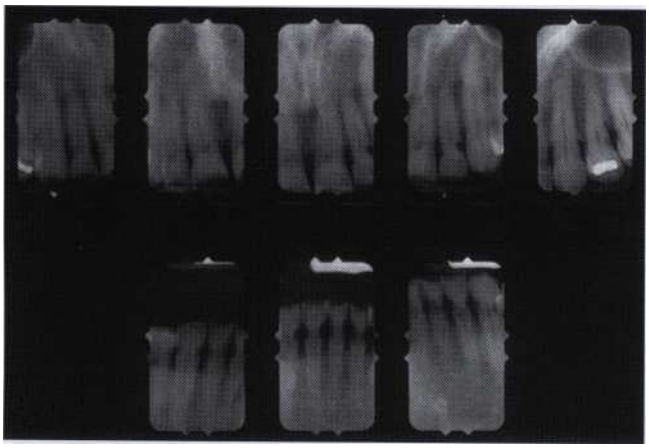

Fig. 38-2 Radiographs of the anterior teeth of a 52-year-old man with postirradiation caries. Patient received 6000-cGy radiation to the posterior mandible and base of tongue for squamous cell carcinoma. Radiation caries developed within 1 year of radiation treatment, affecting the cervical areas and incisal edges of the anterior teeth.

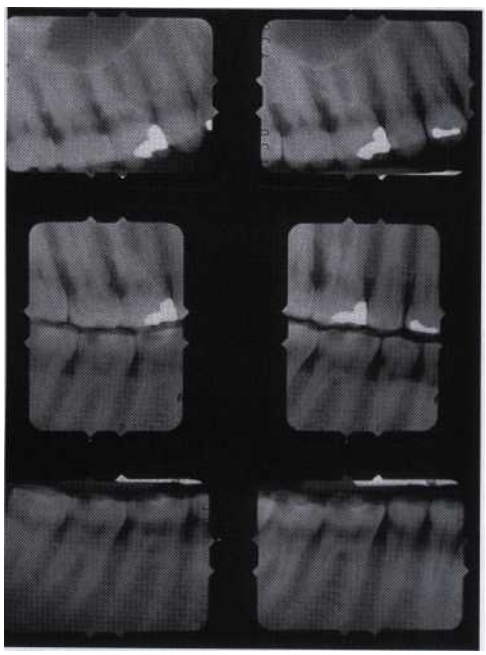

Fig. 38-3 Radiographs of the posterior sextants of the same patient as in Fig. 38-2. Caries affects the cervical areas and cusp tips of the posterior teeth.

For head and neck squamous cell carcinomas, the radiation dose is usually 5000 to 7000 cGy (centigrays; 1 cGy = 1 rad) delivered in a fractionated method (150 to 200 cGy/day over a 6- to 7-week course) .[6,39] This is considered full-course radiation treatment, and the degree of perioral side effects depends on which tissues are irradiated; that is, the radiation fields. If this dose is administered to the salivary gland tissues, xerostomia will ensue. The parotid is the most radiosensitive of the salivary glands; saliva may become extremely viscous or nonexistent, depending on the dose delivered to the particular gland. Xerostomia causes a decrease in the normal salivary cleansing mechanisms, buffering capacity of saliva, and pH of oral fluids.[39] Oral bacterial populations shift to preponderantly cariogenic forms (e.g., *Streptococcus mutans, Actinomyces spp.,* and *Lactobacillus* spp.). Radiation-induced caries may progress very rapidly and affects primarily smooth tooth surfaces (Figs. 38-2 and 38-3).

High-dose radiation therapy results in hypovascularity of irradiated tissues with a reduction in wound healing capacity.[54] Most severe among the resulting oral complications is osteoradionecrosis (ORN). Decreased vascularity renders the bone less capable of resolving trauma or infection. Such events may cause severe destruction of bone. The risk of ORN continues for the remainder of the patient's life and does not decrease with time .[33]

Periodontal disease can be a precipitating factor in ORN.[8,21] Tooth extraction after radiation treatment involves a high risk of developing ORN, and surgical flap procedures are generally discouraged after radiation. For these reasons, it is important that the clinician address the patient's periodontal disease *before* radiation begins, whenever possible. Teeth that are nonrestorable or severely periodontally diseased should be extracted, ideally at least 2 weeks before radiation .[39] Extractions should be performed in a manner that allows primary closure. Mucoperiosteal flaps should be gently elevated; teeth should be extracted in segments; alveolectomy should be performed, allowing no rough bony spicules to remain; and primary closure should be provided without tension. It is unnecessary to extract teeth that can be retained with conservative restorative, endodontic, or periodontal therapy. **However, prudence dictates extraction of questionable teeth because** periodontal treatment after irradiation may be limited to nonsurgical forms of therapy. Flap surgery or extraction of teeth after radia-

tion may lead to ORN. Management of ORN is often difficult and costly, involving progressively more aggressive treatment if bone does not respond to conservative therapy. Costly hyperbaric oxygen therapy is frequently required for complete resolution.

During radiation therapy, patients should receive weekly prophylaxis, oral hygiene instruction, and professionally applied fluoride treatments unless mucositis prevents such treatment. Patients should be instructed to brush daily with a 0.4% stannous or 1.0% sodium fluoride gel. Custom gel trays allow optimum fluoride application.[39] All remaining teeth should receive thorough debridement (scaling and root planing).

Postirradiation follow-up consists of palliative treatment given as indicated. Viscous lidocaine may be prescribed for painful mucositis, and salivary substitutes may be given for xerostomia. Daily topical fluoride application and oral hygiene are the best means of preventing radiation caries in the long-term aspect. A long-term, 3-month recall interval is ideal.

PROSTHETIC JOINT REPLACEMENT

The main treatment consideration for patients with prosthetic joint replacements relates to the potential need for antibiotic prophylaxis before periodontal therapy. Currently, there is no scientific evidence that prophylactic antibiotics prevent late prosthetic joint infections, which might occur from transient bacteremia induced by dental treatment.[16,35] Furthermore, although dental-induced bacteremia could theoretically cause prosthetic joint infection, very few reports demonstrate dental treatment as a source of joint infection, and none of these actually document a cause-and-effect relationship.[13,67] Thus the American Dental Association, American Academy of Orthopaedic Surgeons, American Academy of Oral Medicine, and British Society for Antimicrobial Chemotherapy all agree that routine antibiotic prophylaxis before dental treatment is not indicated for most patients with prosthetic joint replacements.[1,13,19,67] However, prophylaxis is indicated for almost all patients within the first 2 years after joint replacement and for so-called "high-risk" patients including those with previous prosthetic joint infections, immunosuppression, rheumatoid arthritis, systemic lupus erythematosis, type 1 diabetes, hemophilia, and malnourishment.[1] Importantly, patients with severe periodontal disease or other potential dental infections are considered by many authors to be high-risk, and antibiotic prophylaxis may be indicated for these patients before dental treatment.[41–67]

Although the evidence demonstrates no need for antibiotic prophylaxis in most patients, many orthopedic surgeons still prefer such treatmennt.[60] This is most likely due to the high morbidity and potential mortality rates associated with prosthetic joint infections. Consultation with the patient's orthopedic surgeon before periodontal treatment is in the patient's best interest and may help assess the risk for joint infection relative to current dental status and type of periodontal treatment planned. Because individuals with significant periodontal disease are considered "high risk," antibiotic prophylaxis before treatment is common in the periodontal practice. Suggested antibiotic regimens are found in Table 38-7.[1]

TABLE 38-7

Antibiotic Regimens for Prevention of Prosthetic joint Infections

Patient Characteristics	Drug Regimen
Patients *not* allergic to penicillins	Cephalexin, cephradine, or amoxicillin: 2 g orally 1 hour before dental procedure
Patients allergic to penicillins	Clindamycin: 600 mg orally 1 hour before dental procedure
Patients *not* allergic to penicillins but unable to take oral medication	Cefazolin 1 g or Ampicillin 2 g intramuscularly or intravenously 1 hour before dental procedure
Patients allergic to penicillins and unable to take oral medications	Clindamycin 600 mg intravenously 1 hour before dental procedure (must be diluted and injected slowly)

See reference 2.

PREGNANCY

The aim of periodontal therapy for the pregnant patient is to minimize the potential exaggerated inflammatory response related to pregnancy-associated hormonal alterations. Meticulous plaque control, scaling, root planing, and polishing should be the only nonemergency periodontal procedures performed.

The second trimester is the safest time to perform treatment. However, long, stressful appointments and periodontal surgical procedures should be delayed until the postpartum period. As the uterus increases in size during the second and third trimesters, obstruction of the vena cava and aorta may occur if the patient is placed in a supine position. The reduction in return cardiac blood supply may cause supine hypotensive syndrome, with decreased placental perfusion.[65] Decreasing blood pressure, syncope, and loss of consciousness may occur. This can be prevented by placing the patient on her left side or simply by elevating the right hip 5 to 6 inches during treatment. Appointments should be short, and the patient should be allowed to change positions frequently. A fully reclined position should be avoided if possible.

Other precautions during pregnancy relate to the potential toxic or teratogenic effects of therapy on the fetus. Ideally, no medications should be prescribed. However, analgesics, antibiotics, local anesthetics, and other drugs may be required during pregnancy, depending on the patient's needs. All drugs should be reviewed for potential adverse effects on the fetus prior to prescribing.[15,65]

Use of dental radiographs during pregnancy should be

Abn, Abnormal; N, normal.

kept to a minimum, as they should for all patients. The small amount of radiation exposure during diagnostic dental radiography poses little, if any, risk to the fetus as long as the mother is properly shielded.[2,65] The American Dental Association has stated that "normal radiographic guidelines do not need to be altered because of pregnancy."[1] Use of a properly positioned lead apron is an absolute requirement (see also Chapter 37).

HEMORRHAGIC DISORDERS

Patients with a history of bleeding problems caused by disease or drugs should be managed so as to minimize risks of hemorrhage. Identification of these patients via the health history, clinical examination, and clinical laboratory tests is paramount. Health questioning should cover (1) history of bleeding after previous surgery or trauma, (2) past and present drug history, (3) history of bleeding problems among relatives, and (4) illnesses associated with potential bleeding problems.

Clinical examinations should detect the existence of jaundice, ecchymosis, spider telangiectasia, hemarthrosis, petechiae, hemorrhagic vesicles, spontaneous gingival bleeding, or gingival hyperplasia. Laboratory tests should include methods to measure the hemostatic, coagulation, or lytic phases of the clotting mechanism, depending on clues regarding which phase is involved (Table 38-8). These tests include bleeding time, tourniquet test, complete blood cell count, prothrombin time, partial thromboplastin time, and coagulation time. Bleeding disorders may be classified as coagulation disorders, thrombocytopenic purpuras, or nonthrombocytopenic purpuras.

Coagulation Disorders

The main inherited coagulation disorders include hemophiliac A and B and von Willebrand's disease (Table 38-9). Hemophilia A results in a deficiency of coagulation factor VIII, and the clinical severity of the disorder depends on the level of factor VIII remaining.[45] Severe hemophiliacs with less than 1% of normal factor VIII levels may have severe bleeding on the slightest provocation, whereas more moderate hemophiliacs (1% to 5% factor VIII) have less frequent spontaneous hemorrhage but still bleed with minimal trauma.[35] Mild hemophiliacs (6% to 30% factor VIII) rarely bleed spontaneously but may still have hemorrhage after severe trauma or during surgical procedures. The clinician should consult the patient's physician before dental treatment to determine the risk for bleeding and treatment modifications required. To pevent surgical hemorrhage, factor VIII levels of at least 30% are needed.[35,45] Parenteral 1-deamino-8-D-arginine vasopressin (DDAVP) can be used to raise factor VIII levels 2- to 3-fold in patients with mild or moderate hemophilia. DDAVP has the significant advantage of avoiding the risk of viral disease transmission from factor VIII infusion and is considered the drug of choice in responsive patients. Most moderate and severe hemophiliacs require infusion of **factor VIII concentrate** before surgical procedures. Before 1985 the risk of viral disease transmission from these infusions was high. In recent years, virally safe, highly purified monoclonal antibody or recombinant DNA factor VIII products have come into widespread use.

Hemophilia B, or Christmas disease, results in a deficiency of factor IX. The severity of the disorder depends on the relative amount of existing factor IX. Surgical therapy requires a factor IX level of 30% to 50% and is usually achieved by administration of purified prothrombin complex concentrates or factor IX concentrates.[45]

von Willebrand's disease results from a deficiency of von Willebrand factor, which mediates adhesion of platelets to the injured vessel wall and is required for primary hemostasis. von Willebrand factor also carries the coagulant portion of factor VIII in the plasma. The disorder

TABLE 38-9

Inherited Coagulation Disorders

Hemophilia Type	Prolonged	Normal	Treatment
A	Partial thromboplastin time	Prothrombin time Bleeding time	**DDAVP** Factor VIII concentrate or cryoprecipitate Fresh frozen plasma Fresh whole blood Epsilon-aminocaproic acid (EACA) Tranexamic acid
B	Partial thromboplastin time	Prothrombin time Bleeding time	Purified prothrombin complex concentrates Factor IX concentrates Fresh frozen plasma
von Willebrand's disease	Bleeding time Partial thromboplastin time Variable Factor VIII deficiency	Prothrombin time Platelet count	**DDAVP** Factor VIII concentrate or cryoprecipitate

has three major subtypes with a wide range of clinical severity. In fact, many cases of von Willebrand's disease go undiagnosed, and bleeding during dental treatment may be the first sign of the underlying disease. More severe forms require preoperative factor VIII concentrate or cryoprecipitate infusion. Milder forms respond favorably to administration of DDAVP before periodontal surgery or tooth extraction.[4-5,46] Periodontal treatment may be performed in patients with these coagulation disorders, provided that sufficient precautions are taken. Probing, scaling, and prophylaxis can usually be done without medical modification. More invasive treatment such as block local anesthesia, root planing, or surgery dictate prior physician consultation.

During treatment, local measures to ensure clot formation and stability are of major importance. Complete wound closure and application of pressure will reduce hemorrhage. Antihemostatic agents such as oxidized cellulose or purified bovine collagen may be placed over surgical sites or into extraction sockets. The antifibrinolytic agent epsilon-aminocaproic acid (EACA), given orally or intravenously, is a potent inhibitor of initial clot dissolution.[28] Tranexamic acid is a more potent antifibrinolytic agent than EACA and has been shown to prevent excessive oral hemorrhage after periodontal surgery and tooth extraction.[49] It is available in a mouthrinse form that may be used either alone or in combination with systemic tranexamic acid for several days after surgery.[61]

Not all coagulation disorders are hereditary. Liver disease may affect all phases of blood clotting because most coagulation factors are synthesized and removed by the liver. Long-term alcohol abusers or chronic hepatitis patients often demonstrate inadequate coagulation. Coagulation may be impaired by vitamin K deficiency, often caused by malabsorption syndromes, or by prolonged antibiotic administration, which alters the intestinal microflora that produces vitamin K. Dental treatment planning for patients with liver disease should include the following:

1. Physician consultation.
2. Laboratory evaluations: prothrombin time, bleeding time, platelet count, and partial thromboplastin time (in patients in later stages of liver disease).
3. Conservative, nonsurgical periodontal therapy, whenever possible.
4. If surgery is required (may require hospitalization):
   - INR (prothrombin time) should generally be <2.0. For simple surgical procedures, INR < 2.5 is generally safe.[27]
   - Platelet count should be >80,000/mm^3.

Perhaps the most common cause of abnormal coagulation is drug therapy. Patients with prosthetic heart valves or histories of myocardial infarction, stroke, or thromboembolism are frequently placed on anticoagulant therapy using coumarin derivatives such as dicumarol and warfarin.[27,32] These drugs are vitamin K antagonists that decrease production of vitamin K-dependent coagulation factors II, VII, IX, and X. The effectiveness of anticoagulation therapy is monitored via the prothrombin time. The recommended level of anticoagulation for most patients is an INR of 2.0 to 3.0, with prosthetic heart valve patients generally in the 2.5 to 3.5 range.[27] Periodontal treatment should be altered as follows:

1. Consult the patient's physician to determine the nature of the underlying medical problem and the degree of required anticoagulation.
2. The procedure to be done determines the acceptable INR. Infiltration anesthesia, scaling, and root planing may be done safely in patients with an INR <3.0. Block anesthesia, minor periodontal surgery, and simple extractions usually require an INR <2.0. Complex surgery or multiple extractions may require an INR <1.5.
3. The physician should be consulted about discontinuing or reducinganticoagulant dosage until the desired INR is achieved. Frequently, the anticoagulant is discontinued for 2 to 3 days before periodontal treatment (the clearance half-life of warfarin is 36 to 42 hours) and the INR is checked on the day of therapy. If the INR is within the acceptable target range, the procedure is done and the anticoagulant is resumed immediately after treatment.
4. Careful technique and complete wound closure are paramount. For all procedures, application of pressure can minimize hemorrhage. Use of oxidized cellulose, microfibrillar collagen, topical thrombin, and tranexamic acid should be considered for persistent bleeding.

Aspirin interferes with normal platelet aggregation and can result in prolonged bleeding. Because it binds irreversibly to platelets, the effects of aspirin last at least 4 to 7 days. It is generally used in small doses of 325 mg or less per day, which usually does not alter bleeding time. However, higher doses may increase bleeding time and predispose the patient to postoperative bleeding.[35] For patients taking more than 325 mg of aspirin per day, the aspirin should be discontinued at least 7 to 10 days before periodontal therapy in consultation with the physician. Nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen also inhibit platelet function. Because they bind reversibly, the effect is transitory, lasting only a short time after the last drug dose. The bleeding time is used when questions about the potential effect of aspirin or NSAIDs exist. Aspirin should not be prescribed for patients who are receiving anticoagulation therapy or have illnesses related to bleeding tendencies.

Heparin is generally used for short-term anticoagulation and is given intravenously (usually in a hospital environment). It is a powerful anticoagulant with a duration of action of 4 to 8 hours. Periodontal treatment is rarely required while a patient is taking heparin.

Thrombocytopenic Purpuras

Thrombocytopenia is defined as a platelet count <100,000/mm^3. Bleeding due to thrombocytopenia may be seen with idiopathic thrombocytopenic purpuras, radiation therapy, myelosuppressive drug therapy (e.g., chemotherapy), leukemia, or infections. Pupuras are hemorrhagic diseases characterized by extravasation of blood into the tissues under the skin or mucosa, producing spontaneous petechiae (small red patches) or ecchymoses (bruises).

Periodontal therapy for patients with thrombocytopenia should be directed toward reducing inflammation by removing local irritants to avoid the need for more aggressive therapy.[15,45] Oral hygiene instructions and frequent maintenance visits are paramount. Physician referral is indicated for a **definitive diagnosis and to determine any alterations** in planned therapy. Scaling and root planing is generally safe unless platelet counts are <60,000/mm^3. No surgical procedures should be performed unless the platelet count is >80,000/mm^3. Platelet transfusion may be required before surgery. Surgical technique should be as atraumatic as possible, and local hemostatic measures should be applied.

Nonthrombocytopenic Purpuras

Nonthrombocytopenic purpuras occur as a result of either vascular wall fragility or thrombasthenia (impaired platelet aggregation). The former may result from a multitude of causes: hypersensitivity reactions, scurvy, infections, chemicals (phenacetin and aspirin), dysproteinemia, and several others. Thrombasthenia occurs in uremia, Glanzmann's disease, aspirin ingestion, and von Willebrand's disease.[45] Both kinds of nonthrombocytopenic purpuras may result in immediate bleeding after gingival injury. Treatment consists primarily of direct pressure applied for at least 15 minutes. This initial pressure should control the bleeding unless coagulation times are abnormal or reinjury occurs. Surgical therapy should be avoided unless the qualitative and quantitative platelet problems are resolved.

BLOOD DYSCRASIAS

Numerous disorders of red and white blood cells may affect the course of periodontal therapy. Alterations in wound healing, bleeding, tissue appearance, and susceptibility to infection may occur. Clinicians should be aware of the clinical signs and symptoms of blood dyscrasias, availability of screening laboratory tests, and need for physician referral.

Leukemia

Altered periodontal treatment for patients with leukemia is based on such patients' enhanced susceptibility to infections, bleeding tendency, and the effects of chemotherapy.[35] The treatment plan for these patients is as follows:

1. Refer the patient for medical evaluation and treatment. Close cooperation with the physician is required.
2. Before chemotherapy, a complete periodontal treatment plan should be developed with a physician (see the section on treatment for patients receiving chemotherapy).
   - Monitor hematologic laboratory values daily: bleeding time, coagulation time, prothrombin time, and platelet count.
   - Administer antibiotic coverage before any periodontal treatment because infection is a major concern.
   - Extract all hopeless, nonmaintainable, or potentially infectious teeth at least 10 days before the initiation of chemotherapy, if systemic conditions allow.
   - Periodontal debridement (scaling and root planing) should be performed and thorough oral hygiene instructions given if the patient's condition allows. Twice-daily rinsing with 0.12% chlorhexidine gluconate is recommended after oral hygiene procedures. Recognize the potential for bleeding due to thrombocytopenia. Use pressure and topical hemostatic agents as indicated.
3. During the acute phases of leukemia, patients should receive only emergency periodontal care. Any source of potential infection must be eliminated to prevent systemic dissemination. Antibiotic therapy is frequently the treatment of choice, combined with nonsurgical or surgical debridement as indicated.
4. Oral ulcerations or mucositis are treated palliatively with agents such as viscous lidocaine. Systemic antibiotics may be indicated to prevent secondary infection.
5. Oral candidiasis is common in the leukemic patient and can be treated with nystatin suspensions (100,000 U/ml 4 times daily) or clotrimazole vaginal suppositories (10 mg 4 to 5 times daily).[39]
6. For patients with chronic leukemia and those in remission, scaling and root planing can be performed without complication but periodontal surgery should be avoided if possible.
   - Platelet count and bleeding time should be measured on the day of the procedure. If either is low, postpone the appointment and refer the patient to a physician.

Agranulocytosis

Patients with agranulocytosis (cyclic neutropenia and granulocytopenia) have an increased susceptibility to infection. The total white blood cell count is reduced, and granular leukocytes (neutrophils, eosinophils, and/or basophils) are reduced or disappear. These disorders are often marked by early, severe periodontal destruction.[70] When possible, periodontal treatment should be done during periods of disease remission. At such times, treatment should be as conservative as possible while reducing potential sources of systemic infection. After physician consultation, severely affected teeth should be extracted. Oral hygiene instruction should include use of chlorhexidine mouthrinses twice daily. Scaling and root planing should be performed carefully under antibiotic protection.

INFECTIOUS DISEASES

Because many infectious diseases are occult in nature, and because medical histories are often inaccurate or incomplete, all periodontal patients should be treated as though they have an infectious disease. Protection of patients, clinicians, and office staff requires use of universal (standard) precautions for each and every patient, maximizing prevention of infection and cross-contamination. This section provides a brief discussion of hepatitis,

human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), and tuberculosis in relation to the precautions required in periodontal therapy.

Hepatitis

To date, six distinct viruses causing viral hepatitis have been identified: hepatitis A, B, C, D, E, and G viruses.[12,23] These forms of viral hepatitis differ in their virology, epidemiology, and prophylaxis (Table 38-10). Because the majority of hepatitis infections are undiagnosed, the clinician must be aware of high-risk groups such as renal dialysis patients, health care workers, immunosuppressed patients, patients who have received multiple blood transfusions, homosexuals, drug users, and institutionalized patients.

Hepatitis A and E are both self-limiting infections with no associated chronic liver disease. These viruses are primarily transmitted via the fecal-oral route. HAV transmission in the U.S. usually occurs due to close personal household, sexual or daycare center contact. Conversely, HEV is transmitted mainly through fecally contaminated drinking water and is thus relatively uncommon in the U.S. Currently a vaccination is available to protect against HAV infection but not HEV infection.

Hepatitis B infection may result in chronic liver disease and a chronic carrier state. Chronic HBV infection develops in about 5% to 10% of infected individuals, with much higher rates among infants and children. Because it is transmitted primarily through a hematogenous route, HBV is a major concern for health care workers. Among health care workers, the highest rates of HBV infection are found among dentists and oral surgeons.[23] Percutaneous or permucosal injury with contaminated instruments or needles is the most common route of infection in the dental office. The hepatitis B vaccine is recommended for all health care workers.

Hepatitis D virus is a defective virus that requires the presence of HBV for its survival, replication, and infectivity. The HDV genetic material is packaged within the HBV surface antigen coating. Thus prevention of HDV infection is similar to prevention for HBV and relies strongly on HBV vaccination. Once antibody titers to HBV are elevated to a protective level, the patient is also protected against HDV infection.

Hepatitis C is probably the most serious of all viral hepatitis infections due to its high chronic infection rate. Only 15% of patients infected with HCV recover completely; 85% develop chronic HCV infection, which dramatically increases the risk for cirrhosis, hepatocellular carcinoma, and liver failure. In fact, HCV infection is the leading cause of liver transplantation in the U.S. Unfortunately, no vaccine is available for HCV. Because HCV is transmitted primarily via a percutaneous or permucosal route, health care workers are at risk from injury with contaminated instruments.

Hepatitis G is a newly discovered virus, and its epidemiology and virology are not clearly understood at this time. HGV rarely occurs as a solitary infection, usually appearing as a coinfection with hepatitis A, B, or C. HGV is known to be transmitted via the blood.

The following guidelines are offered for treating hepatitis patients:

1. If the disease, regardless of type, is active, do not provide periodontal therapy unless the situation is an emergency. In an emergency case, follow the protocol for HB$Ag (HBV surface antigen)-positive patients.
2. For patients with a past history of hepatitis, consult the physician to determine the type of hepatitis, course and length of the disease, mode of transmission, and any chronic liver disease or viral carrier state.
3. For recovered hepatitis A or E patients, perform routine periodontal care.
4. For recovered hepatitis B and D patients, consult with the physician and order HB$Ag and anti-HBs (antibody to HBV surface antigen) laboratory tests.
   - If HB$Ag and anti-HBs tests are negative but hepatitis B virus is suspected, order another HBs determination.
   - Patients who are HB$Ag positive are probably infective (chronic carriers); the degree of infectivity is measured via an HB$Ag determination.
   - Patients who are anti-HBs positive may be treated routinely (they have antibody to the HBs antigen).
   - Patients who are HB$Ag negative may be treated routinely.
5. For hepatitis C patients, consult with the physician to determine the patient's risk for transmissibility and current status of chronic liver disease.
6. If a patient with active hepatitis, positive HB$Ag (HBV carrier) status or positive HCV carrier status requires emergency treatment, use the following precautions:
   - Consult the patient's physician regarding status.
   - If bleeding is likely during or after treatment, measure prothrombin time and bleeding time. Hepatitis may alter coagulation; alter treatment accordingly.
   - All personnel in clinical contact with the patient should use full barrier technique, including masks, gloves, glasses or eye shields, and disposable gowns.
   - Use as many disposable covers as possible, covering light handles, drawer handles, and bracket trays. Headrest covers should also be used.
   - All disposable items (gauze, floss, saliva ejectors, masks, gowns, gloves, etc.) should be placed in one lined wastebasket. After treatment, these items and all disposable covers should be bagged, labeled, and disposed of, following proper guidelines for biohazardous waste.
   - Aseptic technique should be followed at all times. Minimize aerosol production by not using ultrasonic instrumentation, air syringe, or high-speed handpieces; remember that saliva contains a distillate of the virus. Prerinsing with chlorhexidine gluconate for 30 seconds is highly recommended.
   - When the procedure is completed, all equipment should be scrubbed and sterilized. If an item cannot be sterilized or disposed of, it should not be used.

If a percutaneous or permucosal injury occurs during dental treatment of a HBV carrier, current Centers for

TABLE 38-10

Comparison of Hepatitis Viruses

	A	B	C	D	E	G
Source	Feces	Blood and body fluids	Blood and body fluids	Blood and body fluids	Feces	Blood
Primary Modes of Transmission	Fecal-oral	Percutaneous/ permucosal; sexual	Percutaneous/ permucosal	Percutaneous/ permucosal (occurs only after previous infection with HBV or as a coinfection with HBV)	Fecal-oral	Percutaneous (usually occurs as coinfection with other hepatitis viruses)
Incubation Period	15-50 days	50-160 days	15-150 days	15-150 days	15-60 days	Unknown
Risk of Chronic Infection	No chronic infection	Varies with age: Adults 5% to 10%; children 25% to 50%; infants >85%	Very high (>85%)	5% when acquired as a coinfection with HBV; >70% when acquired as a second infection in a chronic HBV carrier	No chronic infection	Unknown whether chronic infection occurs
Protective Immunity after Infection?	Yes: anti-HAV antibody	Usually: antibody to core antigen, e-antigen and surface antigen are produced; anti-HB surface antigen antibody is most protective; chronic carrier state exists	No: anti-HCV antibody is produced but is usually not protective	Because HDV infection requires previous infection or coinfection with HBV, protective immmunity is similar to Hepatitis B	Unknown	Unknown
Vaccine Available?	Yes	Yes	No	Yes (HBV vaccine protects against HDV)	No	No

Disease Control and Prevention (CDCP) guidelines recommend administration of hepatitis B immune globulin (HBIG).[10] The HBV vaccine should also be administered if the injured individual has not previously received it. Unfortunately, postexposure prophylaxis with immune globulin or antiviral agents is generally ineffective if a percutaneous injury occurs during treatment of a hepatitis C carrier.[9, 12]

HIV and AIDS

Since the beginning of the AIDS epidemic, a wide range of oral lesions have been associated with HIV infection. These lesions are discussed in Chapters 29 and 51.

As with hepatitis, not all HIV-infected patients know that they are infected when they report for dental treatment. Furthermore, individuals with known HIV infection may not admit their status on the medical history. Therefore every patient receiving dental treatment should be managed as a potentially infected person, using universal precautions for all therapy.

Extensive periodontal treatment plans must be considered in light of their relationship to the patient's systemic health, prognosis, and survival time.[35] There are large variations in progression of HIV disease among individuals, and selection of an appropriate treatment plan depends on the state of the patient's overall health. Although there appear to be few contraindications to routine dental treatment for many HIV-infected patients, the periodontal treatment plan is influenced by the patient's overall systemic health and coincident oral infections or diseases. An awareness of oral disorders associated with HIV infection may allow the clinician to recognize previously undiagnosed disease or modify treatment protocols appropriately.

Tuberculosis

The patient with tuberculosis should receive emergency care only, following the guidelines listed in the section on hepatitis. If the patient has completed chemotherapy, his or her physician should be consulted regarding infectivity and the results of sputum cultures for *Mycobacterium tuberculosis.* When medical clearance has been given and the sputum culture results are negative, these patients may be treated normally. Any patient who gives a history of poor medical follow-up (e.g., lack of yearly chest radiographs) or shows signs or symptoms indicative of tuberculosis should be referred for evaluation. Adequate treatment of tuberculosis requires a minimum of 18 months, and thorough posttreatment follow-up should include chest radiographs, sputum cultures, and a review of the patient's symptoms by the physician at least every 12 months.

CONCLUSION

During the late 20th century, the proportion of older adults experienced significant growth with greater increases expected in the 21St century. Currently, almost 70% of older adults have natural teeth." The future trend will be more people with more teeth at risk for periodontal disease. Aging does not cause disease; however, age is associated with more disease. This association was addressed by Jim Beck at the 1996 World Workshop on Periodontics: "It may be that risk factors do change as people or at least the relative importance of risk factors change."

The focus of this chapter is to provide the reader with information on the interrelationship between aging and oral health, with emphasis on periodontal health.

DEMOGRAPHICS

Population Distributions

In 1990, 4% of the U.S. population, or 3.1 million people, were age 65 or older. By 1994, these numbers grew to 13%, or 33.2 million people. From 2001 to 2010, persons aged 65+ years will grow by 13%, aged 85+ years by 29%, and aged 100+ years by 65%. In the first half of the 21st century, the U.S. population is expected to increase by 42%. Fig. 39-1 shows that during the same time period, people aged 65+ years are expected to increase 126%, aged 85+ years by 316%, and centenarians (100+) 956%.[20]

The growth in the older population is the result of the dramatic increase in life expectancy during the past century. Average life expectancy was 47 years in 1900 and 75 years by 1990. In 2000, life expectancy (at birth) was projected to be 77 years. People who reached the age of 65 in 1990 had an average of 17 remaining years of life expectancy.[18,20]

Health Status

Despite the advances in modern medicine that have increased life expectancy, the number of older adults with acute and chronic diseases continues to increase.[20] Visual

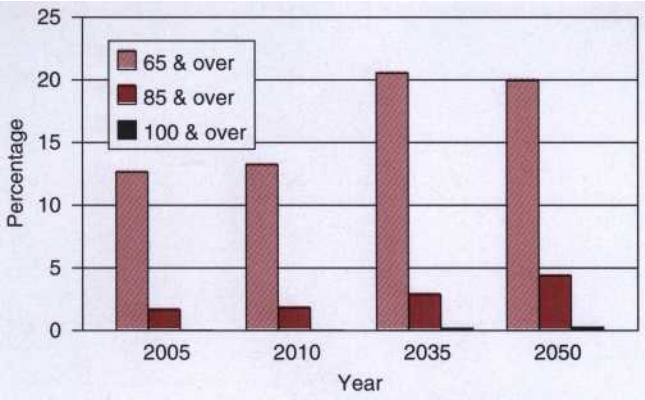

Fig. 39-1 Projected U.S. population trends for older adults. (From US Department of Commerce, Bureau of the Census: Report,]an 20, 1998. Available at *www.census.gov.)*

impairments, cataracts, glaucoma, and hearing impairments increase in frequency with advancing age.[21] Nearly half of people aged 65+ years have arthritis.[21] Most older adults have at least one chronic condition and many have several chronic conditions.' In 1994 the number of chronic conditions that occurred most often per 100 older persons were as follows: arthritis (50), hypertension (36), heart disease (32), hearing impairments (29), cataracts (17), orthopedic impairments (16), sinusitis (15), and diabetes (10).[2] Heart disease remains the leading cause of death among older adults. Approximately 7 in 10 deaths among older adults were caused by heart disease, cancer, or stroke.[2o]

The prevalence of sensory impairments and arthritis can have dramatic influences on the oral health of older adults. It is more difficult for older adults with hearing, visual, and dexterity limitations to effectively communicate oral health care needs and concerns and perform good oral hygiene.

Social and Psychologic Issues Affecting Dental Treatment

The education level of older adults is increasing. In 1995, only 64% of noninstitutional older adults completed at least high school and 13% possessed a bachelor's degree. By the year 2015, it is estimated that 76% of older adults will have completed at least high school, with 20% obtaining a bachelor's degree. Those with higher education tend to be better off financially than those with low education. Poverty is less prevalent today among older adults for all race, gender, and ethnic groups.[19,20] In general, older adults have the highest disposable income of all age groups and they spend more money on luxury items such as vacations and automobiles.[23] Higher educational achievement with lower poverty levels suggests an increase in demand for oral health care among older adults.[10]

TABLE 39-1

Percentage Dentate by Age and Gender, U.S., 1988-91

Age Group	All Persons	Gender	
		Male	Female
50-54	88	90	86
55-59	82	82	83
60-64	76	77	76
65-69	74	73	75
70-74	69	71	67
75+	56	53	58

See reference 14.

Dentate Status

Over the past several decades, the prevalence of tooth loss and edentulism has been declining in the U.S. Table 39-1 shows the most current estimates of tooth loss and retention in the U.S. These data indicate that 75% of adults aged 65 to 69 years are dentate and just over half of adults aged 75+ years are dentate.[14]

Periodontal Status

Recent data suggest that older adults who retain teeth are likely to be less susceptible to periodontitis.[6] Advanced periodontal disease among older adults is not as common as once thought.[6] Moderate levels of attachment loss are seen in a high proportion of older adults; however, severe loss is detected in only a small proportion of older adults.12 The amount of periodontal disease that is associated with age does not appear to be clinically significant, and it is unclear whether the higher prevalence of periodontal disease is a function of age or time.12 Figs. 39-2 to 39-4 illustrate periodontal disease data from Phase I of the Third National Health and Nutrition Examination Survey (NHANES III) conducted in the U.S. from 1988 to 1991.[5] Fig. 39-2 shows that gingival recession increases with advancing age, with one third (35%) of persons aged 55 to 84 years and less than half (46%) of persons aged 85+ years having 3 mm or more of gingival recession. Fig. 39-3 shows that pocket depth of 6 mm or greater was detected in 7% of persons aged 45 to 54 years, 8% of persons aged 55 to 64 years, and 7% of persons aged 65+ years. Attachment loss, which is displayed in Fig. 39-4, increases with age. Less than half of persons aged 65+ years had loss of attachment measuring 5 mm or greater.

The prevalence of periodontal disease increases with age and appears to be age associated.[4] Age increases the risk for periodontal destruction but is probably consistent with successful aging, not pathology.[12] Periodontal disease in older adults is probably not due to greater susceptibility but instead is the result of cumulative disease progression over time.[6]

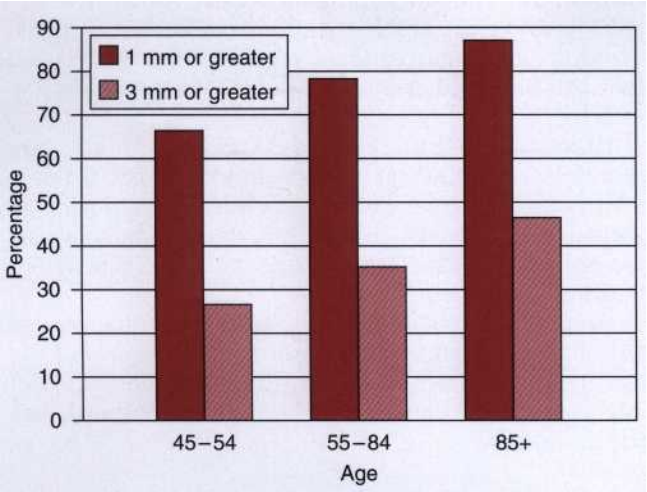

Fig. 39-2 Percentage of persons with gingival recession, 1988-91. (From Brown LJ, Brunelle JA, Kingman A: Periodontal status in the United States, 1988-1991: Prevalence, extent, and demographic variation. J Dent Res 1996; 75(Spec Iss):672.)

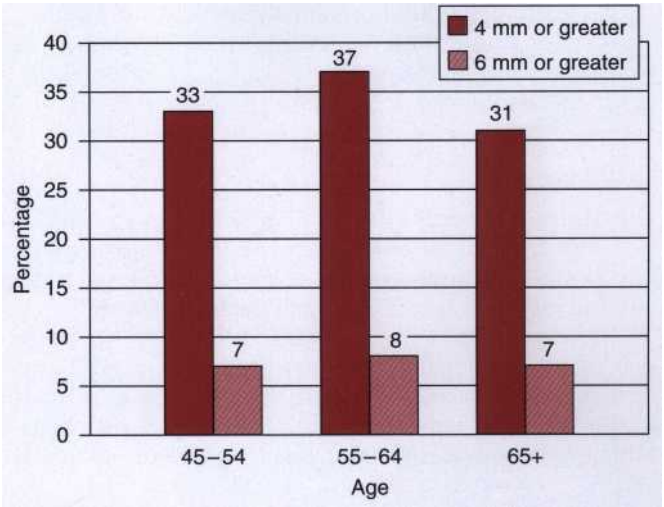

Fig. 39-3 Percentage of persons with pocket depths by age, 1988-91. (From Brown LJ, Brunelle JA, Kingman A: Periodontal status in the United States, 1988-1991: Prevalence, extent, and demographic variation. J Dent Res 1996; 75(Spec Iss):672.)

Caries Status

Root caries is a disease that is particular to older adults. Exposed root surfaces in combination with compromised health status and use of multiple medications make older adults at high risk for root caries. Caries examinations from the Phase I of NHANES III indicate that root caries prevalence increased greatly with age. Decayed or filled root surfaces were detected in 47% of persons aged 65 to 74 years and in 55.9% of persons 75+ years [27]

Dental Visits

Dental visits by older adults are correlated with having teeth, not age [23] Data from the 1995 Behavioral Risk Factor Surveillance System (BRFSS), which is a continuous state-based, random-digit-dialed telephone survey of the U.S. noninstitutional population aged 18+ years, indicate that older adults are frequent users of dental services. Of all persons responding to the oral health section, 69% reported having a dental visit in the past year. Among adults aged 65+ years, 62% reported having a dental visit during the previous year. However, 75% of adults aged 65+ years with natural teeth reported a dental visit in the past year.' Dental expenditure data indicate that older adults have a higher cost per visit than younger persons and are willing to make a significant investment in dental care [23]

Xerostomia

Saliva plays an essential role in maintaining oral health. Many older adults take medications for chronic medical conditions and disorders. More than 500 prescription and over-the-counter medications are associated with decreased saliva, dry mouth, and xerostomia. The medications most often associated with xerostomia and decreased saliva are the tricyclic antidepressants, antihistamines, antihypertensives, and diuretics. Medication use is frequently associated with dry mouth; however, certain medical diseases, disorders, or conditions such as radiation treatment for oral, head, neck, and thyroid cancers; Sjogren's syndrome; poorly controlled diabetes; bone marrow transplantation; thyroid disorders; and depression are also associated with dry mouth. [9]

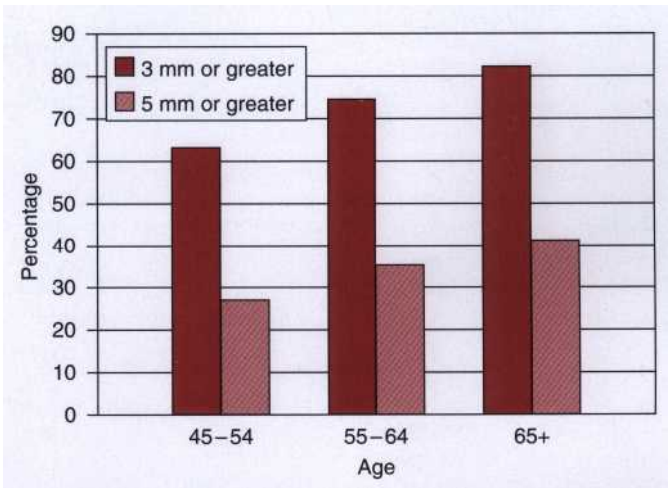

Fig. 39-4 Percentage with loss of attachment by age, 1988-91. (From Brown LJ, Brunelle JA, Kingman A: Periodontal status in the United States, 1988-1991: Prevalence, extent, and demographic variation. J Dent Res 1996; 75(Spec Iss):672.)

Medications that induce xerostomia may also be associated with compromised chewing, speaking, tasting, or swallowing and increased risk for caries, periodontal disease, and candidiasis.

Candidiasis

The overproliferation of *Candida albicans* and its infiltration into the oral mucosal layers results in a pathogenic infection. The causes can be both local and systemic, and the infection is collectively termed *candidiasis.11*

Any condition compromising a patient's immune system can be considered a risk factor for candidiasis. Oral candidiasis can occur with long-term use of medications such as antibiotics, steroid therapies, or chemotherapy. Diabetes mellitus, head and neck radiation therapy, and human immunodeficiency virus (HIV) are risk factors for acute pseudomembranous candida. Pseudomembranous candida presents as white lesions that can be wiped away with gauze, leaving an erythematous area."

Chronic atrophic candidiasis presents most commonly as an erythematous area under a maxillary denture and is associated with poor oral hygiene. In patients without a prosthesis, chronic atrophic candidiasis may present as a generalized redness or even generalized burning of the mouth."

Chronic atrophic candidiasis, or angular cheilitis, can also manifest itself in the creases or commissures of the lips. This occurs when a patient has a tendency to pool saliva around the corners of the mouth or constantly lick the lips in some cases.11

TABLE 39-2

Top 20 Drugs Prescribed in the U.S., 1998

Product	Drug Class
1. Premarin Tabs	Estrogen hormone
2. Synthroid	Thyroid hormone
3. Trimox	Antibiotic
4. Hydrocodone w/APAP	Combination narcotic analgesic
5. Prozac	Antidepressant/SSRI
6. Prilosec	Antisecretory compound/GI acid
7. Zithromax	Antibiotic
8. Lipitor	HMG-CoA reductase inhibitor
9. Norvasc	Calcium channel blocker
10. Claritin	H1-receptor antagonist/ antihistamine
11. Lanoxin	Cardiac glycoside
12. Zoloft	Antidepressant/SSRI
13. Albuterol Aerosol	β2-agonist bronchodilator
14. Paxil	Antidepressant/SSRI
15. Amoxicillin	Antibiotic
16. Prempro	Estrogen and progestin combination
17. Zestril	ACE inhibitor
18. Vasotec	ACE inhibitor
19. Augmentin	Antibiotic
20. Cephalexin	Antibiotic

DENTAL AND MEDICAL ASSESSMENTS

Review of Dental History

At the very least, the review should include past restorative, periodontal, and other dental treatment; head and neck cancer and its treatment; allergies, oral hygiene care techniques; tobacco and alcohol use; and any difficulties or problems associated with dental treatment. In addition, the dental history should review past injuries, the individual's perception of past and future dental treatment outcomes, the fluoride status of the drinking water (bottled, well, community), and the type of toothpaste used (fluoride versus nonfluoride).

Review of Medical History

The medical history should be detailed and include a careful review of past and current medical and mental conditions including allergies and invasive procedures. The review should focus on a careful evaluation of systemic diseases and disorders, particularly those that influence dental treatment such as bleeding disorders and use of anticoagulants, diabetes, heart valve problems, certain cardiovascular conditions, stroke, artificial joints, and use of corticosteroids. A consultation with the individual's physician is advisable, especially for individuals with medical problems or if complicated or invasive procedures are planned. Although obtaining a complete medical history may take longer with older adults, the dialogue between the dentist and the patient often yields valuable medical, psychologic, and dental treatment information.

Review of Medication Use

Older adults are high users of prescription and over-the-counter medications. Table 39-2 lists the top 20 drugs prescribed in the U.S. in 1998. Many medications used by older adults can have a negative impact on oral health. To obtain a complete list of prescription and over-the-counter medications, ask patients to bring each medication bottle or package to the dental office. This helps not only obtain a complete medication list but

also provides additional information such as medication dose and number of physicians prescribing medications.

Assessment of Risk

The American Society of Anesthesiologists established a useful tool to predict risk of surgical mortality.[3,16] The tool (Box 39-1) stratifies patients into five categories, adjusts for age by not allowing an older adult to be assigned into Class I, and has been validated for patients aged 80+ years. This classification system was originally designed to assess surgical risk under general anesthesia; however, it is also currently used to assess risk before diagnostic testing and outpatient surgery. Dentists can use this tool for patient assessment before invasive periodontal procedures.[16]

In addition to assessing medical risk, the dentist should evaluate the risk factors that influence the progression of periodontal disease. The prognostic risk factors that influence periodontal therapy are smoking, genetic susceptibility, compliance, and diabetes.25

Intraoral and Extraoral Examination

In addition to assessing past dental treatment, tooth loss, restorations, past dental interventions, dental caries, and periodontal status, the comprehensive dental examination should include a complete head and neck examination of soft tissues. Oral and pharyngeal cancer is an age-related oral disease with serious consequences.

Skin of the face and neck should be inspected and palpated for lesions, enlarged lymph nodes, or both. Intraorally, the lips, cheeks, tongue, gingiva, floor of mouth, palate, retromolar trigon, and oropharynx should be inspected and palpated to detect soft tissue abnormalities, particularly red or white patches, ulcerations, or swellings.

The risk for oral and pharyngeal cancer increases with age, tobacco use, frequent use of alcohol, and exposure to sunlight (lip). Oral cancer is treatable if discovered and treated early. Oral and pharyngeal cancer detected at later stages can cause disfigurement, loss of function, decreased quality of life, and death. Surveillance, Epidemiology, and End Results (SEER) data indicate that more than 50% of tongue and floor of mouth cancers had metastasized to a distant site at time of diagnosis.[17] In addition, over the last 25 years, the 5-year survival rate of oral cancer has not improved." Oral and pharyngeal cancer lesions may not be painful. Oral cancer may appear as an ulceration, a swelling, or a red or white sore that does not heal within 1 to 2 weeks. Other signs of oral cancer may be swollen lymph nodes and difficulty swallowing and speaking.$

PERIODONTAL DISEASES IN OLDER ADULTS

Etiology

The relationship between age and periodontal disease is age associated and not a consequence of aging.' Periodontal disease in older adults is commonly referred to as *chronic periodontitis.*[11,16] Because periodontitis is a chronic disease, much of the ravages of the disease detected in older adults results from an accumulation of the disease over time. Research has shown that the advanced stages of periodontitis are less prevalent than the moderate stages in the older-adult population.[5,11,16] One theory is that many sites of advanced periodontal disease have resulted in tooth loss earlier in life, suggesting that older age is not a risk factor for periodontal disease.[11,16]

Little evidence is available as to whether the risk factors for periodontal disease differ with age.' General health status, immune status, diabetes, nutrition, smoking, genetics, medications, mental health status, salivary flow, functional deficits, or finances may possibly modify the relationship between periodontal disease and age.4,25

Some medications that are frequently prescribed to older adults can alter the gingival tissues. Steroid-induced gingivitis has been associated with postmenopausal women on steroid therapy. Gingival overgrowth can be induced by certain medications such as cyclosporines, calcium channel blockers, and anticonvulsants (e.g., nifedipine or phenytoin) in the presence of poor oral hygiene. This gingival overgrowth further decreases a person's ability to maintain good oral hygiene."

Relationship to Systemic Disease

A recent review of the literature conducted by Loesche indicates poor oral health has been associated with medical conditions such as aspiration pneumonia and cardiovascular disease. In particular, periodontal disease can be associated with coronary heart disease and cerebrovascular accidents.[13] In addition, the Surgeon General's Report on Oral Health emphasizes that animal and population-based studies demonstrate an association between periodontal disease and diabetes, cardiovascular disease, and stroke.22

PERIODONTAL TREATMENT PLANNING

Generally, periodontal disease in older adults is not a rapidly progressive disease but often presents as long-standing chronic disease. Because periodontal disease

BOX 39-1

American Society of Anesthesiologists (ASA) Classification of Physical Status

1. A normal healthy patient.
2. A patient with mild systemic disease.
3. A patient with severe systemic disease that limits activity but is not incapacitating.
4. A patient with an incapacitating systemic disease that is a constant threat to life.
5. A moribund patient not expected to survive 24 hours with or without operation.

See reference 3.

has periods of exacerbation and remission, understanding and documenting periods of active disease versus quiescent periods is essential to the formulation of the treatment plan and prognosis.[16]

Periodontal disease must be diagnosed regardless of age. The goal of periodontal treatment for both young and old patients is to preserve function and eliminate or prevent the progression of inflammatory disease.24 Several factors must be considered during treatment planning for older individuals.[16] Periodontal healing and recurrence of disease are not influenced by age.' Factors to consider are medical and mental health status, medications, functional status, and lifestyle behaviors that influence periodontal treatment, outcome, or progression of disease.24 Periodontal disease severity, medical and mental status, medications, function, ability to perform oral hygiene procedures, and the individual's ability to tolerate treatment should be evaluated and considered during treatment planning.[16] The risks and benefits of both surgical and nonsurgical therapy should be considered.[16] Also important is the amount of remaining periodontal support or past periodontal destruction, tooth type, number of occlusal contacts, and individual patient preferences.24 Dental implants are a reliable replacement for missing teeth in older adults.26 Age alone is not a contraindication for implant placement.

For older adults, a nonsurgical approach is often the first treatment choice.24 Depending on the nature and extent of periodontal disease, surgical therapy may be indicated.[16,24] Surgical technique should minimize the amount of additional root exposure.[24] Individuals responding best to surgical therapy are those who are able to maintain the surgical result.[16] Age alone is not a contraindication to surgery.[16] For individuals who are not able to comply with treatment, have poor oral hygiene, or are medically or mentally compromised or functionally impaired, palliative supportive periodontal care instead of surgical periodontal treatment is often the optimal treatment approach.[24]

A common goal for all older adults is to decrease bacteria through oral hygiene and mechanical debridement. Clinical trials involving older adults show that the development or progression of periodontal disease can be prevented or arrested by the control of plaque. For certain patients, topical antibiotic therapy may complement repeated subgingival instrumentation during supportive care. Oral hygiene maintenance should also focus on root surfaces susceptible to caries.[24]

PREVENTION OF PERIODONTAL DISEASE AND MAINTENANCE OF PERIODONTAL HEALTH IN OLDER ADULTS

For both younger and older persons, the most important factor determining a successful outcome of periodontal treatment is plaque control and frequency of professional care.24 Advanced age does not decrease plaque control; however, older adults may have difficulty performing adequate oral hygiene because of compromised health, mental status, medications, and altered mobility and dexterity.24 Older adults may change toothbrush habits due to disabilities such as hemiplegia secondary to CVA, visual difficulties, dementia, and arthritis. The newer, lightweight, electric-powered toothbrushes may be more beneficial than a manual toothbrush for older adults with physical and sensory limitations. The proportion of people who report flossing decreases with age >40 years.[23] This may be partly due to impairment of fine motor skills secondary to disease or injury. Interproximal brushes, shaped wooden toothpicks, or mechanical flossing devices often can be used in place of traditional flossing with satisfactory outcomes.

Chemotherapeutic Agents

Antiplaque Agents

Patients who are unable to adequately remove plaque secondary to disease or disability may benefit from antiplaque agents such as chlorhexidine and Listerine or its generic counterparts.[16,23]

Chlorhexidine is a cationic bisbiguanide that has been used as a broad-spectrum antiseptic in medicine since the 1950s. In Europe, a 0.2% concentration of chlorhexidine has been used for years as a preventive and therapeutic agent.[16,23] Chlorhexidine binding to oral structures results in substantivity. It is either bacteriostatic or bactericidal depending on the dose. Some adverse effects of chlorhexidine include an increase in calculus formation, staining of teeth, dysgeusia (altered taste), and permanent staining of teeth.' Chlorhexidine is a prescription rinse for short-term use (<6 months); long-term use (>6 months) has not been extensively studied.[23] The American Dental Association (ADA) Council on Dental Therapeutics has approved chlorhexidine to help prevent and reduce supragingival plaque and gingivitis.[1,23] Although chlorhexidine has not been studied in older adults, outcomes in younger persons, including those with disabilities, suggest that it is also effective in older adults. Chlorhexidine may be particularly useful for older adults who have difficulty with plaque removal and those who take phenytoin, calcium channel blockers, and cyclosporins and are at risk for gingival hyperplasia.[16,23]

Listerine antiseptic and its generic counterparts are approved by the ADA Council on Dental Therapeutics to help prevent and reduce supragingival plaque and gingivitis.[16,23] The active ingredients in Listerine are methyl salicylate and three essential oils (eucalyptol, thymol, and menthol).[1,23] Listerine has been shown to be effective in reducing plaque and gingivitis when compared with placebo rinses in young healthy adults. Listerine, which is high in alcohol (ranging from 21.6% to 26.9%), may exacerbate xerostomia and is generally contraindicated in patients under treatment for alcoholism who take Antabuse (disulfiram). Listerine may benefit patients who do not tolerate the taste or staining of chlorhexidine, is sold over the counter, and is less expensive and easier to obtain than chlorhexidine.[16,23]

Fluoride. Fluoride, nature's cavity fighter, is the most effective caries preventive agent currently available. Fluoride's effects are to (1) reduce enamel solubility; (2) promote remineralization of early carious lesions; (3) bactericidally affect metabolic process of bacterial plaque.[16,23]

Topical fluorides are recommended for the prevention and treatment of dental caries. Over-the-counter fluorides include fluoride dentifrices, rinses, and gels that contain concentrations of 230 to 1500 PPM fluoride ions. Prescription 1.1% neutral sodium fluoride gels are available with a fluoride concentration of 5000 PPM fluoride ion. Professionally applied fluoride gel, foam, or varnish products are between 9050 and 22,600 PPM fluoride ion.'

Saliva Substitutes. Saliva substitutes, which are intended to match the chemical and physical traits of saliva, are available to relieve the symptoms of dry mouth. Their composition is varied; however, they usually contain salt ions, a flavoring agent, paraben (preservative), cellulose derivative or animal mucins, and fluoride. The ADA's seal of approval has been granted for some artificial saliva products such as Saliva **Substitute and Salivart.1 Most saliva substitutes can be used ad** libitum by patients and are dispensed in spray bottle, rinse/swish bottle, or oral swabstick.1,23 In addition, products such as dry mouth toothpastes and moisturizing gels are also available.

Patients with dry mouth may also benefit by stimulating saliva flow with sugarless candies and sugarless gum. Xylitol chewing gum has been shown to have anticariogenic properties in children. Although no studies have confirmed the effectiveness of xylitol gum in preventing caries in adults, patients with high root caries prevalence and xerostomia may benefit from chewing xylitol gum."

CONCLUSION

Future oral health care trends will see increased numbers of older adults seeking periodontal therapy. Dental practitioners of the 21St century should be comfortable providing comprehensive periodontal care for this segment of the population. Aging dental patients have particular oral and general health conditions that dentists should be familiar with detecting, consulting, and treating. Medical diseases and conditions that occur more often with age may require modification to periodontal preventive tools as well as the planning and treatment phases of periodontal care.

Treatment of Refractory Periodontitis, Aggressive Periodontitis, Necrotizing Ulcerative Periodontitis, and Periodontitis Associated with Systemic Diseases

CHAPTER

Richard J. Nagy and Michael G. Newman

CHAPTER OUTLINE

DIAGNOSIS OF REFRACTORY PERIODONTITIS
TREATMENT MODALITIES
Refractory Periodontitis
Aggressive Periodontitis
Generalized Aggressive Periodontitis
Necrotizing Ulcerative Periodontitis
Periodontitis Associated with Systemic Disease
TREATMENT ALGORITHM
MAINTENANCE

The majority of patients with the commonly encountered forms of chronic periodontitis usually respond well to conventional therapies. Typically, these include nonsurgical debridement and possibly surgery in some patients, followed by adequate long-term maintenance. However, some patients (as many as 17%) with atypical and less frequently encountered types of periodontitis do not respond to these conventional treatment approaches. The major classifications of these atypical forms of periodontitis are refractory, aggressive, necrotizing ulcerative, and periodontitis associated with systemic diseases.13,23

The treatment of all of these types of periodontitis is complex and often requires the use of the most intensive and comprehensive therapeutic modalities. Because these patients do not respond "normally" to conventional methods, the logical question is whether there are problems associated with their host response systems. Although there have been many attempts to clarify the immunologic profile of these patients, there have been no major or definitive breakthroughs important for improving the outcomes of therapy. The best treatment for these patients appears to be the combination of a thorough root debridement with or without surgical access, antimicrobial therapy and a closely monitored supportive periodontal therapy maintenance program. Bacterial identification appears to be of value for treatment in these patients, because the information can be used to determine the antibiotic susceptibility of suspected pathogens. Similarly, other bacterial tests have been used to monitor the microflora that recolonize after treatment.

DIAGNOSIS OF REFRACTORY PERIODONTITIS

Although refractory periodontitis is not a currently accepted diagnosis (see Chapter 4), many patients fail to respond to conventional therapy, and their management will be discussed. A diagnosis of refractory periodontitis requires the gathering of baseline data and a subsequent evaluation. This is the major way in which the clinician can determine the normality of the patient's response to treatment (see Chapter 27). A few individuals may appear for the first time with unusually severe forms of periodontal destruction for their age. In these cases the initial diagnosis is not refractory periodontitis, but one of the other aggressive diseases discussed later in this chapter.

A patient with refractory periodontitis often does not have any distinguishing clinical characteristics on initial examination compared with other types of periodontitis. Therefore the initial treatment would follow conventional therapeutic modalities for chronic periodontitis.

After treatment, the differential diagnosis of refractory periodontitis should exclude the following:

Improperly treated periodontitis. Most forms of periodontitis can be treated effectively with currently available modalities if such modalities are performed properly. If, during a posttreatment examination, it is determined that the patient has not adequately responded to treatment, it must be determined whether the therapy was correctly implemented. The only way to rule out inadequately treated periodontitis is to perform the most thorough treatment available. Treatment to eradicate or control all etiologic factors and use of the most advanced techniques is essential.

2. *Periodontitis associated with poor plaque control by the patient.* Because plaque control is a prerequisite for the success of periodontal treatments,[27,34,35] special attention should be paid to the careful evaluation of plaque control before deciding on classifying a case as refractory periodontitis. Truly refractory periodontitis presupposes a type of periodontal disease that is far more nonresponsive or tenacious than the usual cases. A patient who does not comply with adequate oral hygiene procedures may also be viewed by many clinicians as a failure of the dental professional to adequately motivate, educate, and control the patient. If considered from this perspective, these cases should be included in the "improperly treated periodontitis" category.
3. *Endodontic lesions.* The presence of endodontic involvement should be suspected and ruled out before a diagnosis of refractory periodontitis is made. The clinician should suspect an endodontic etiology especially in those patients with localized recurrent disease.

A true case of refractory periodontitis can be diagnosed if loss of attachment has occurred after well-executed treatment and plaque removal has been performed by both the clinician and the patient and all etiologic agents have been controlled.

TREATMENT MODALITIES

Refractory Periodontitis

Estimates of prognosis and treatment predictability must be based on the evidence available from the literature and the clinician's own experience.25 The first step in the treatment of refractory periodontitis with antimicrobial therapy must be microbial diagnostic and susceptibility tests. These microbiologic tests include culture analysis, microscopic assessment, nucleic acid probe analysis, restriction endonuclease analysis, detection of bacterial antigens and enzymes, and analysis using polymerase chain reaction. The results of these tests provide information about the presence and relative percentages of suspected periodontal pathogens and, more importantly, determine the organism's sensitivity to specific antimicrobials. This information enables the clinician to make the most informed and appropriate decision about antibiotic selection.

A combination of thorough root debridement and systemic antibiotic treatment can reduce bleeding on probing, suppuration, pocket depth, and incidence of active lesions and can suppress or eliminate periodontal pathogens in patients who present with refractory periodontitis. Mechanical debridement with scaling and root planing can reduce total supra- and subgingival bacterial masses, but major pathogens such as *Actinobacillus actinomycetemcomitans* may escape the effect of treatment due to their ability to invade periodontal tissues or to reside in furcations or other tooth structures outside the reach of hand instruments or due to poor host defense mechanisms. Surgical treatment may also eliminate the marginal tissues that might be invaded by bacteria." In addition, the morphology of the gingival tissues should be modified to facilitate daily plaque removal by the patient.

Systemic antibiotic therapy aims to reinforce mechanical periodontal treatment and support the host defense system in overcoming the infection by killing subgingival pathogens that remain after conventional mechanical periodontal therapy. Antibiotic therapy in the treatment of refractory periodontitis is based on the results obtained from microbial diagnostic tests. Many antibiotics have been used according to the target microflora (Table 40-1) with various degrees of success.[12] For refractory periodontitis patients who fail to respond to initial antibiotic therapy, subsequent treatment should include antimicrobial susceptibility testing of the remaining flora, which is accomplished through culturing only.

Patients diagnosed as having refractory periodontitis often present with a history of tetracycline therapy and microflora that is relatively resistant to this drug, owing

TABLE 40-1

Antibiotic Therapy in the Treatment of Refractory or Rapidly Progressive Periodontitis

Associated Microflora	Antibiotic of Choice
Gram-positive organisms	Amoxicillin-clavulanate potassium (Augmentin)[6,44]
Gram-negative organisms	Clindamycin11,12.43,44
Nonoral gram-negative facultative rods	Ciprofloxacin"
Pseudomonads, staphylococci	
Black-pigmented bacteria and spirochetes	Metronidazole",[39]
Prevotella intermedia, Porphyromonas gingivalis	Tetracycline[31]
A. actinomycetemcomitam	Metronidazole/ amoxicillin"•[19]
	Metronidazole/Ciprof loxacin
	Tetracycline[20,28]
P. gingivalis	Azithromycin[29]

to the frequent use of this antibiotic. [16,24,42,44] Tetracycline-resistant bacteria containing the Tet m gene for resistance have been isolated from patients with refractory periodontitis.[28] However, some patients with refractory periodontitis may still benefit from the use of tetracycline or one of its derivatives.

Cases of refractory periodontitis in which the associated microflora consists primarily of gram-positive microorganisms have been successfully treated with amoxicillin-clavulanate potassium. Many efforts have been made to establish the most appropriate regimen of antibiotic therapy for these patients. Similar antimicrobials, consisting of 250 mg amoxicillin and 125 mg potassium clavulanate, have been administered three times daily for 14 days along with scaling and root planing and produced a reduction in attachment loss for at least 12 months. A regimen of one capsule containing the same amount of drug every 6 hours for 2 weeks, with intrasulcular full-mouth lavage with a 10% povidone-iodine solution and chlorhexidine mouthwash rinses twice daily, showed a reduction in attachment loss that persisted at approximately 34 months .[6] A regimen of 500 mg metronidazole three times daily for 7 days was shown to be effective in treating refractory periodontitis in patients who were culture positive for *Bacteroides forsythus* in the absence of A. *actinomycetemcomitans.*[45]

Clindamycin is a potent antibiotic that penetrates well into gingival fluid, although it is not usually effective against A. *actinomycetemcomitans* and *Eikenella corrodens.*[41] However, it has been demonstrated to be effective in controlling the extent and rate of disease progression in refractory cases in patients who have a microflora susceptible to this antibiotic.' [1,22,43] A regimen of clindamycin hydrochloride 150 mg four times daily for 7 days combined with scaling and root planing produced a decrease in the incidence of disease activity from an annual rate of 8% to 0.5% of sites per patient." Clindamycin should be prescribed with caution due to the potential for pseudomembranous colitis from superinfections with *Clostridium di fficile.* Azithromycin may be effective in refractory periodontitis in patients infected with *Porphyromonas* gingivalis.[29]

Combinations of antibiotic therapy may offer greater promise as adjunctive treatment for the management of refractory periodontitis.[1,7,24] The rationale is based on the diversity of putative pathogens [10,39] and the fact that no single antibiotic is bactericidal for all known pathogens. Combination antibiotic therapy may help broaden the antimicrobial range of the therapeutic regimen beyond that attained by any single antibiotic. Other advantages include lowering the dose of individual antibiotics by exploiting possible synergy between two drugs against targeted organisms. In addition, combination therapy may prevent or forestall the emergence of bacterial resistance.

Many combinations of antibiotics (e.g., metronidazole [Augmentin] [717] or metronidazole/amoxicillin for the treatment of A. actinomycetemcomitans-associated periodontitis; metronidazole/doxycycline for the prevention of recurrent periodontitis; metronidazole/ciprofloxacin[32] for the treatment of recurrent cases containing a microflora associated with enteric rods and pseudomonads; and amoxicillin/doxycycline[24] in the treatment of A. *actinomycetemcomitans*- and/or *Porphyromonas* gingivalis-associated periodontitis) have demonstrated significant improvement in the clinical aspects of the disease.[24]

Some cases of refractory periodontitis may not respond to a given antibiotic regimen. When this occurs, the clinician should consider a different antimicrobial therapy based on microbial susceptibility analysis. At this point in the therapy, strong consideration should be given to consulting with the patient's physician for an evaluation of a possible host immune system deficiency or a metabolic problem such as diabetes.

Although there have been no studies of the treatment of refractory periodontitis with local delivery systems, it is possible that this method could be used in localized forms of this disease, particularly localized aggressive periodontal diseases. The advantage of local therapy is that smaller dosages of topical chemotherapy can be delivered inside the pocket, avoiding the side effects of systemic antibacterial agents. These local therapies are in the forms of gels, fibers, or chips. *'All*

Another approach for treating refractory periodontitis and other forms of periodontal disease is through modulation of the host response by subantimicrobial or nonsteroidal antiinflammatory drugs (NSAIDs) in conjunction with conventional therapy. The use of low-dose doxycycline may aid in preventing the destruction of the periodontal attachment through controlling the activation of matrix metalloproteinases, primarily collagenase and gelatinase, from both infiltrating and resident cells of the periodontium, primarily the neutrophils.[38] Other agents such as flurbiprofen, indomethacin, and naproxen may reduce inflammatory mediator production during chronic periodontal disease." Further research needs to be done to substantiate the effects of these agents.

The approach to restorative treatment for these patients should be made based on one single premise: Plan *for* future tooth loss. The teeth with the best prognosis should be identified and considered when planning the restorative work. However, the predictive value of the traditional prognosis categorization can be as low as 43% in patients with refractory periodontitis.[13] The lower cuspids and first premolars are generally more resistant to loss. As a rule, an extensive fixed prosthesis should be avoided, and removable partial dentures should be planned in such a way as to allow for the addition of teeth. The use of dental implants should be considered with great caution, especially in partially edentulous patients.

Although a cause-and-effect relationship has not yet been established between periodontitis and peri-implantitis, a relationship between the microflora associated with periodontal and peri-implant pockets, has been described.[20.31,33] The combination of implants and periodontally diseased teeth may be possible, but the risks involved should be clearly explained to the patient and avoided until the patient's disease is stabilized.

Aggressive Periodontitis

The prognosis for patients with aggressive periodontitis (formerly early onset periodontitis) depends on whether

the disease is generalized or localized and on the degree of destruction present at the time of examination. The generalized forms, which are usually associated with some systemic disease (see Chapter 28), have a worse prognosis than the localized forms. Aggressive periodontitis rarely undergoes spontaneous remission. It is important to obtain earlier radiographs to assess the stage of the disease.

The following treatments for localized aggressive periodontitis have been attempted in the past, with various degrees of success:

1. *Extraction.* After the involved teeth, usually the first molars, have been extracted, uneventful healing ensues. The enlargement of the maxillary sinus has been mentioned as an unfavorable sequela that would make future treatment of neighboring teeth difficult.' Transplantation of developing third molars to the sockets of previously extracted first molars has also been attempted.
2. *Standard periodontal therapy.* Such therapy has included scaling and root planing, curettage, flap surgery with and without bone grafts, root amputations, hemisections, occlusal adjustment, and strict plaque control.[3,37] However, response has been unpredictable. Frequent maintenance visits appear to be most important.[19,40]
3. *Antibiotic therapy.* In the late 1970' and early 1980s, the identification of *A. actinomycetemcomitans* as a major culprit and the discovery that this organism penetrates the tissues clarified the pathogenesis and provided a more solid basis for therapy.[5] Several authors have reported success using antibiotics as adjuncts to standard therapy. Genco and colleagues'° reported the treatment of localized aggressive periodontitis with scaling and root planing plus tetracycline (250 mg four times daily for 14 days every 8 weeks). Measurements of vertical defects were made at intervals of up to 18 months after the initiation of therapy. Bone loss had stopped, and one third of the defects demonstrated an increase in bone level, whereas in the control group, bone loss continued.

Liljenberg and Lindhe[18] treated patients with localized aggressive periodontitis with tetracycline (250 mg four times daily for 2 weeks), modified Widman flaps, and periodic recall visits (one visit every month for 6 months, then one visit every 3 months). The lesions healed more rapidly and more completely than similar lesions in patients with chronic periodontitis. These investigators reevaluated their results after 5 years and found that the treatment had resulted in resolution of gingival inflammation, gain of clinical attachment, and refill of bone in angular defects.[19]

Several investigators have noted excellent bone fill in cases of localized aggressive periodontitis treated with tetracycline plus flap surgery and placement of grafts.[21,46] Figs. 40-1 and 40-2 show pretreatment destruction and bone repair in a patient treated by Barnett and Baker.[4]

The lack of response of juvenile periodontitis to local therapy alone has been interpreted as the result of the presence of *A. actinomycetemcomitans* in the tissues,[5,36] where it remains after therapy to reinfect the pocket. The systemic use of antibiotics is needed to eliminate bacteria from the tissues."

Current Approach to Therapy. Patients who are diagnosed as having an early form of aggressive periodontitis may respond to standard periodontal therapy. In general, the earlier the disease is diagnosed (as determined by less destruction), the more conservative the therapy may be and the more predictable the outcome.

In almost all cases, systemic tetracycline (250 mg of tetracycline hydrochloride four times daily for at least 1 week) should be given in conjunction with local mechanical therapy. If surgery is indicated, systemic tetracycline should be prescribed, with the patient instructed to begin taking the antibiotic approximately 1 hour before surgery. Doxycycline 100 mg/day may also be used. Chlorhexidine rinses should also be prescribed and continued for several weeks to aid healing and augment plaque control.

In refractory localized aggressive periodontitis cases, tetracycline-resistant *Actinobacillus* species have been suspected. After performing antibiotic susceptibility tests, the clinician may consider a combination of amoxicillin and metronidazole, similar to the regimen suggested for refractory periodontitis patients.[1,30,39]

Generalized Aggressive Periodontitis

In general the treatment of patients with generalized forms of aggressive periodontitis should be very similar to that of patients with refractory forms of the disease. To date, there are no available data that suggest any alterations in the approach used for refractory forms of the disease.

The rate of disease progression may be faster in these younger individuals, and therefore the clinician should monitor such patients more often. Close collaboration between members of the treatment team, which includes the periodontist, the general dentist, the dental hygienist, and the patient's physician, is required.

It is important to monitor and observe the patient's overall physical status, as weight loss, mental depression, and malaise have been reported in patients with generalized aggressive periodontitis. Similarly, flare-ups of proliferative gingival inflammation can be observed early when the patient is on a frequent monitoring cycle. Currently, monitoring every 3 weeks or less is suggested while the disease is in an active phase.

Necrotizing Ulcerative Periodontitis

Patients with necrotizing ulcerative periodontitis (NUP) are unusual and should be treated in consultation with the physician. As indicated in Chapter 27, these patients often have an underlying predisposing systemic factor that renders the patient susceptible to necrosis of the periodontal structures. It is mandatory that these patients be treated aggressively. This includes a medical evaluation and local, topical, and systemic antimicrobials based on the results of laboratory tests.

These patients often harbor bacteria, fungi, viruses, and other non-oral microorganisms, making the selection

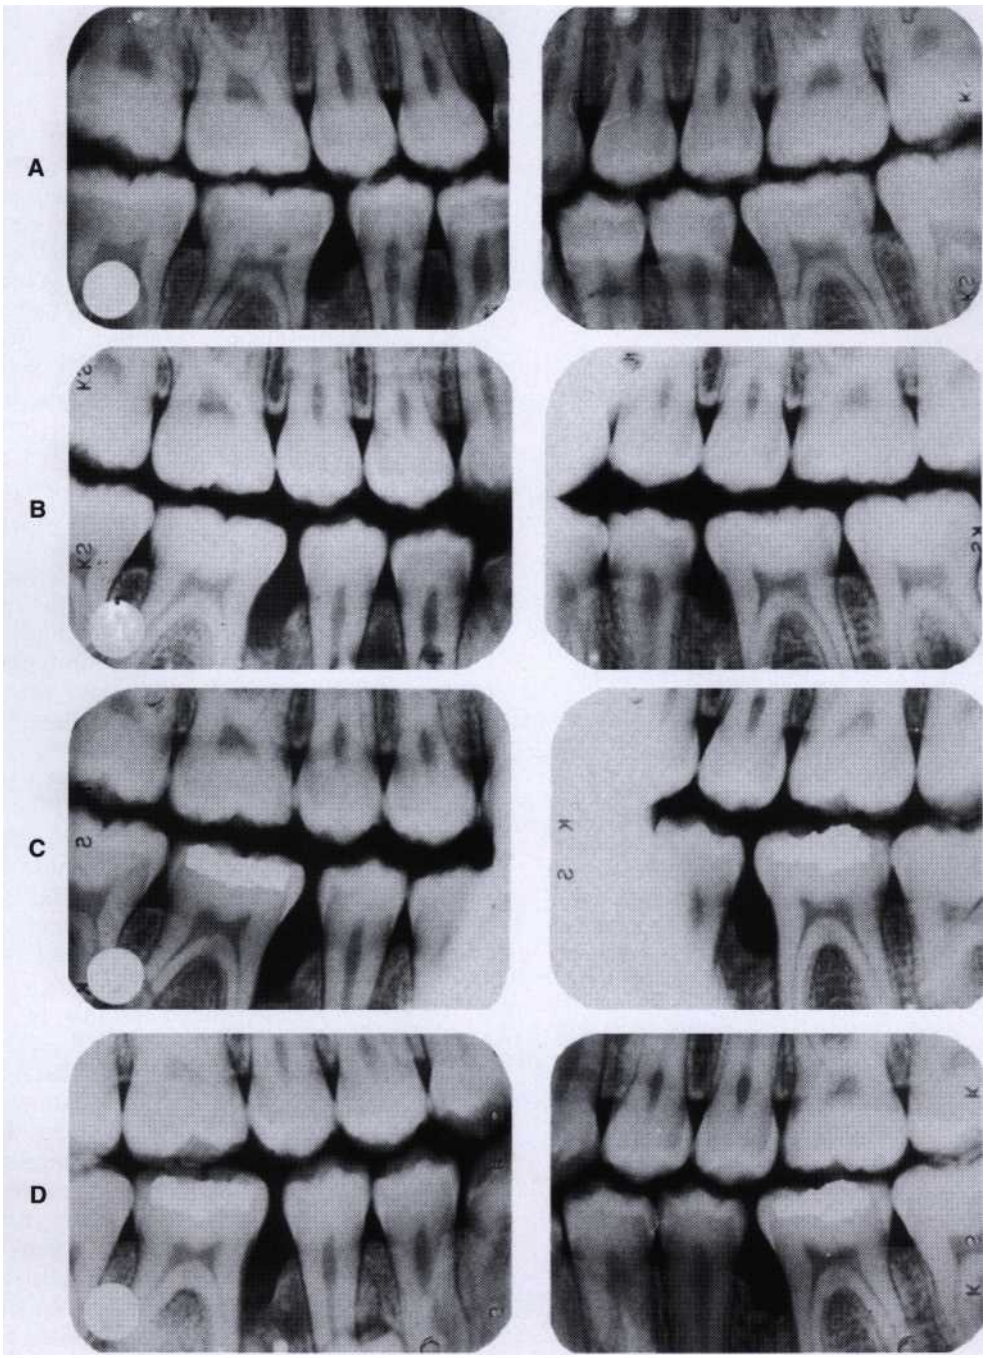

Fig. 40-1 Radiographs depicting progression of the osseous lesion in a case of localized aggressive periodontitis (formerly localized juvenile periodontitis). A, **January** 29, **1979;** B, **August** 16, **1979; C, February 22, 1980; D, May 15, 1981. Note the progressive deterioration of the osseous level. (From Barnett ML, Baker RL: The formation and healing of osseous lesions in a patient with localized juvenile periodontitis. Case report. J Periodontol 1983; 54:148.)**

of treatment complicated. Oral hygiene for these patients is complicated by the sometimes painful tissues. In such cases, irrigation with diluted cleansing and antibacterial agents can be of some benefit. The treatment of acquired immunodeficiency syndrome (AIDS) -associated NUP is presented in Chapter 51.

Periodontitis Associated with Systemic Disease

Several systemic diseases appear to predispose the individuals who have them to periodontitis which may be of the aggressive type (see Chapter *28),* but which may differ considerably from the aggressive forms described previously. Treatment considerations, however, are similar.

Fig. 40-2 Postoperative radiographs of the patient shown in Fig. 40-1. A, November 6, 1981; B, March 3, 1982. Treatment consisted of oral hygiene instruction; scaling and root planing concurrently with 1 g of tetracycline per day for 2 weeks; and, finally, modified Widman flaps. (From Barnett ML, Baker RL: The formation and healing of osseous lesions in a patient with localized juvenile periodontitis. Case report. J Perk odontol 1983; 54:148.)

This includes a medical evaluation and local, topical, and systemic antimicrobials based on the results of laboratory tests. It is mandatory that these patients be treated aggressively.

TREATMENT ALGORITHM

Individualizing treatment based on information about the patient's bacteria can be difficult because (1) patients with the same clinical presentation can have great differences in their periodontal microflora and (2) patients with the same microflora can have great variations in their clinical presentations.[25]

Fig. 40-3 shows a decision pathway, or algorithm, for a patient with refractory periodontitis. This algorithm can also be used as a general guide for many types of patients with aggressive forms of disease considered in this chapter.[26] It begins with the identification of the patient's disease (A) or nondisease (B) status. The presence of periodontal disease (A) guides the clinician to perform a series of treatments (C) that usually begins with scaling and root planing and often continues to periodontal surgery.[6]

After treatment, reevaluation of the patient (D) is done to determine whether the patient is stable (E) or not stable (F). At this stage, the patient presents with a combination of clinical signs that are a result of an etiologic agent interacting with a predisposing factor to produce the patient's observed clinical status. As an example, we will use the presence of periodontal pathogens as the target etiologic factor. There are four possible conditions that describe the patient's status (Boxes 1, 2, 3, and 4 in Fig. 40-4).

Fig. 40-4, Box 1 represents a situation in which both clinical signs of disease and periodontal pathogens are present. Clinical therapy is strongly recommended, because the tooth is clearly at risk for progression of disease.

Fig. 40-4, Box 2 indicates a situation in which clinical signs of disease are present in the absence of periodontal pathogens as detected by the particular test used for the patient. In this case, treatment should be performed. The rationale for this decision is based on the presence of disease and the fact the particular test used in this case may have "missed" some pathologic organisms because it was not designed to detect them. Similarly, in this group of patients, unusual microorganisms may be encountered, and initial testing may not be sufficient. Thus the clinical status dictates the course of treatment.

Fig. 40-4, Box 3 represents the inverse of Box 2. In this case, periodontal pathogens are present in the absence of clinical signs. The presence of pathogens puts the site, and therefore the tooth, at risk and suggests a worse prognosis. Treatment may vary considerably among patients but is aimed at the elimination of pathogens. This situation may be encountered after initial treatment is rendered and follow-up monitoring is used to determine the status of the previously diseased site.

At periodic reevaluation (see Fig. 40-3), patients can also be "completely" stable (E), a situation in which no

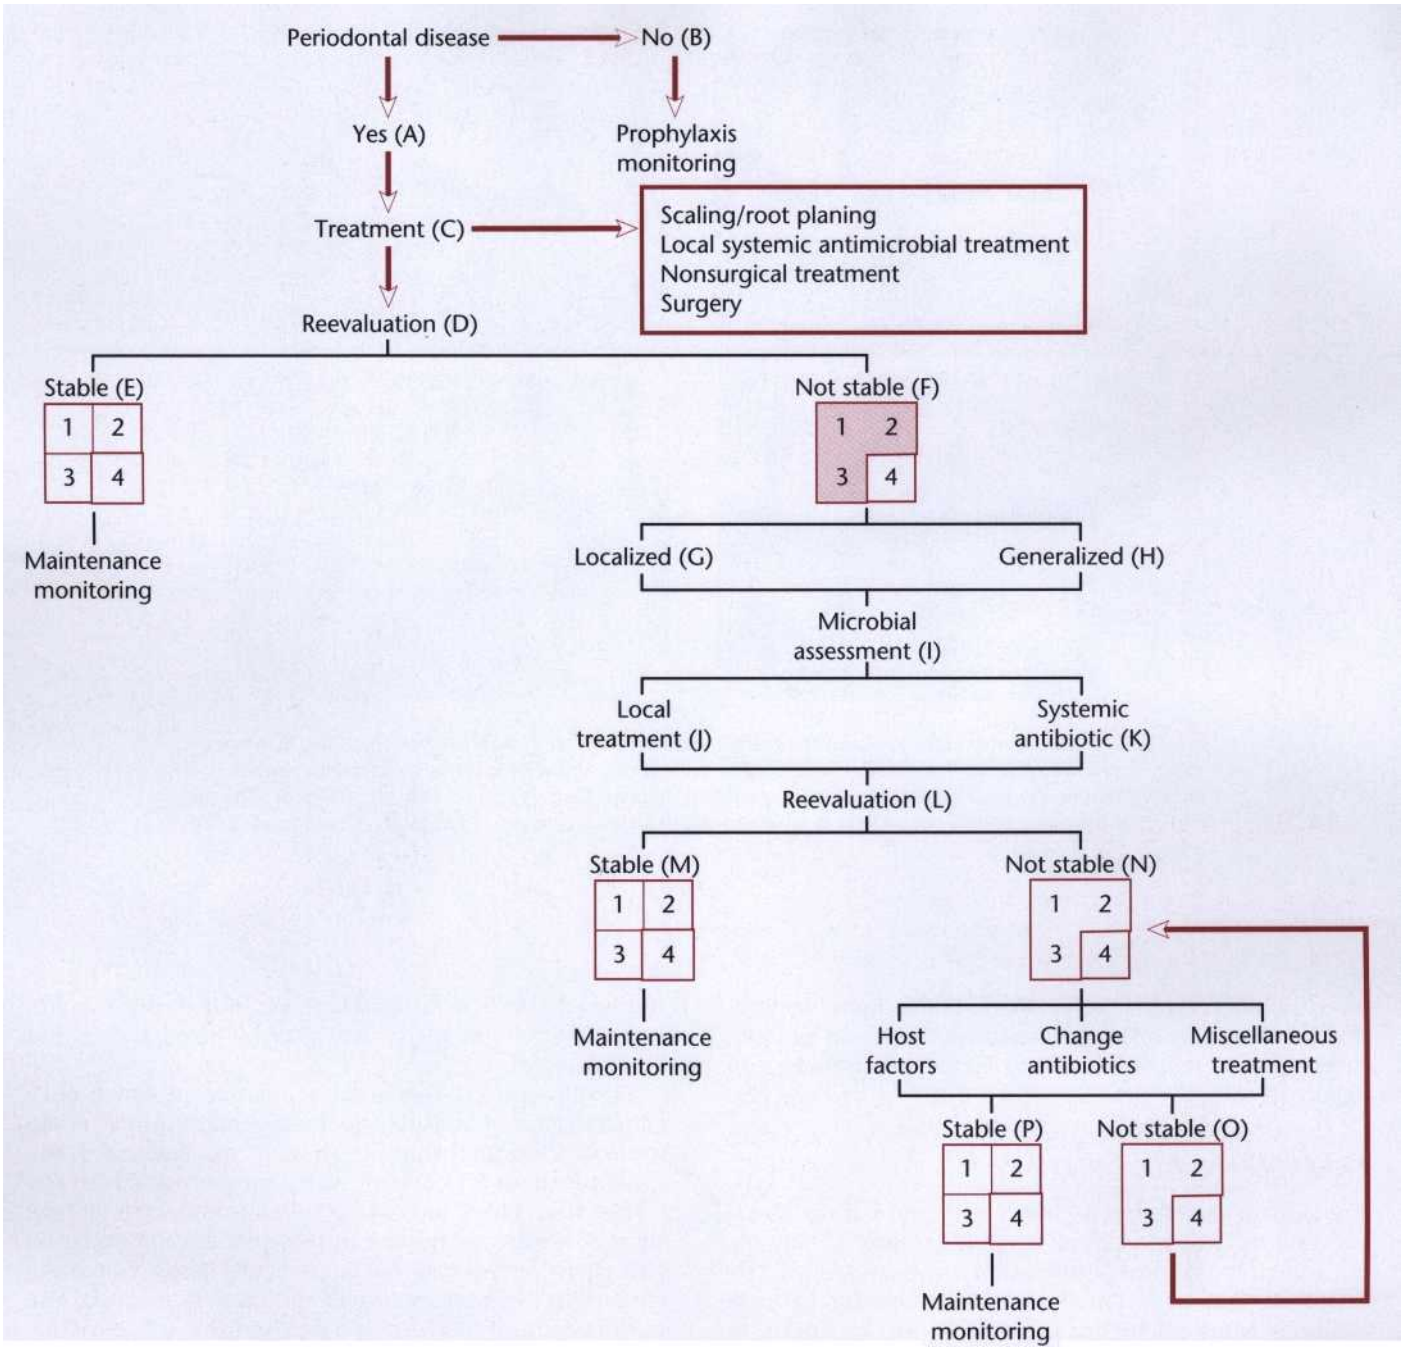

Fig. 40-3 Decision pathway.

pathogens or clinical signs of disease (i.e., bleeding on probing, loss of attachment, or loss of bone) are found (see Fig. *40-4, Box 4).* Therefore normal maintenance and monitoring are indicated.

In the three unstable situations (see Fig. *40-4, Boxes 1,* 2, and 3), it is important to assess whether the manifestations of the disease are localized (G) or generalized (H). As stated previously, microbial assessment (I) is recommended.

Local treatment (J) can consist of a variety of procedures, including topical chlorhexidine and local drug delivery. In cases of generalized manifestations, a systemic antibiotic (K) can be suggested based on the results of microbial testing. Topical chlorhexidine should also be prescribed during systemic antibiotic therapy.

Once again, the clinician should reevaluate (L) to judge whether the patient is stable (M), and therefore ready for maintenance (supportive periodontal treatment [SPT]), or whether disease is still present (N). The clinician should evaluate a possible deficiency of the host immune system by consulting the patient's physician, and a different antibiotic regimen may be considered. If disease persists (O), the clinician must try to block the triggers of the disease process by employing

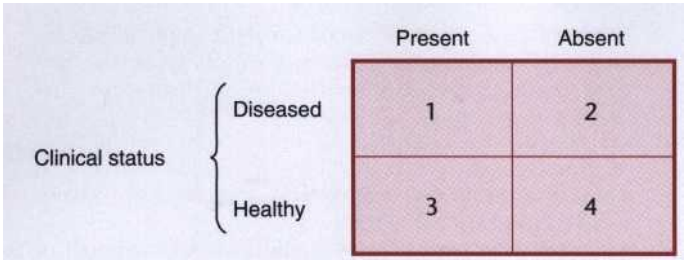

Fig. 40-4 Four possible combinations of the patient's microbial and clinical status. 1, Clinical signs of disease present/pathogens present. 2, Clinical signs of disease present/pathogens absent. 3, Clinical signs of disease absent (healthy)/pathogens present. 4, Clinical signs of disease absent (healthy)/pathogens absent. (Adapted from Newman MG, Kornman KS, Holtzman S: Association of clinical risk factors with treatment outcomes. J Periodontol 1994; 65:489.)

trial-and-error approaches to treatment, which can be frustrating and often unsuccessful. When such treatment is unsuccessful, the disease is labeled refractory or treatment resistant.

If the patient responds to treatment (P), maintenance and monitoring are preferred on a regular basis.

MAINTENANCE

A supportive periodontal therapy program aimed at early detection and treatment of sites that begin to lose attachment should be established. The duration between these recall visits is usually short during the first period after the patient's evaluation, generally no longer than 3 months.

Patients with refractory periodontitis, when transferred to maintenance care, must have a stable periodontal status, similar to the situation presented in Fig. 40-4, Box 4. The maintenance visit should consist of examination and evaluation of the patient's current oral health; thorough root debridement, followed by prophylaxis, and a review of oral hygiene instructions. When signs of disease recur, monitoring with bacterial testing is recommended.

CHAPTER OUTLINE

CLASSIFICATION OF PERIODONTAL INSTRUMENTS
- **Periodontal Probes**
- **Explorers**
- **Scaling and Curettage Instruments**
- **Cleansing and Polishing Instruments**

SURGICAL INSTRUMENTS
- **Excisional and Incisional Instruments**
- **Surgical Curettes and Sickles**
- **Periosteal Elevators**
- **Surgical Chisels and Hoes**
- **Surgical Files**
- **Scissors and Nippers**
- **Needleholders**

SHARPENING OF PERIODONTAL INSTRUMENTS

SHARPNESS AND HOW TO EVALUATE IT
- **The Objective of Sharpening**
- **Sharpening Stones**
- **Principles of Sharpening**
- **Sharpening Individual Instruments**

Periodontal instruments are designed for specific purposes, such as removing calculus, planing root surfaces, curetting the gingiva, or removing diseased tissue. On first investigation, the variety of instruments available for similar purposes appears confusing. With experience, however, clinicians select a relatively small set that fulfills all requirements.

CLASSIFICATION OF PERIODONTAL INSTRUMENTS

Periodontal instruments are classified according to the purposes they serve as follows:

1. *Periodontal probes* are used to locate, measure, and mark pockets, as well as determine their course on individual tooth surfaces.
2. Explorers are used to locate calculus deposits and caries.
3. *Scaling, root planing, and curettage instruments* are used for removal of plaque and calcified deposits from the crown and root of a tooth, removal of altered cementum from the subgingival root surface, and debridement of the soft tissue lining the pocket. Scaling and curettage instruments are classified as follows:
   - *Sickle scalers* are heavy instruments used to remove supragingival calculus.
   - *Curettes* are fine instruments used for subgingival scaling, root planing, and removal of the soft tissue lining the pocket.
   - *Hoe, chisel, and file scalers* are used to remove tenacious subgingival calculus and altered cementum. Their use is limited compared with that of curettes.

* **Material in this chapter was drawn freely from Pattison A, Pattison G: Periodontal Instrumentation, ed 2. Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ.**

- *Ultrasonic and sonic instruments* are used for scaling and cleansing tooth surfaces and curetting the soft tissue wall of the periodontal pocket. [7,8,15]

4. The *periodontal endoscope is* used to visualize deep subgingivally in pockets and furcations enabling the detection of deposits.
5. *Cleansing and polishing instruments* such as rubber cups, brushes, and dental tape are used to clean and polish tooth surfaces. Also available are air-powder abrasive systems for tooth polishing.

The wearing and cutting qualities of some types of steel used in periodontal instruments have been tested, [17,18,33] but specifications vary among manufacturers." Stainless steel is used most commonly in instrument manufacture. High-carbon steel instruments are also available and are considered by some clinicians to be superior.

Each group of instruments has characteristic features; individual therapists often develop variations with which they operate most effectively. Small instruments are recommended to fit into pockets without injuring the soft tissues.[22,35]

The parts of each instrument, referred to as the working end, shank, and handle, are shown in Fig. 41-1.

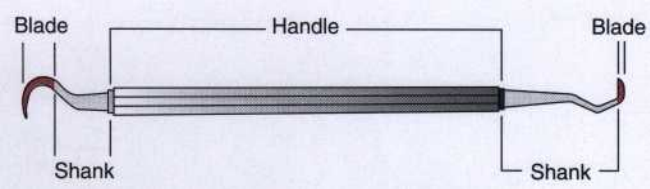

Fig. 41-1 Parts of a typical periodontal instrument.

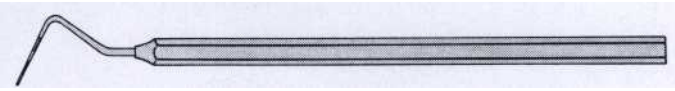

Fig. 41-2 The periodontal probe is composed of the handle, shank, and calibrated working end.

Periodontal Probes

Periodontal probes are used to measure the depth of pockets and to determine their configuration. The typical probe is a tapered, rodlike instrument calibrated in millimeters, with a blunt, rounded tip (Fig. 41-2). There are several other designs with various millimeter calibrations. The World Health Organization (WHO) probe has millimeter markings and a small round ball at the tip (Fig. 41-3). Ideally, these probes are thin, and the shank is angled to allow easy insertion into the pocket. Furcation areas can best be evaluated with the curved, blunt Nabers probe (Fig. 41-4).

When measuring a pocket, the probe is inserted with a firm, gentle pressure to the bottom of the pocket. The shank should be aligned with the long axis of the tooth surface to be probed. Several measurements are made to determine the level of attachment along the surface of the tooth.

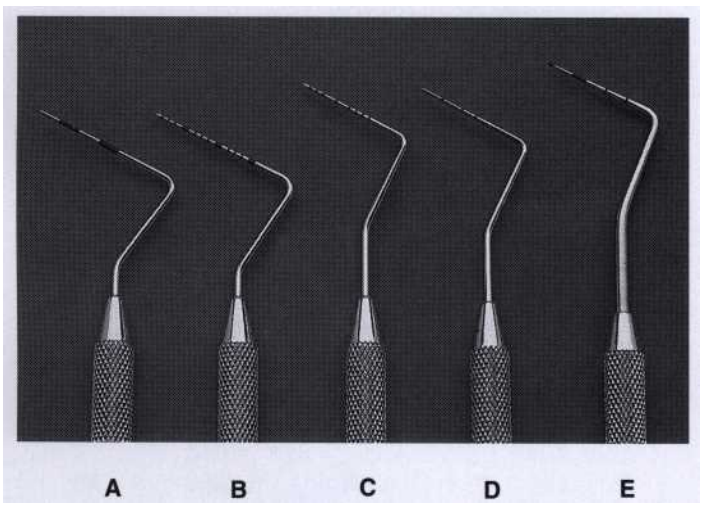

Fig. 41-3 Types of periodontal probes. A, The Marquis color-coded probe. Calibrations are in 3-mm sections. B, The UNC-15 probe, a 15-mm-long probe with millimeter markings at each millimeter and color coding at the 5th, 10th, and 15th mm. C, The University of Michigan "O" probe, with Williams markings (at 1, 2, 3, 5, 7, 8, 9, and 10 mm). D, The Michigan "O" probe with markings at 3, 6, and 8 mm. E, The WHO (World Health Organization) probe, which has a 0.5 mm ball at the tip and millimeter markings at 3.5, 8.5, and 11.5 millimeters and color coding from 3.5 to 5.5 mm.

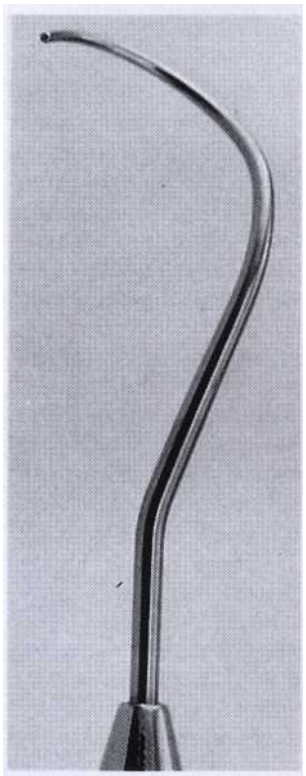

Fig. 41-4 The curved Nabers probe for detection of furcation areas.

Explorers

Explorers are used to locate subgingival deposits and carious areas and to check the smoothness of the root surfaces after root planing. Explorers are designed with different shapes and angles for a variety of uses. Some of the most commonly used explorers are shown in Fig. 41-5, and their uses and limitations are shown in Fig. 41-6. The periodontal probe can also be useful in the detection of subgingival deposits (see Fig. 41-6).

Scaling and Curettage Instruments

Scaling and curettage instruments are illustrated in Fig. 41-7.

Sickle Sealers (Supragingival Sealers). Sickle sealers have a flat surface and two cutting edges that converge in a sharply pointed tip. The shape of the instrument makes the tip strong so that it will not break off during use (Fig. 41-8). The sickle is used primarily to remove supragingival calculus (Fig. 41-9). Because of the design of this instrument, it is difficult to insert a large sickle blade under the gingiva without damaging the surrounding gingival tissues (Fig. 41-10). Small, curved sickle sealer blades such as the 204SD can be inserted under ledges of calculus a few mm below the gingiva. Sickle sealers are used with a pull stroke.

It is important to note that sickle sealers with the same basic design can be obtained with different blade sizes and shank types to adapt to specific uses. The U15/30 (Fig. 41-11), Ball, and Indiana University sickles are large. The Jaquette sickles #1, 2, and 3 have medium-size blades. The curved 204 sickles are available with large, medium, or small blades. The Nevi 2 posterior

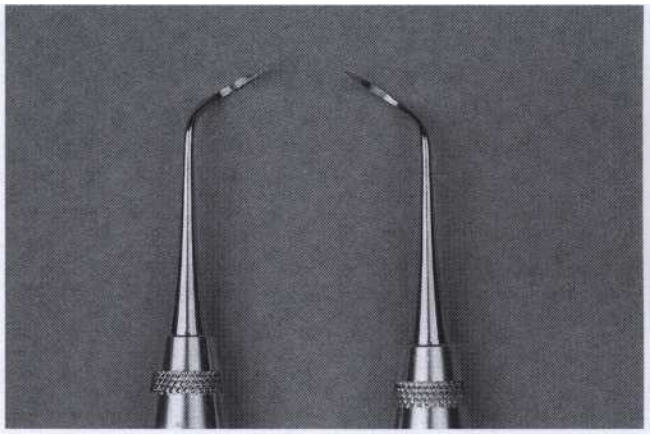

Fig. 41-12 Both ends of a NEVI 2 posterior sickle scaler.

sickle scaler is a new design that is thin enough to be inserted several mm subgingivally for removal of moderate ledges of calculus (Fig. 41-12). The selection of these instruments should be based on the area to be scaled. Sickles with straight shanks are designed for use on anterior teeth and premolars. Sickle scalers with contra-angled shanks adapt to posterior teeth.

Curettes. The curette is the instrument of choice for removing deep subgingival calculus, root planing altered cementum, and removing the soft tissue lining the periodontal pocket (Fig. 41-13). Each working end has a cutting edge on both sides of the blade and a rounded toe. The curette is finer than the sickle scalers and does not have any sharp points or corners other than the cutting edges of the blade (Fig. 41-14). Therefore curettes can be adapted and provide good access to deep pockets, with minimal soft tissue trauma (see Fig. 41-10). In cross section, the blade appears semicircular with a convex base. The lateral border of the convex base forms a cutting edge with the face of the semicircular blade. There are cutting edges on both sides of the blade. Both single- and double-end curettes may be obtained, depending on the preference of the operator.

As shown in Fig. 41-10, the curved blade and rounded toe of the curette allow the blade to adapt better to the root surface, unlike the straight design and pointed end of a sickle scaler, which can cause tissue laceration and trauma. There are two basic types of curettes: universal and area-specific.

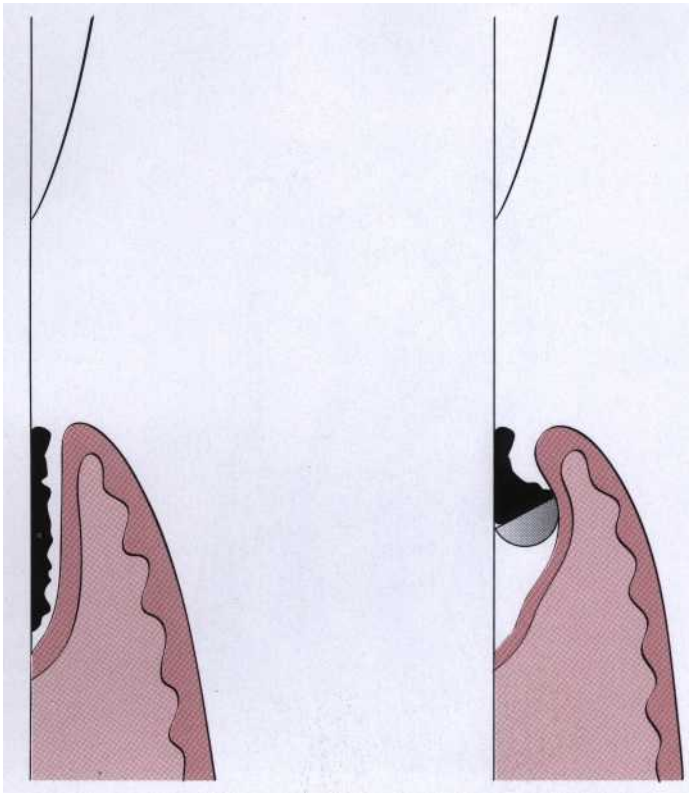

Fig. 41-13 The curette is the instrument of choice for subgingival scaling and root planing.

Fig. 41-14 Basic characteristics of a curette: spoon-shaped blade and rounded tip.

Universal Curettes. Universal curettes have cutting edges that may be inserted in most areas of the dentition by altering and adapting the finger rest, fulcrum, and hand position of the operator. The blade size and the angle and length of the shank may vary, but the face of the blade of every universal curette is at a 90-degree angle (perpendicular) to the lower shank when seen in cross section from the tip (Fig. 41-15, A). The blade of the universal curette is curved in one direction from the head of the blade to the toe. The Barnhart curettes #1-2 and 5-6

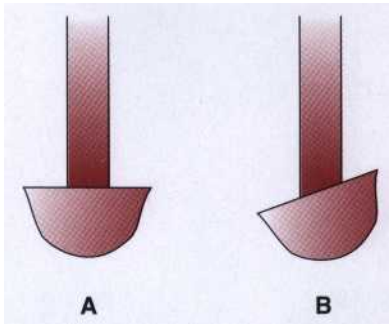

Fig. 41-15 Principal types of curettes as seen from the toe of the instrument. A, Universal curette. B, Gracey curette. Note the offset blade angulation of the Gracey curette.

and the Columbia curettes #13-14, 2R-2L, and 4R-4L (Figs. 41-16 and 41-17) are examples of universal curettes.

Area-Specific Curettes

GRACEY CURETTES. Gracey curettes are representative of the area-specific curettes, a set of several instruments designed and angled to adapt to specific anatomic areas of the dentition (Fig. 41-18).

These curettes and their modifications are probably the best instruments for subgingival scaling and root planing because they provide the best adaptation to complex root anatomy.

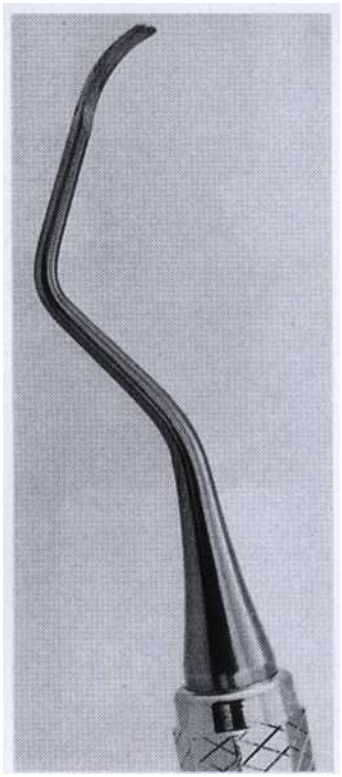

Fig. 41-17 Columbia #4R-4L universal curette.

Fig. 41-18 Reduced set of Gracey curettes. From left, #5-6, #7-8, #11-12, and #13-14.

Fig. 41-19 Gracey #11-12 curette. Note the double turn of the shank.

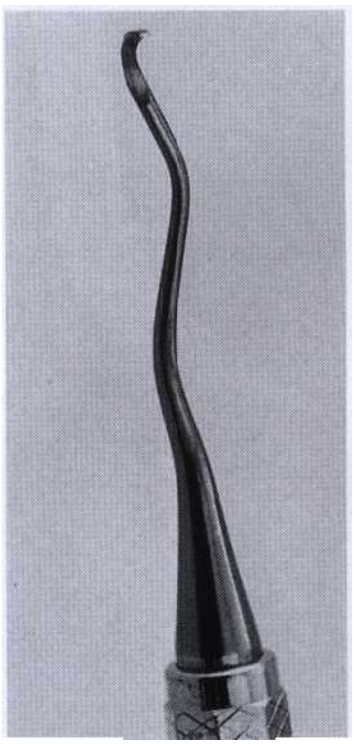

Fig. 41-20 Gracey #13-14 curette. Note the acute turn of the blade.

Double-ended Gracey curettes are paired in the following manner:

Gracey #1-2 and 3-4: Anterior teeth
Gracey #5-6: Anterior teeth and premolars
Gracey #7-8 and 9-10: Posterior teeth: facial and lingual
Gracey #11-12: Posterior teeth: mesial (Fig. 41-19)
Gracey #13-14: Posterior teeth: distal (Fig. 41-20)

Single-ended Gracey curettes can also be obtained; for these curettes a set comprises 14 instruments. Although these curettes are designed to be used in specific areas described above, an experienced operator can adapt each instrument for use in several different areas by altering the position of his or her hand and the position of the patient.

The Gracey curettes also differ from the universal curettes in that the blade is not at a 90-degree angle to the lower shank. The term *offset blade is* used to describe Gracey curettes, because they are angled approximately 60 to 70 degrees from the lower shank (see Fig. 41-15, B). This unique angulation allows the blade to be inserted in the precise position necessary for subgingival scaling and root planing, provided that the lower shank is parallel with the long axis of the tooth surface being scaled.

Area-specific curettes also have a curved blade. Whereas the blade of the universal curette is curved in one direction, the Gracey blade is curved from head to toe and also along the side of the cutting edge (Fig. 41-21). Thus only a pull stroke can be used. Some of the major differences between Gracey (area-specific) curettes and universal curettes are listed in Table 41-1.

Gracey curettes are available with either a "rigid" or a "finishing" type of shank. The rigid Gracey has a larger, stronger, and less flexible shank and blade than the standard finishing Gracey. The rigid shank makes it possible to remove moderate-to-heavy calculus without having to employ a separate set of heavy scalers such as sickles and hoes. Although some clinicians prefer the enhanced tactile sensitivity that the flexible shank of the finishing Gracey provides, both types of Graceys are suitable for root planing.

Recent additions to the Gracey curette set have been the Gracey #15-16 (Fig. 41-22) and 17-18. The Gracey #15-16 is a modification of the standard 11-12 and is designed for the mesial surfaces of posterior teeth. It consists of a Gracey #11-12 blade combined with the more acutely angled #13-14 shank. When the clinician is using an intraoral finger rest, it is often difficult to position the lower shank of the Gracey #11-12 so that it is parallel with the mesial surfaces of the posterior teeth, especially on the mandibular molars. The new shank angulation of the Gracey #15-16 allows better adaptation to posterior mesial surfaces from a front position with intraoral rests. If alternative fulcrums such as extraoral or opposite-arch rests are used, the Gracey #11-12 works well, and the new #15-16 is not essential. The Gracey #17-18 is a modification of the #13-14. It has a terminal shank elongated by 3 mm and a more accentuated angulation of the shank to provide complete occlusal clearance and better

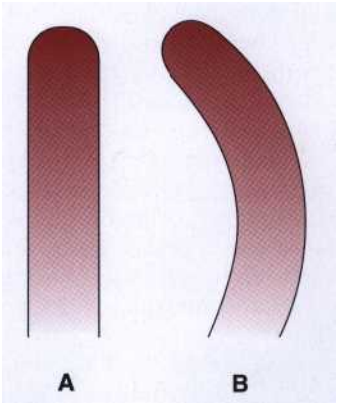

Fig. 41-21 A, Universal curette as seen from the blade. Note that the blade is straight. B, Gracey curette as seen from the blade. The blade is curved; only the convex cutting edge *is* used.

TABLE 41-1

Comparison of Specific (Gracey) and Universal Curettes

	Gracey Curette	**Universal Curette**
Area of use	Set of many curettes designed for specific areas and surfaces	One curette designed for all areas and surfaces
Cutting Edge		
Use	*One cutting edge used;* work with outer edge only	Both cutting edges used; work with either outer or inner edge
Curvature	*Curved in two planes:* blade curves up and to the side	Curved in one plane: blade curves up, not to side
Blade angle	*Offset blade:* face of blade beveled at 60 degrees to shank	Not offset: face of blade beveled at 90 degrees to shank

Modified from Pattison G, Pattison A: Periodontal Instrumentation, ed 2. Norwalk, CT, Appleton & Lange, 1992.

access to all posterior distal surfaces. The horizontal handle position minimizes interference from opposing arches and allows a more relaxed hand position when scaling distal surfaces. In addition, the blade is 1 mm shorter to allow better adaptation of the blade to distal tooth surfaces.

EXTENDED SHANK CURETTES. Extended shank curettes such as the Hu-Friedy After Five curettes are modifications of the standard Gracey curette design. The terminal shank is 3 mm longer, allowing extension into deeper periodontal pockets of 5 mm or more (Figs. *41-23* and *41-24).* Other features include a thinned blade for smoother subgingival insertion and reduced tissue distention and a large-diameter, tapered shank. All standard Gracey numbers except for the #9-10 (i.e., *#1-2, 3-4, 5-6, 7-8, 11-12, 13-14)* are available in the After Five series. The After Five curettes are available in finishing or rigid designs. For heavy or tenacious calculus removal, rigid After Fives should be used. For light scaling or deplaquing in a periodontal maintenance patient, the thinner, finishing After Fives will insert subgingivally more easily.

MINI-BLADED CURETTES. Mini-bladed curettes such as the Hu-Friedy Mini Five curettes are modifications of the After Five curettes. They feature blades that are half the length of the After Five or standard Gracey curettes (Fig. *41-25).* The shorter blade allows easier insertion and adaptation in deep, narrow pockets; furcations; developmental grooves; line angles; and deep, tight, facial, lingual, or palatal pockets. In any area where root morphology or tight tissue prevents full insertion of the standard Gracey or After Five blade, the Mini Five curettes can be used with vertical strokes, with reduced tissue distention, and without tissue trauma (Fig. *41-26).* In the past, the only solution in most of these areas of difficult access was to use the Gracey curettes with a toe-down horizontal stroke. The Mini Five curettes, along with other short-bladed instruments relatively recently introduced, open a new chapter in the history of root instrumentation by allowing access to areas that previously were extremely difficult or impossible to reach with standard instruments. The Mini Five curettes are available in both the finishing and rigid designs. Rigid Mini Fives are recommended for calculus removal. The more flexible shanked, finishing Mini Fives are appropriate for light scaling and deplaquing in periodontal maintenance patients with tight pockets. As with the After Fives, the Mini Fives are available in all standard Gracey numbers except for the #9-10.

The Gracey Curvettes. The Gracey curvettes are another set of four mini-bladed curettes; the Sub-0 and the *#1-2* are used for anteriors and premolars, the #11-*12* is used for posterior mesial surfaces, and the *#13-14* is used for posterior distal surfaces. The blade length of these instruments is *50%* shorter than that of the conventional Gracey curette, and the blade has been curved slightly upward (Fig. *41-27).* This curvature allows the Gracey curvettes to adapt more closely to the tooth surface than any other curettes, especially on the anterior teeth and online angles (Fig. *41-28).* However, this curvature also carries the potential for gouging or grooving into the root surfaces on the proximal surfaces of the posterior teeth when the Gracey curvette *#11-12* or *13-14* is used. Additional features that represent improvements on the standard Gracey curettes are a precision-balanced blade tip in direct alignment with the handle, a blade tip perpendicular to the handle, and a shank closer to parallel with the handle.

Fig. 41-22 Gracey #15-16. New Gracey curette, designed for mesioposterior surfaces, combines a Gracey #11-12 blade with a Gracey #13-14 shank.

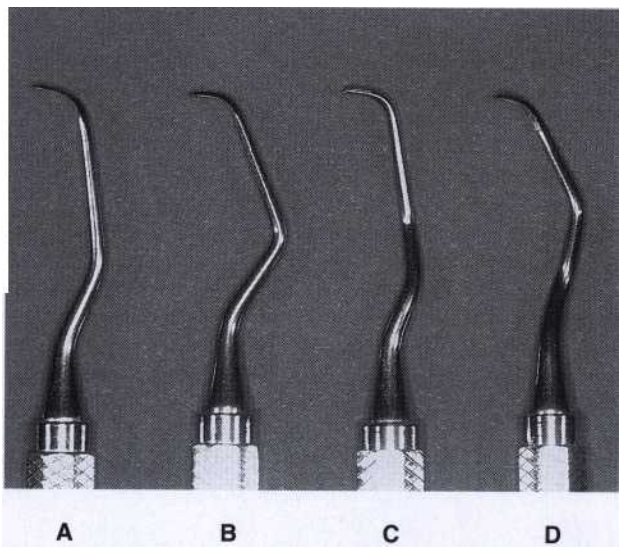

Fig. 41-23 After Five curette. Note the extra 3 mm in the terminal shank of the After Five curette compared with the standard Gracey curette. A, #5-6; B, #7-8; C, #11-12; D, #13-14.

For many years, the Morse scaler, a miniature sickle, was the only mini-bladed instrument available. However, the mini-bladed curettes have largely replaced this instrument (Fig. 41-29).

Langer and Mini-Langer Curettes. This set of three curettes combines the shank design of the standard Gracey #5-6, 11-12 and 13-14 curettes with a universal blade honed at 90 degrees rather than the offset blade of the Gracey curette. This marriage of the Gracey and universal curette designs allows the advantages of the area-specific shank to be combined with the versatility of

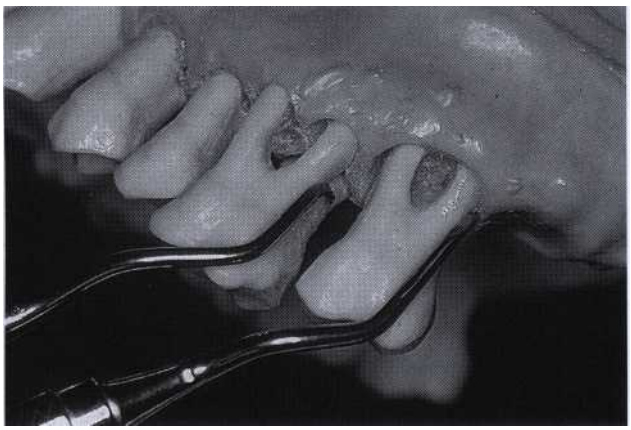

Fig. 41-24 Comparison of the After Five curette with standard Gracey curette. Rigid Gracey #13-14 adapted to the distal surface of the first molar and rigid After Five #13-14 adapted to the distal surface of the second molar. Notice the extra long shank of the After Five, which allows deeper insertion and better access.

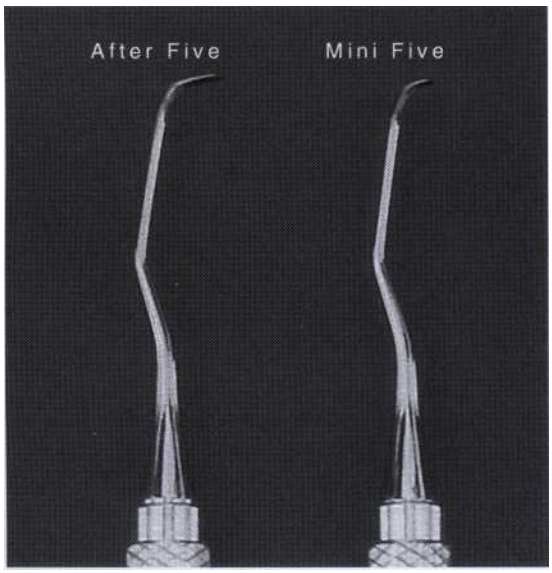

Fig. 41-25 Comparison of the After Five curette and the Mini Five curette. The shorter Mini Five blade (half the length) allows increased access and reduced tissue trauma.

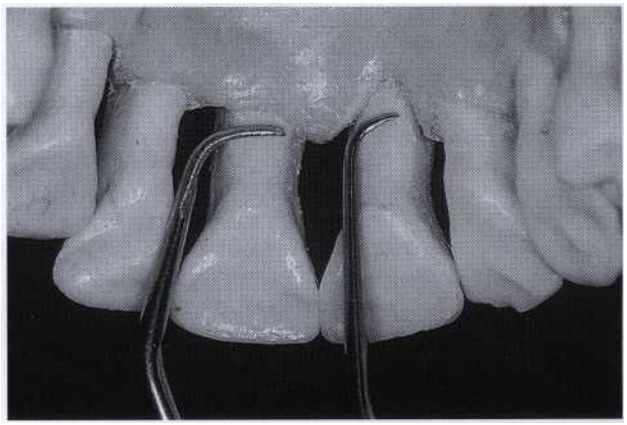

Fig. 41-26 Comparison of a standard rigid Gracey #5-6 with a rigid Mini Five #5-6 on the palatal surfaces of the maxillary central incisors. The Mini Five can be inserted to the base of these tight anterior pockets and used with a straight vertical stroke. A standard Gracey or After Five usually cannot be inserted vertically in this area because the blade is too long.

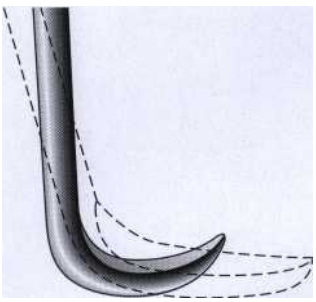

Fig. 41-27 Gracey Curvette blade. This diagram shows the 50% shorter blade of the Gracey Curvette superimposed on the standard Gracey curette blade *(dotted lines).* Notice the upward curvature of the Curvette blade and blade tip. (Redrawn from Pattison G, Pattison A: Periodontal Instrumentation, ed 2. Norwalk, CT, Appleton & Lange, 1992.)

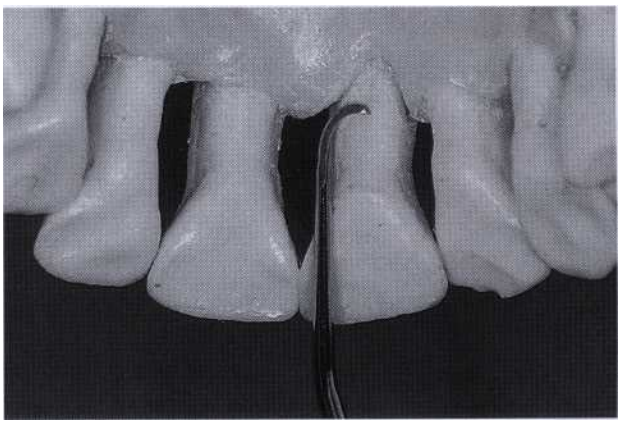

Fig. 41-28 Gracey Curvette Sub-0. Curvette Sub-0 on the palatal surface of a maxillary central. The long shank and short, curved, and blunted tip make this a superior instrument for deep anterior pockets. This curette provides excellent blade adaptation to the narrow root curvatures of the maxillary and mandibular anterior teeth.

the universal curette blade. The Langer #5-6 curette adapts to the mesials and distals of anterior teeth; the Langer #1-2 curette (Gracey #11-12 shank) adapts to the mesial and distal surfaces of mandibular posterior teeth; and the Langer #3-4 curette (Gracey #13-14 shank) adapts to the mesial and distal surfaces of maxillary posterior teeth (Fig. 41-30). These instruments can be adapted to both the mesial and distal tooth surfaces without changing instruments. The standard Langer curette shanks are heavier than a finishing Gracey but less rigid than the rigid Gracey. They are also available with either rigid or finishing shanks and can be obtained in the extended shank (After Five) and mini-bladed (Mini Five) versions.

Fig. 41-29 Comparison of mini-bladed instruments. Four different mini-bladed instruments designed for use on the maxillary and mandibular anteriors. A, Morse sickle scaler; B, Gracey Curvette Sub-0; C, Mini Five #5-6.

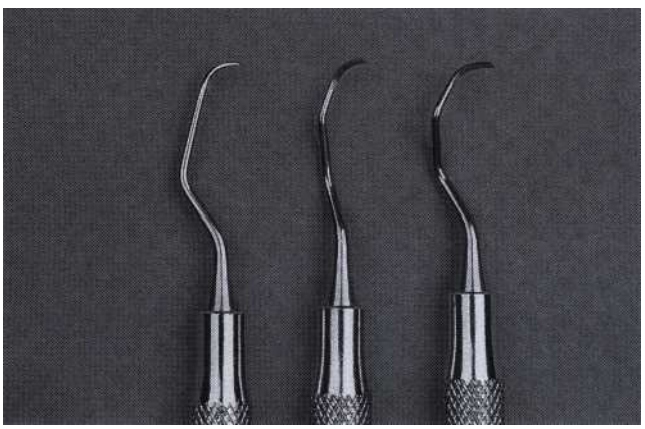

Fig. 41-30 Langer curettes combine Gracey-type shanks with universal curette blades; from left to right: #5-6, #1-2, #3-4.

Schwartz Periotrievers. The Schwartz Periotrievers are a set of two double-ended, highly magnetized instruments designed for the retrieval of broken instrument tips from the periodontal pocket (Figs. 41-31 and 41-32). They are indispensable when the clinician has broken a curette tip in a furcation or deep pocket.[29]

Plastic Instruments for Implants. Several different companies are manufacturing plastic instruments for use on titanium and other implant abutment materials. It is imperative that plastic rather than metal instruments be used to avoid scarring and permanent damage to the implants (Figs. 41-33 and 41-34).[5,6,8,10,13,20,28]

Hoe Scalers. Hoe scalers are used for scaling of ledges or rings of calculus (Fig. 41-35). The blade is bent at a 99-degree angle; the cutting edge is formed by the junction of the flattened terminal surface with the inner aspect of the blade. The cutting edge is beveled at 45 degrees. The blade is slightly bowed so that it can maintain contact at two points on a convex surface. The back of the blade is rounded, and the blade has been reduced

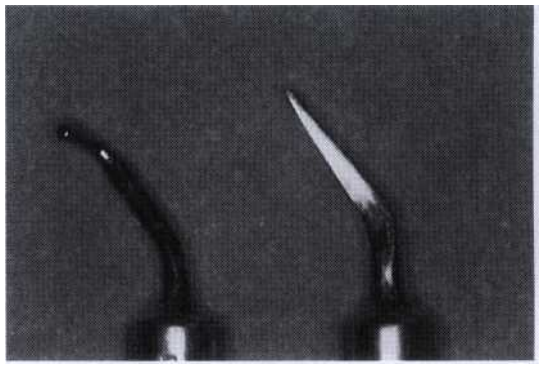

Fig. 41-31 Schwartz Periotriever tip designs. The long blade is for general use in pockets, and the contra-angled tip is for use in furcations. (From Pattison G, Pattison A: Periodontal Instrumentation, ed 2. Norwalk, CT, Appleton & Lange, 1992.)

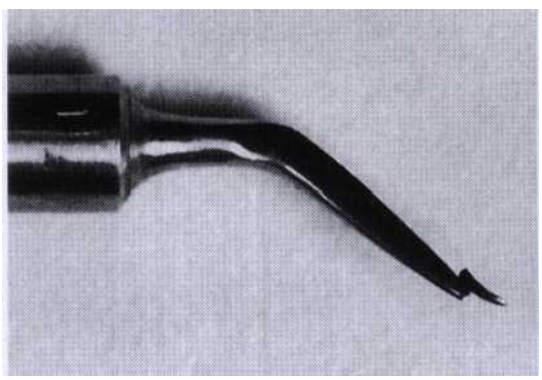

Fig. 41-32 Broken instrument tip attached to the magnetic tip of the Schwartz Periotriever. (From Pattison G, Pattison A: Periodontal Instrumentation, ed 2. Norwalk, CT, Appleton & Lange, 1992.)

to minimal thickness to permit access to the roots without interference from the adjacent tissues.

Hoe scalers are used in the following manner:

1. The blade is inserted to the base of the periodontal pocket so that it makes two-point contact with the tooth (see Fig. 41-35). This stabilizes the instrument and prevents nicking of the root.
2. The instrument is activated with a firm pull stroke toward the crown, with every effort being made to preserve the two-point contact with the tooth.

McCall's hoe scalers #3, 4, 5, 6, 7, and 8 are a set of six hoe scalers designed to provide access to all tooth surfaces. Each instrument has a different angle between the shank and handle.

Files. Files have a series of blades on a base (Fig. 41-36). Their primary function is to fracture or crush tenacious calculus. Files can easily gouge and roughen root surfaces when used improperly. Therefore they are not suitable for fine scaling and root planing. Mini-bladed curettes are currently preferred for areas where files were once commonly used. Files are sometimes used for removing overhanging margins of dental restorations.

Chisel Scalers. The chisel scaler, designed for the proximal surfaces of teeth too closely spaced to permit the use of other scalers, is usually used in the anterior part of the mouth. It is a double-ended instrument with a curved shank at one end and a straight shank at the other (see Fig. 41-36); the blades are slightly curved and have a straight cutting edge beveled at 45 degrees.

The chisel is inserted from the facial surface. The slight curve of the blade makes it possible to stabilize it against the proximal surface, whereas the cutting edge engages the calculus without nicking the tooth. The instrument is activated with a push motion while the side of the blade is held firmly against the root.

Ultrasonic and Sonic Instruments. Ultrasonic instruments may be used for removing plaque, scaling, curetting, and removing stain.[7,8,15,36] The two types of ultrasonic units are magnetostrictive and piezoelectric. In both types, alternating electrical current generates oscillations in materials in the handpiece that cause the scaler tip to vibrate. Depending on the manufacturer, these ultrasonic vibrations at the tip of the instruments of both types range from 20,000 to 45,000 cycles/second (also referred to as *Hertz [Hz]).* In magnetostrictive units (Fig. 41-37), the pattern of vibration of the tip is elliptical, which means that all sides of the tip are active and will work when adapted to the tooth. In piezoelectric units (Fig. 41-38), **the pattern of vibration of the tip is linear, or** back and forth, meaning that the two sides of the tip are the most active (see Chapter 43).

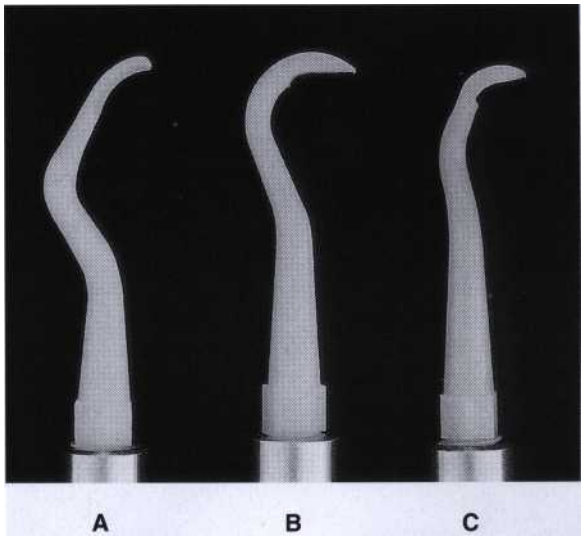

Fig. 41-34 Implacare implant instruments. These implant instruments from the Hu-Friedy Company have autoclavable stainless steel handles and three different cone-socket plastic tip designs. A, The Columbia 4R-4L curette tip; B, The H6-H7 sickle scaler tip; C, The 2045 sickle scaler tip.

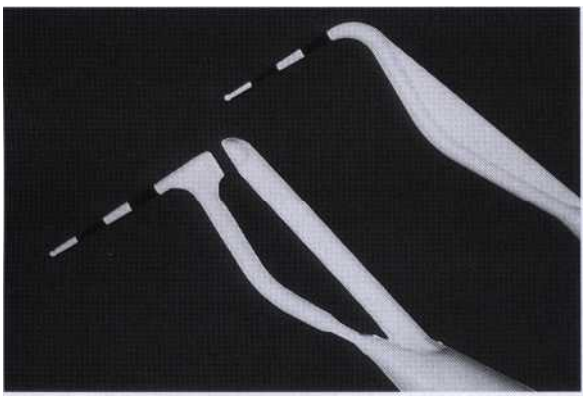

Fig. 41-33 Plastic probes. (Courtesy Professional Dental Technologies, Inc., Batesville, AR)

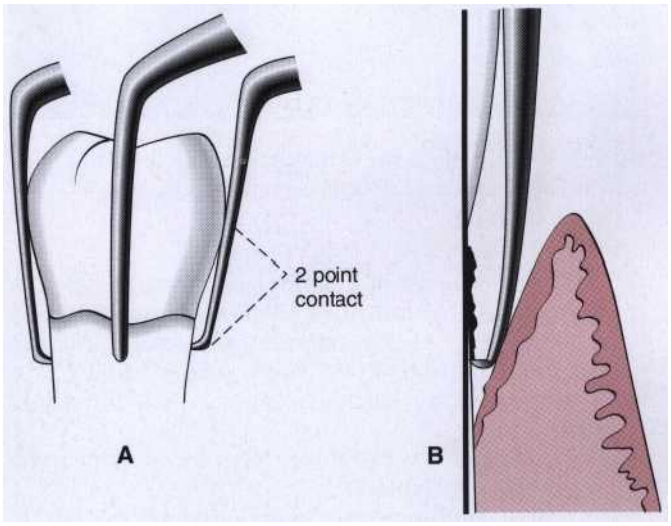

Fig. 41-35 Hoe scalers. A, Hoe scalers designed for different tooth surfaces, showing "two-point" contact. B, Hoe scaler in a periodontal pocket. The back of the blade is rounded for easier access. The instrument contacts the tooth at two points for stability.

Fig. *41-36* **Chisel scaler and file scaler.**

Fig. *41-38* **Piezoelectric ultrasonic unit. Piezon Master 400. (Courtesy EMS-Electromedical Systems, Dallas, TX.)**

Fig. *41-37* **Magnetostrictive ultrasonic unit. The Cavitron SPS ultrasonic scaler. (Courtesy Dentsply International Inc., York, PA.)**

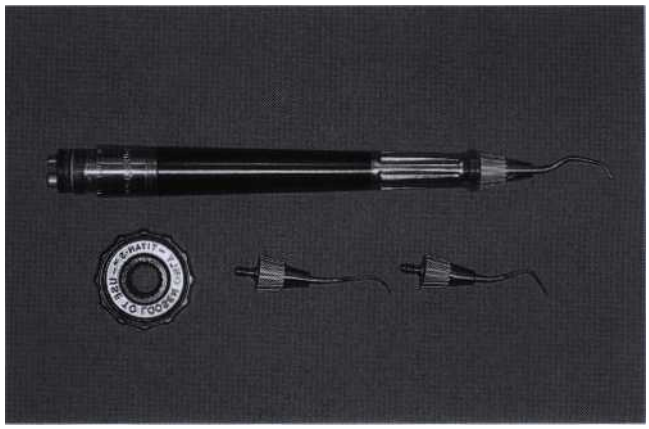

Fig. *41-39* **Sonic scaler. The Titan-S sonic scaler from Star Dental Products, Valley Forge, PA.**

Sonic units consist of a handpiece that attaches to a compressed air line and uses a variety of specially designed tips (Fig. 41-39). Vibrations at the sonic tip range from 2000 to 6500 cycles per second, which provides less power for calculus removal than ultrasonic units.

A comparison of the three types of power-driven scalers is shown in Table 41-2.

Ultrasonic and sonic tips with **different shapes are available for scaling, curetting,** root planing, and debriding during periodontal surgery (Fig. 41-40). For many years, only large, bulky tips designed for supragingival removal of heavy calculus were available. In recent years, however, thinner, more delicate tips designed for subgingival debridement have become available15 (Fig. 41-41). All tips are designed to operate in a wet field and have attached water outlets. The spray is directed at the end of the tip to dissipate the heat generated by the ultrasonic vibrations. Within the water droplets of this spray mist are tiny vacuum bubbles that quickly collapse, releasing energy in a process known as cavitation. The cavitating water spray also serves to flush calculus, plaque, and debris dislodged by the vibrating tip from the pocket. Sonic units do not release heat the way ultrasonic units do, but they still have water for cooling and flushing away debris.

TABLE 41-2

Comparison of Sonic and Ultrasonic Scaling Units

		ULTRASONIC	
	Sonic	**Magnetostrictive**	**Piezoelectric**
Advantages			
Calculus removal	good	excellent	excellent
Treatment time	low	low	low

Restoration damage	medium	medium	medium
Heat production	low	high	high
Cost	medium	high	high
Maintenance	medium	high	high
Noise level	high	medium	medium

NOTE: This table is meant merely as a guide to choosing power-operated instruments. The clinician is advised to investigate the various types and models of sonic and ultrasonic scaling devices, because technical improvements and changes have affected and will continue to affect the way powered instruments are used in dentistry.

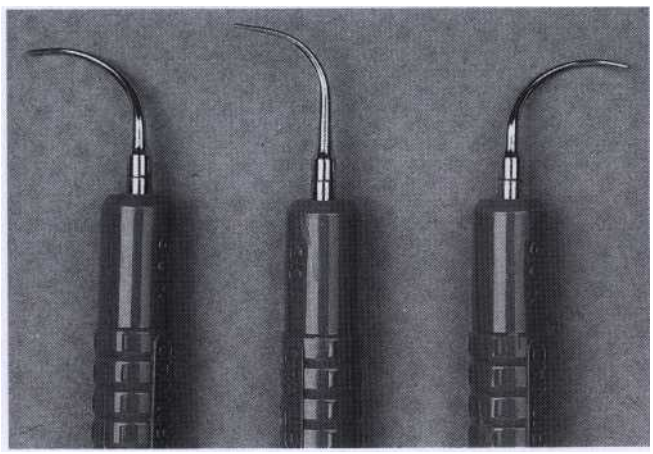

Fig. 41-41 Cavitron FSI® Slim Line ultrasonic tips. Thin inserts from Dentsply Cavitron allow better insertion into deep periodontal pockets and furcations.

The Dental Endoscope. A dental endoscope has been introduced recently for use subgingivally in the diagnosis and treatment of periodontal disease (Fig 41-42). Produced by DentalView, Inc. and called the Perioscopy System, it consists of a 0.99 mm-diameter reusable fiberoptic endoscope over which is fitted a disposable, sterile sheath. The fiberoptic endoscope fits onto periodontal probes and ultrasonic instruments that have been designed to accept it (Fig 41-43). The sheath delivers water irrigation that flushes the pocket while the

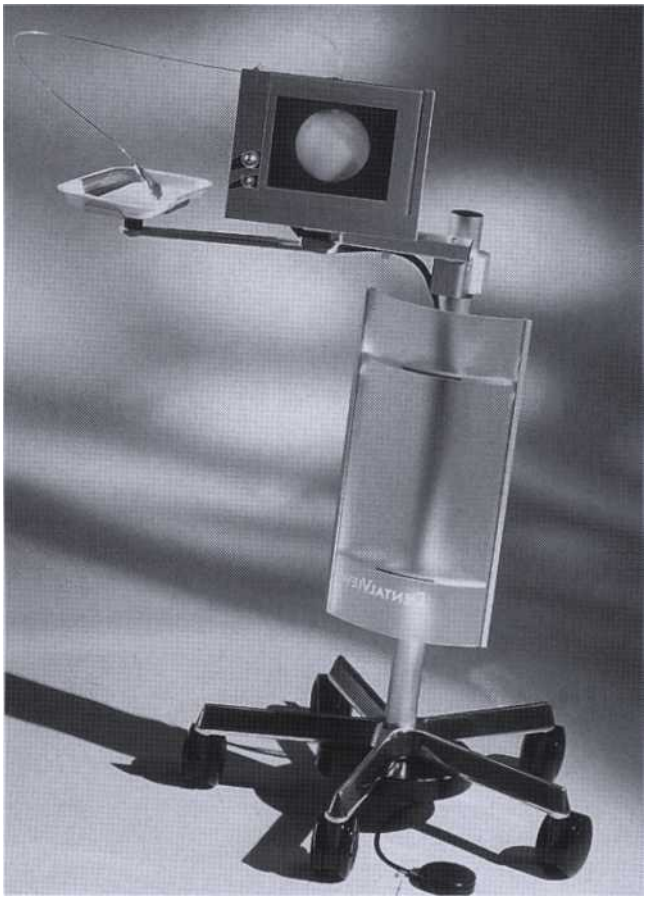

Fig. 41-42 The Perioscopy® System, dental endoscope. (Courtesy DentalView, Inc., Irvine, CA.)

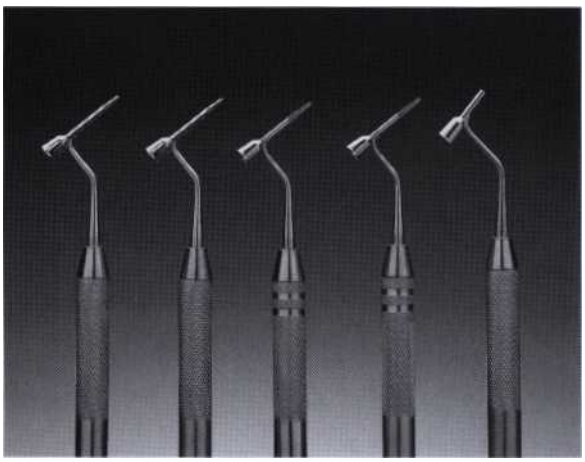

Fig. 41-43 Viewing periodontal explorers (left/right/full viewing) for the Perioscopy® system. (Courtesy DentalView, Inc., Irvine, CA.)

endoscope is in use and keeps the field clear. The fiberoptic endoscope attaches to a medical grade charged coupled device (CCD) video camera and light source that produces an image on a flat panel video monitor for viewing during subgingival exploration and instrumentation. This

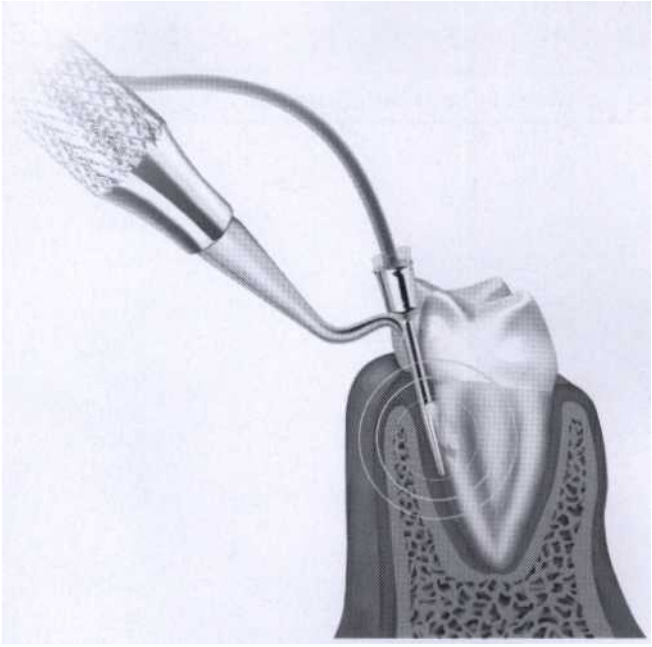

Fig. 41-44 Perioscope® instrumentation permits deep subgingival visualization in pockets and furcations. (Courtesy DentalView, Inc., Irvine, CA.)

device allows clear visualization deep subgingivally in pockets and in furcations (Fig. 41-44). It enables the operator to detect the presence and location of subgingival deposits and guides the operator in their thorough removal. Magnification ranges from 24x to 46x, enabling visualization of even minute deposits of plaque and calculus. Using this device, it is possible to achieve levels of root debridement and cleanliness that are much more difficult or impossible to produce without it. The Perioscopy System' can also be used to evaluate subgingivally for caries, defective restorations, root fractures, and resorption.

The EVA System. Probably the most efficient and least traumatic instruments for correcting overhanging or overcontoured proximal alloy and resin restorations are the motor-driven diamond files of the EVA prophylaxis instrument. These files, which come in symmetric pairs, are made of aluminum in the shape of a wedge protruding from a shaft; one side of the wedge is diamond coated; the other side is smooth. The files can be mounted on a special dental handpiece attachment that generates reciprocating strokes of variable frequency. When the unit is activated interproximally with the diamond-coated side of the file touching the restoration and the smooth side adjacent to the papilla, the oscillating file swiftly planes the contour of the restoration and reduces it to the desired shape.

Cleansing and Polishing Instruments

Rubber Cups. Rubber cups consist of a rubber shell with or without webbed configurations in the hollow interior (Fig. 41-45). They are used in the handpiece with a special prophylaxis angle. The handpiece, prophylaxis angle, and rubber cup must be sterilized after each

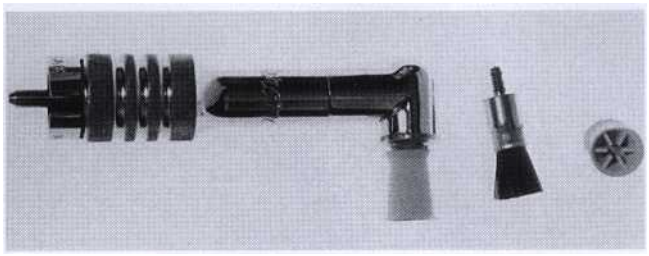

Fig. 41-45 Prophylaxis handpiece with rubber cup and brush.

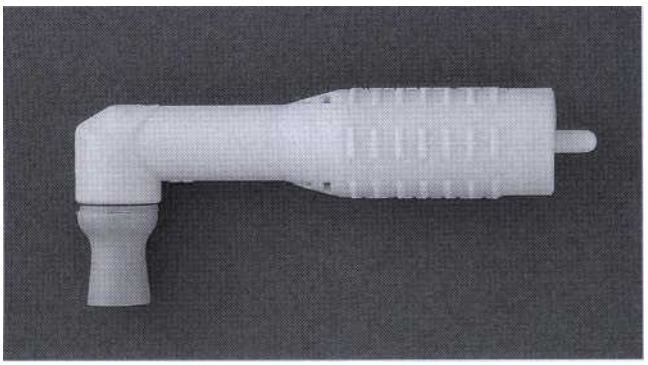

Fig. 41-46 Disposable plastic prophylaxis angle with rubber cup.

patient use, or a disposable plastic prophylaxis angle and rubber cup (Fig. 41-46) may be used and then discarded. A good cleansing and polishing paste that contains fluoride should be used and kept moist to minimize frictional heat as the cup revolves. Polishing pastes are available in fine, medium, or coarse grits and are packaged in small, convenient, single-use containers. Aggressive use of the rubber cup with any abrasive may remove the layer of cementum, which is thin in the cervical area.

Bristle Brushes. Bristle brushes are available in wheel and cup shapes (see Fig. 41-45). The brush is used in the handpiece with a polishing paste. Because the bristles are stiff, use of the brush should be confined to the crown to avoid injuring the cementum and the gingiva.

Dental Tape. Dental tape with polishing paste is used for polishing proximal surfaces that are inaccessible to other polishing instruments. The tape is passed interproximally while being kept at a right angle to the long axis of the tooth and is activated with a firm labiolingual motion. Particular care is taken to avoid injury to the gingiva. The area should be cleansed with warm water to remove all remnants of paste.

Air-Powder Polishing. In the early 1980s, a specially designed handpiece was introduced that delivers an air-powered slurry of warm water and sodium bicarbonate; this instrument is called the *Prophy-jet* (Fig. 41-47). This system is effective for the removal of extrinsic stains and soft deposits. The slurry removes stains rapidly and efficiently by mechanical abrasion and provides warm water for rinsing and lavage. The flow rate of abrasive cleansing power can be adjusted to increase the amount of powder for heavier stain removal.

Fig. 41-47 Prophy-Jet air-powder polishing device. (Courtesy Dentsply International, Inc., York, PA.)

The results of studies on the abrasive effect of the air-powder polishing device on cementum and dentin show that tooth substance can be lost.[4,23] Damage to gingival tissue is transient and insignificant clinically, but amalgam restorations, composite resins, cements, and other nonmetallic materials can be roughened.[2,9,19,23] Air-powder polishing can be used safely on titanium implant surfaces.[16,26]

Patients with medical histories of respiratory illnesses, hypertension, hemodialysis, sodium-restricted diets and those on medications affecting the electrolyte balance are not candidates for the use of the air-powder polishing device.[25,32,34] Patients with infectious diseases should not be treated with this device because of the large quantity of aerosol created. A preprocedural rinse with 0.12% chlorhexidine gluconate should be used to minimize the microbial content of the aerosol.[3] High speed evacuation should also be used to eliminate as much of the aerosol as possible.[14]

SURGICAL INSTRUMENTS

Periodontal surgery is accomplished with numerous instruments; Fig. 41-48 shows a typical surgical cassette. Periodontal surgical instruments are classified as follows:

1. Excisional and incisional instruments
2. Surgical curettes and sickles
3. Periosteal elevators
4. Surgical chisels
5. Surgical files
6. Scissors
7. Hemostats and tissue forceps

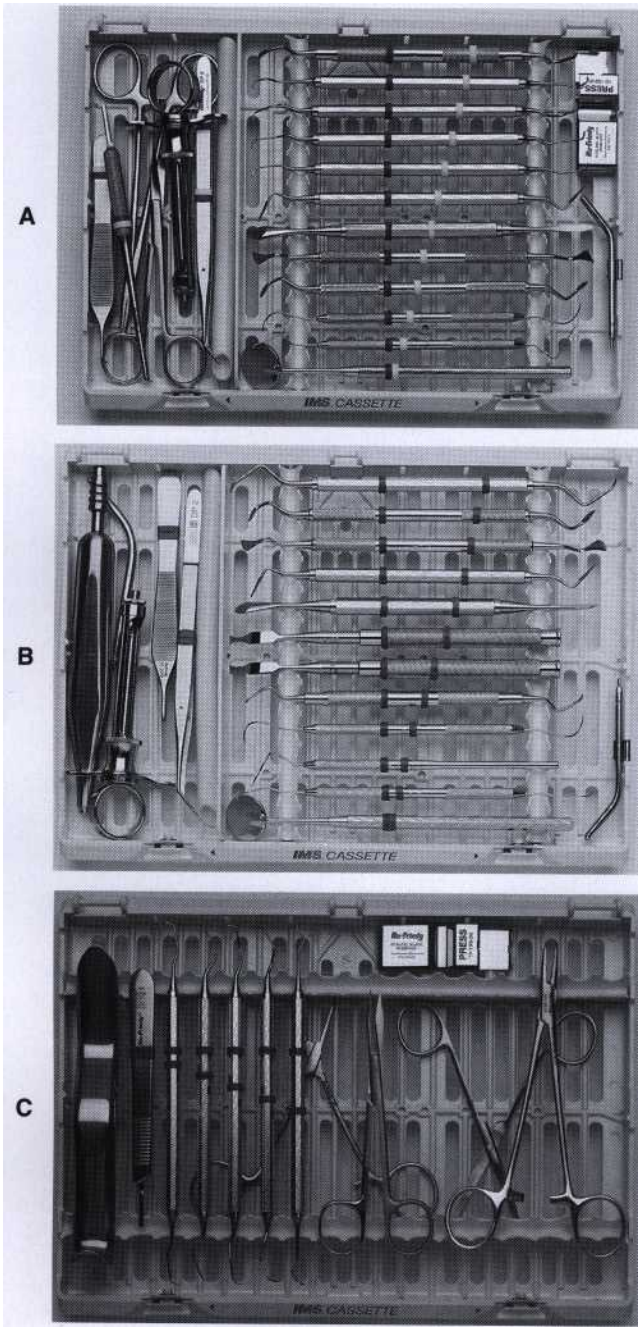

Fig. 41-48 Instrument cassettes for periodontal surgery. Cassettes shown in A and B are to be used together for involved cases, while the cassette shown in C is a reduced set for simple cases. Additional instruments may be used according to individual preferences and case requirements. A, Mirror, explorer, probe, furcation probe, chisels, periosteal elevator, file, knives, surgical curette, dressing pliers, tissue pliers, aspirator tip. B, Retractor, scalpel handle, root planing curettes, universal curette, hemostat, scissors, needleholders, suture scissors, scalpel blade remover. C, Simplified set: mirror, explorer-probe, furcation probe, knives, periosteal elevator, file, root planing curettes, universal curette, chisel, scalpel handle, dressing pliers, tissue pliers, needleholder, scissors, scalpel blade remover. (Courtesy Hu-Friedy Instrument Company, Chicago.)

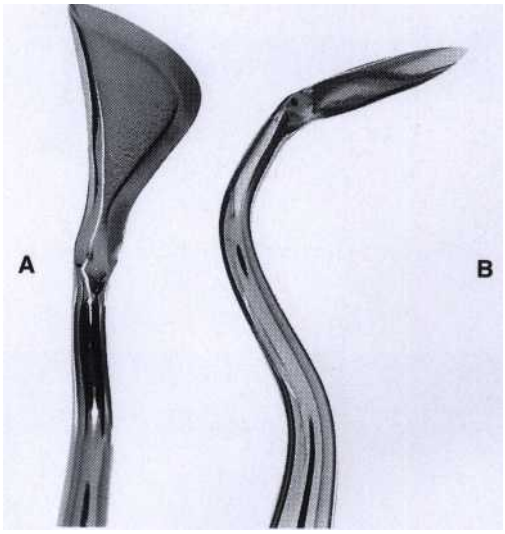

Fig. 41-49 Gingivectomy knives. A, Kirkland knife. B, Orban interdental knife.

Excisional and Incisional Instruments

Periodontal Knives (Gingivectomy Knives). The Kirkland knife is representative of knives commonly used for gingivectomy. These knives can be obtained as either double-ended or single-ended instruments. The entire periphery of these kidney-shaped knives is the cutting edge (Fig. 41-49, A).

Interdental Knives. The Orban knife #1-2 (Fig. 41-49, B) and the Merrifield knife #1, 2, 3, and 4 are examples of knives used for interdental areas. These spear-shaped knives have cutting edges on both sides of the blade and are designed with either double-ended or single-ended blades.

Surgical Blades. Scalpel blades of different shapes and sizes are used in periodontal surgery. The most commonly used blades are #12D, 15, and 15C (Fig. 41-50). The #12D blade is a beak-shaped blade with cutting edges on both sides, allowing the operator to engage narrow, restricted areas with both pushing and pulling cutting motions. The #15 blade is used for thinning flaps and for all-around use. The #15C blade, a narrower version of the #15 blade, is useful for making the initial, scalloping type incision. The slim design of this blade allows for incising into the narrow interdental portion of the flap. All of these blades are discarded after one use.

Electrosurgery (Radiosurgery) Techniques and Instrumentation. The term electrosurgery or radiosurgery3o is currently used to identify surgical techniques performed on soft tissue using controlled high-frequency electrical (radio) currents in the range of 1.5 to 7.5 million cycles per second or megahertz (Fig. 41-51). There are three classes of active electrodes: single-wire electrodes for incising or excising; loop electrodes for planing tissue; and heavy, bulkier electrodes for coagulation procedures.[11,21]

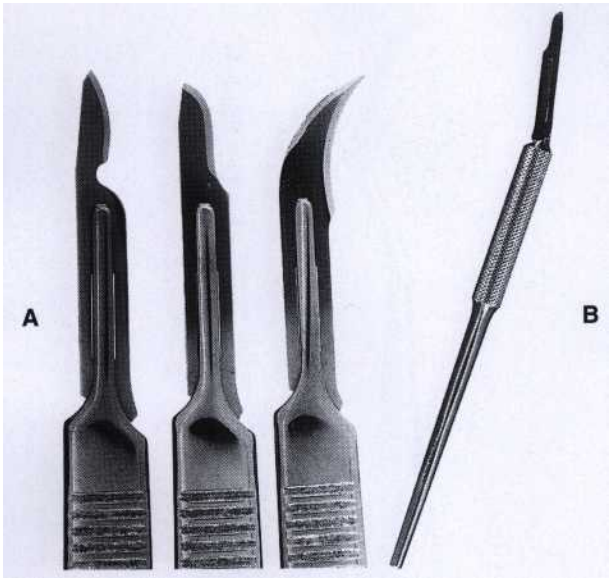

Fig. 41-50 Surgical blades. A, #15C, 15, and *12D. B,* **Contra-angled scalpel handle.**

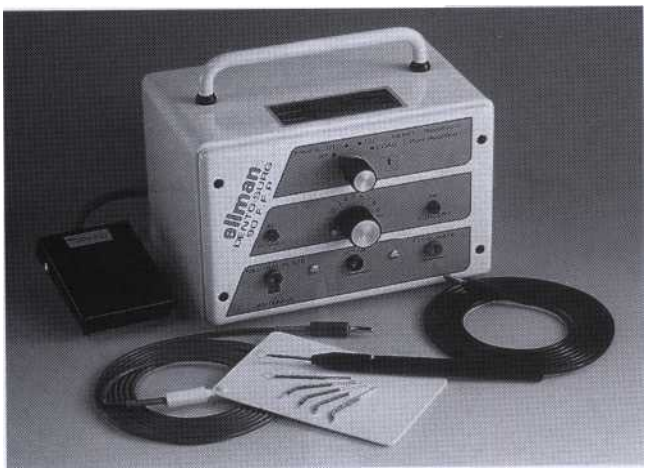

Fig. 41-51 Radiosurgical (electrosurgical) unit. Dento-Surg 90 UP (Courtesy Ellman International Inc., Hewlett, NY.)

The four basic types of electrosurgical techniques are electrosection, electrocoagulation, electrofulguration, and electrodesiccation.

Electrosection, also referred to as *electrotomy* or *acusection, is* used for incisions, excisions, and tissue planing. Incisions and excisions are performed with single-wire active electrodes that can be bent or adapted to accomplish any type of cutting procedure.

Electrocoagulation provides a wide range of coagulation or hemorrhage control obtained by using the electrocoagulation current. Electrocoagulation can prevent bleeding or hemorrhage at the initial entry into soft tissue, but it cannot stop bleeding after blood is present. All forms of hemorrhage must be stopped first by some form of direct pressure (e.g., air, compress, or hemostat). After bleeding has momentarily stopped, final sealing of the capillaries or large vessels can be accomplished by a short application of the electrocoagulation current. The active electrodes used for **coagulation are** much bulkier than the fine tungsten wire used for electrosection.

Electrosection and electrocoagulation are the procedures most commonly used in all areas of dentistry. The two monoterminal techniques, electrofulguration and electrodesiccation, are not in general use in dentistry.

The most important basic rule of electrosurgery is: *always keep the tip moving.* Prolonged or repeated application of current to tissue induces heat accumulation and undesired tissue destruction, whereas interrupted application at intervals adequate for tissue cooling (5 to 10 seconds) reduces or eliminates heat buildup. Electrosurgery is not intended to destroy tissue; it is a controllable means of sculpturing or modifying oral soft tissue with little discomfort and hemorrhage for the patient.

The indications for electrosurgery in periodontal therapy and a description of wound healing after electrosurgery are presented in Chapter 58. Electrosurgery is contraindicated for patients who have noncompatible or poorly shielded cardiac pacemakers.

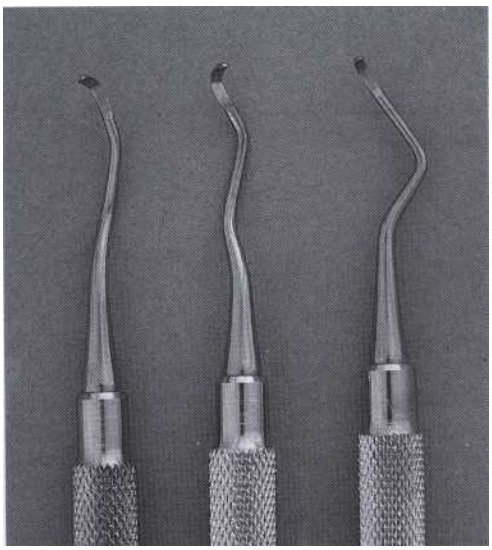

Fig. 41-52 Kramer heavy surgical curettes *#11, 2,* and 3.

Surgical Curettes and Sickles

Larger and heavier curettes and sickles are often needed during surgery for the removal of granulation tissue, fibrous interdental tissues, and tenacious subgingival deposits. The Kramer curettes #1, 2, and 3 (Fig. 41-52) and the Kirkland surgical instruments are heavy curettes, whereas the Ball scaler #B2-B3 is a popular heavy sickle. The wider, heavier blades of these instruments make them suitable for surgical procedures.

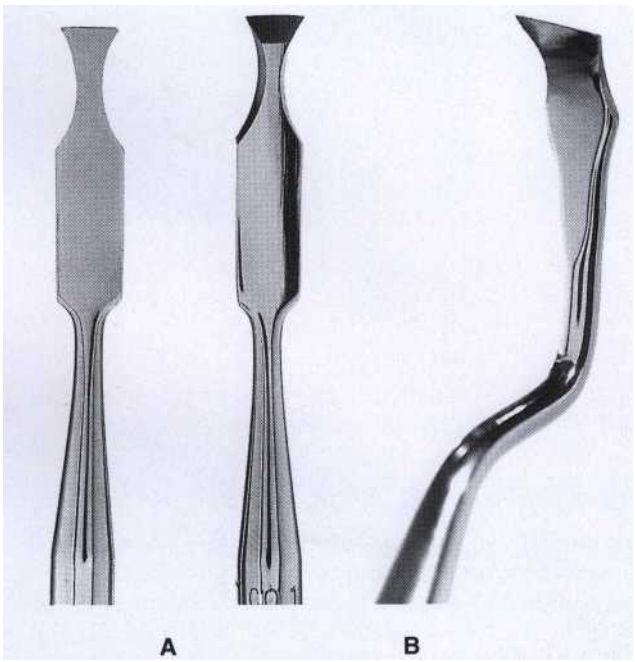

Fig. 41-55 Surgical chisels. A, Ochsenbein chisels. B, Rhodes chisel.

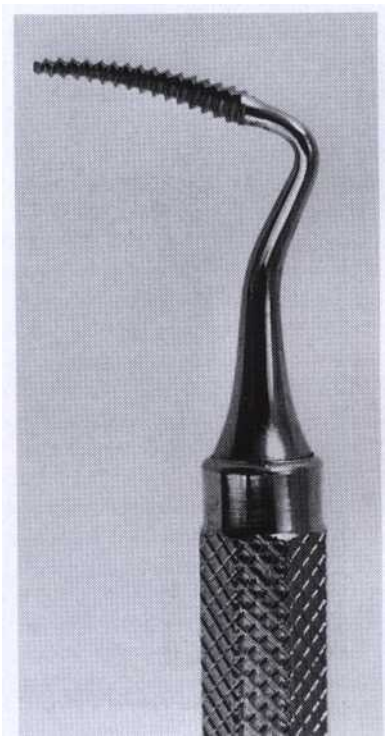

Fig. 41-56 Schluger #9-10 surgical file.

Periosteal Elevators

These instruments are necessary to reflect and move the flap after the incision has been made for flap surgery. The #24G (Fig. 41-53) and the Goldman-Fox #14 are well-designed periosteal elevators.

Surgical Chisels and Hoes

Chisels and hoes are used during periodontal surgery for removing and reshaping bone. The hoe shown in Fig. 41-54 has a curved shank and blade, whereas the Wiedelstadt and Todd-Gilmore chisels are straight shanked. The surgical hoe has a flattened, fishtail-shaped blade with a pronounced convexity in its terminal portion. The cutting edge is beveled with rounded edges and projects beyond the long axis of the handle to preserve the effectiveness of the instrument when the blade is reduced by sharpening. The surgical hoe is generally used for detaching pocket walls after the gingivectomy incision, but it is also useful for smoothing root and bone surfaces made accessible by any surgical procedure. The Ochsenbein #1-2 (Fig. 41-55, A) is a useful chisel with a semicircular indentation on both sides of the shank that allows the instrument to engage around the tooth and into the interdental area. Surgical hoes are usually used with a pull stroke, whereas chisels are engaged with a push stroke. The Rhodes chisel is shown in Fig. 41-55, *B.*

Surgical Files

Periodontal surgical files are used primarily to smooth rough bony ledges and to remove all areas of bone. The Schluger (Fig. 41-56) and Sugarman files are similar in design and can be used with a push-and-pull stroke, primarily in the interdental areas.

Scissors and Nippers

Scissors and nippers are used in periodontal surgery for such purposes as removing tabs of tissue during gingivectomy, trimming the margins of flaps, enlarging incisions in periodontal abscesses, and removing muscle attachments in mucogingival surgery. There are many types, and the choice is a matter of individual preference. Fig. 41-57 shows the Goldman-Fox #16 scissors with a curved beveled blade with serrations and the nippers.

Needleholders

Needleholders are used to suture the flap at the desired position after the surgical procedure has been completed. The regular type of needleholder is illustrated in Figure 41-58, A, whereas Fig. 41-58, *B* shows the Castroviejo needleholder, which is used for delicate, precise techniques requiring quick and easy release and grasp of the suture.

SHARPENING OF PERIODONTAL INSTRUMENTS

It is impossible to carry out periodontal procedures efficiently with dull instruments. A sharp instrument cuts more precisely and quickly than a dull instrument. To do its job at all, a dull instrument must be held more firmly and pressed harder than a sharp instrument. This reduces tactile sensitivity and increases the possibility that the instrument will inadvertently slip. *Therefore to avoid*

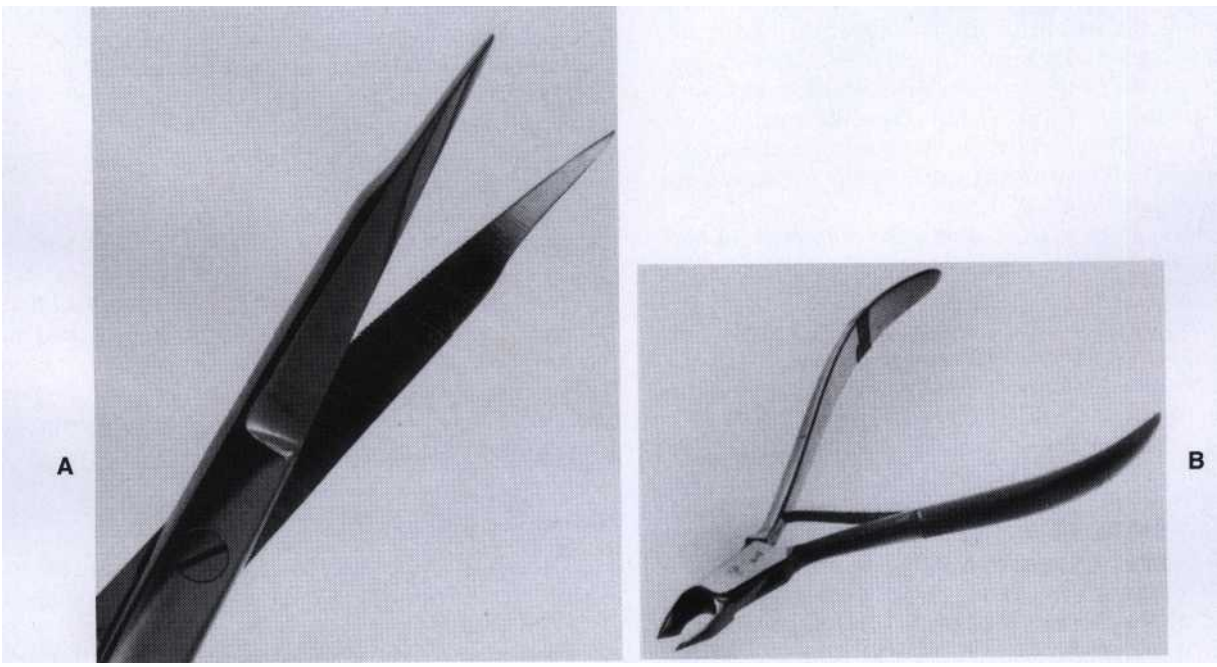

Fig. 41-57 A, Goldman-Fox #16 scissors. B, Nippers.

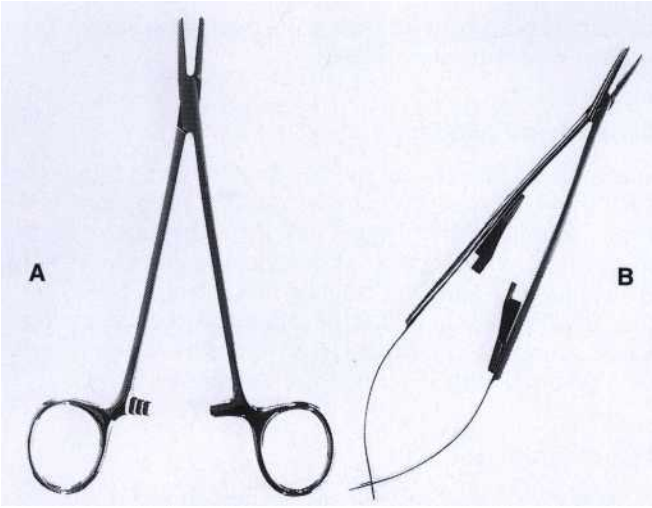

Fig. 41-58 A, Conventional needleholder. B, Castroviejo needleholder.

wasting time and operating haphazardly, clinicians must be thoroughly familiar with the principles of sharpening and able to apply them to produce a keen cutting edge on the instruments they are using. Development of this skill requires patience and practice, but clinical excellence cannot be attained without it.

SHARPNESS AND HOW TO EVALUATE IT

The cutting edge of an instrument is formed by the angular junction of two surfaces of its blade. The cutting edges of a curette, for example, are formed where the face of the blade meets the lateral surfaces (Fig. 41-59).

When the instrument is sharp, this junction is a fine line running the length of the cutting edge. As the instrument is used, metal is worn away at the cutting edge, and the junction of the face and lateral surface becomes rounded or dulled',' (Fig. 41-60). Thus the cutting edge becomes a rounded surface rather than an acute angle. This is why a dull instrument cuts less efficiently and requires more pressure to do its job.[12]

Sharpness can be evaluated by sight and touch in one of the following ways:

1. When a dull instrument is held under a light, the rounded surface of its cutting edge reflects light back to the observer. It appears as a bright line running the length of the cutting edge (Fig. 41-61). The acutely angled cutting edge of a sharp instrument, on the other hand, has no surface area to reflect light. When a sharp instrument is held under a light, no bright line can be observed (see Fig. 41-59).
2. Tactile evaluation of sharpness is performed by drawing the instrument lightly across an acrylic rod known as a *sharpening "test stick."* A dull instrument will slide smoothly, without "biting" into the surface and raising a light shaving as a sharp instrument would.[36]

The Objective of Sharpening

The objective of sharpening is to restore the fine, thin, linear cutting edge of the instrument. This is done by grinding the surfaces of the blade until their junction is once again sharply angular rather than rounded. For any given instrument, several sharpening techniques may produce this result. A technique is acceptable if it produces a sharp cutting edge without unduly wearing the instrument or altering its original design. To maintain the original design, the operator must understand the location and course of the cutting edges and the angles between the surfaces that form them. It is important to restore the cutting edge without distorting the original angles of the instrument. When these angles have been altered, the instrument does not function as it was designed to function, which limits its effectiveness.

Sharpening Stones

Sharpening stones may be quarried from natural mineral deposits or produced artificially. In either case, the surface of the stone is made up of abrasive crystals that are harder than the metal of the instrument to be sharpened. Coarse stones have larger particles and cut more rapidly; they are used on instruments that are dull. Finer stones with smaller crystals cut more slowly and are reserved for final sharpening to produce a finer edge and for sharpening instruments that are only slightly dull.[27-31] India and Arkansas oilstones are examples of natural abrasive stones. Carborundum, ruby, and ceramic stones are synthetically produced (Fig. 41-62).

Sharpening stones can also be categorized by their method of use.

Mounted Rotary Stones. These stones are mounted on a metal mandrel and used in a motor-driven handpiece. They may be cylindric, conical, or disc shaped. These stones are generally not recommended for routine use, because (1) they are difficult to control precisely and can ruin the shape of the instrument, (2) they tend to wear down the instrument quickly, and (3) they can generate quite a bit of frictional heat, which may affect the temper of the instrument.

Unmounted Stones. These come in a variety of sizes and shapes. Some are rectangular with flat or grooved surfaces, whereas others are cylindric or cone shaped. Unmounted stones may be used in two ways: the instrument may be stabilized and held stationary while the stone is drawn across it, or the stone may be stabilized and held stationary while the instrument is drawn across it.

Principles of Sharpening

1. Choose a stone suitable for the instrument to be sharpened-one that is of an appropriate shape and abrasiveness.
2. Use a sterilized sharpening stone if the instrument to be sharpened will not be resterilized before it is used on a patient.

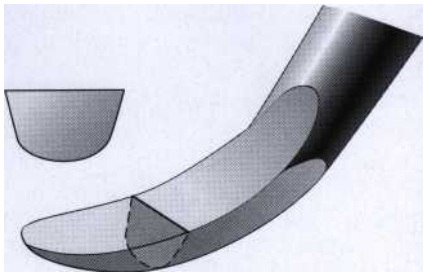

Fig. 41-59 The cutting edge of a curette is formed by the angular junction of the face and the lateral surfaces of the instrument. When the instrument is sharp, the cutting edge is a fine line.

Fig. 41-60 The cutting edge of a dull curette is rounded.

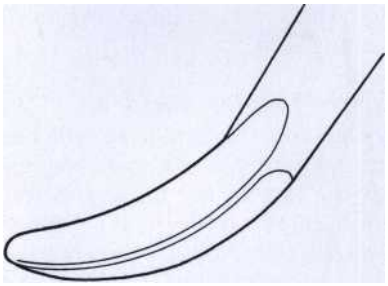

Fig. 41-61 Light reflected from the rounded cutting edge of a dull instrument appears as a bright line.

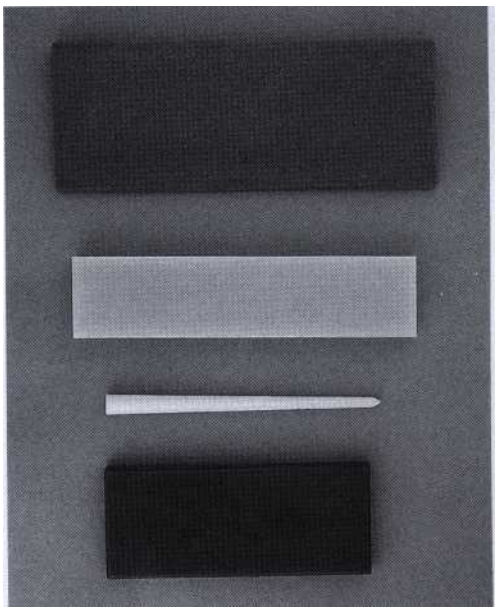

Fig. 41-62 Sharpening stones. Top *to bottom,* **A flat India stone, a flat Arkansas stone, a cone-shaped Arkansas stone, and a ceramic stone.**

3. Establish the proper angle between the sharpening stone and the surface of the instrument on the basis of an understanding of its design.
4. Maintain a stable, firm grasp of both the instrument and the sharpening stone. This ensures that the proper angulation is maintained throughout the controlled sharpening stroke. In this manner, the entire surface of the instrument can be reduced evenly, and the cutting edge is not improperly beveled.
5. Avoid excessive pressure. Heavy pressure causes the stone to grind the surface of the instrument more quickly and may shorten the instrument's life unnecessarily.
6. Avoid the formation of a "wire edge," characterized by minute filamentous projections of metal extending as a roughened ledge from the sharpened cutting edge.[1,12,24,36] When the instrument is used on root surfaces, these projections produce a **grooved surface rather than a** smooth surface. A wire edge is produced when the direction of the sharpening stroke is away from, rather than into or toward, the cutting edge.[1,24] When back-and-forth or up-and-down sharpening strokes are used, formation of a wire edge can be avoided by finishing with a down stroke toward the cutting edge."
7. Lubricate the stone during sharpening. This minimizes clogging of the abrasive surface of the sharpening stone with metal particles removed from the instrument.[12,24,36] It also reduces heat produced by friction. Oil should be used for natural stones and water for synthetic stones.
8. Sharpen instruments at the first sign of dullness. A grossly dull instrument is inefficient and requires more pressure when used, which hinders control. Furthermore, sharpening such an instrument requires the removal of a great deal of metal to produce a sharp cutting edge. This shortens the effective life of the instrument.

Sharpening Individual Instruments

Universal Curettes. Several techniques will produce a properly sharpened curette. Regardless of the technique used, the clinician must keep in mind that the angle between the face of the blade and the lateral surface of any curette is 70 to 80 degrees (Fig. 41-63). This is the most effective design for removing calculus and root planing. Changing this angle distorts the design of the instrument and makes it less effective. A cutting edge of less than 70 degrees is quite sharp but also thin (Fig. 41-64). It wears down quickly and becomes dull. A cutting edge of 90 degrees or more requires heavy lateral pressure to remove deposits. Calculus removal with such an instrument is often incomplete, and root planing cannot be done effectively (see Fig. 41-64).

The following technique is recommended because it enables the clinician to visualize the critical 70- to

80-degree angle easily and thereby consistently restores an effective cutting edge:

Sharpening the Lateral Surface. When a flat, hand-held stone is correctly applied to the lateral surface of a curette to maintain the 70- to 80-degree angle, the angle between the face of the blade and the surface of the stone will be 100 to 110 degrees (see Fig. 41-63). This can best be visualized by holding the curette so that the face of the blade is parallel with the floor. A palm grasp should be used and the upper arm braced against the body for support.

1. Apply the sharpening stone to the lateral surface of the curette so that the angle between the face of the blade and the stone is 100 to 110 degrees (Fig. 41-65; see Fig. 41-63).
2. Beginning at the shank end of the cutting edge and working toward the toe, activate the stone with short up-and-down strokes. Use consistent, light pressure and keep the stone continuously in contact with the blade. Make sure that the 100- to 110-degree angle is constantly maintained (see Fig. 41-65).
3. Check for sharpness as previously described, and continue sharpening as necessary. To prevent the toe of the curette from becoming pointed, sharpen the entire blade from shank end to toe. When approaching the toe, be sure to sharpen around it to preserve its rounded form (Fig. 41-66).
4. As the stone is moved along the cutting edge, finish each section with a down stroke into or toward the cutting edge. This will minimize the formation of a wire edge. Check the cutting edge under a light.
5. Sharpening the curette in this manner tends to flatten the lateral surface. This can be corrected by lightly grinding the lateral surface and the back of the instrument, away from the cutting edge, each time the instrument is sharpened.
6. When one edge has been properly sharpened, the opposite cutting edge can be sharpened in the same manner.

Sharpening the Face of the Blade. This may be done by moving a hand-held cylindric or cone-shaped stone back and forth across the face of the blade. A similar stone mounted in a hand-piece may also be used by applying it to the face of the blade with the stone rotating toward the toe. These methods are not recommended for routine use for the following reasons:

1. The angulation between the instrument and the stone is difficult to maintain, and therefore the blade may be improperly beveled (Fig. 41-67).'

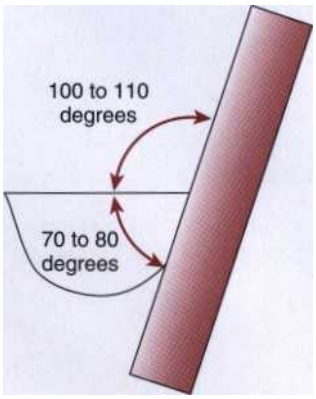

Fig. 41-63 When the sharpening stone forms a 100- **to 110-degree angle with the face of the** blade, **the 70- to 80-degree angle between the face and the lateral surface is automatically preserved.**

Fig. 41-64 At the left is a properly sharpened curette that maintains a 70- to 80-degree angle between its face and lateral surface. The curette in the center has been sharpened so that one of its cutting edges is less than 70 degrees. This fine edge is quite sharp but dulls easily. One of **the cutting edges of the curette on the right** has been sharpened to 90 degrees. Heavy lateral pressure must be applied to the tooth to remove deposits with such an instrument.

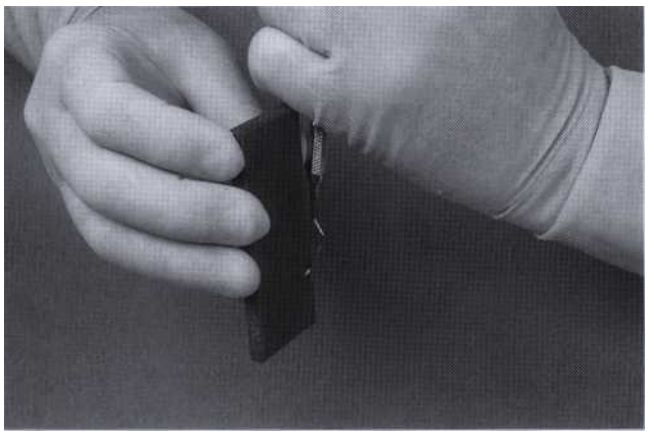

Fig. 41-65 Using a palm grasp, one holds **the universal curette so that the face of the blade is parallel to the floor.** The stone makes a 100- to 110-degree angle with the face of the blade.

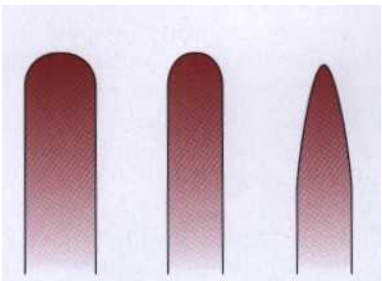

Fig. 41-66 At the left is a new, unsharpened curette viewed from directly above the face of the blade. **The curette in the center has been correctly** sharpened to maintain the rounded toe. The curette at the right has been incorrectly sharpened, producing a pointed toe.

2. Sharpening the face of the blade narrows the working end from face to back. This weakens the blade and makes it likely to bend or break while in use [1,18,24,29] (see Fig. 41-67).
3. Sharpening the face of the blade with a handheld stone using a back-and-forth motion produces a wire edge that interferes with the sharpness of the blade.'

Area-Specific (Gracey) Curettes. Like a universal curette, a Gracey curette has an angle of 70 to 80 degrees between the face and lateral surface of its blade. Therefore the technique described for sharpening a universal curette can be used to sharpen a Gracey curette. However, several unique design features that distinguish a Gracey from a universal curette must be understood to avoid distorting the design of the instrument while sharpening (see Gracey Curettes, pp. 571-574).

Gracey curettes have what is known as an *offset blade (i.e.,* the face of the blade is not perpendicular to the shank of the instrument, as it is on a universal curette, but is offset at a 70-degree angle [Fig. 41-68]). A Gracey curette is further distinguished by the curvature of its cutting edges. When viewed from directly above the face of the blade, the cutting edges of a universal curette extend in straight lines from shank to toe; both cutting edges can be used for scaling and root planing. The cutting edges of a Gracey curette, on the other hand, curve gently from shank to toe, and only the larger, outer cutting edge is used for scaling and root planing (Fig. 41-69).

With these points in mind, a Gracey curette is sharpened in the following manner:

1. Hold the curette so that the face of the blade is parallel with the floor. Because the blade is offset, the shank of the instrument will not be perpendicular to the floor, as it is with universal curettes (Fig. 41-70).

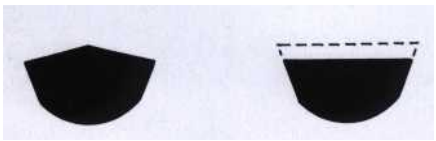

Fig. 41-67 Angulation is difficult to control when sharpening the face of the blade and often results in unwanted beveling, as shown at the left. Sharpening the face also weakens the blade by narrowing it from face to back, as shown at the right.

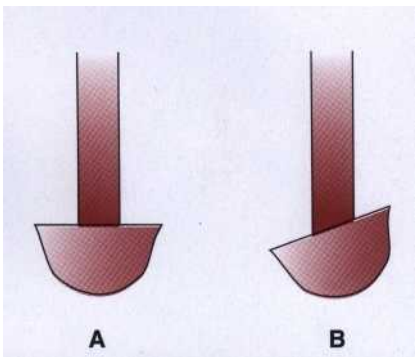

Fig. 41-68 A, The face of a universal curette is at 90 degrees to its shank. B, The face of a Gracey curette is offset, forming a 70-degree angle with its shank.

2. Identify the edge to be sharpened. Remember that only one cutting edge is used, so only that edge must be sharpened. Apply the stone to the lateral surface so that the angle between the face of the blade and the stone is 100 to 110 degrees.
3. Activate short up-and-down strokes, working from the shank end of the blade to the curved toe. Finish with a down stroke.
4. Remember that the cutting edge is curved. Preserve the curve by turning the stone while sharpening from shank to toe. If the stone is kept in one place for too many strokes, the blade will be flattened (Fig. 41-71).
5. Evaluate sharpness as previously described. Continue sharpening as necessary.

Extended Shank and Mini-Bladed Gracey Curettes. Extended shank Gracey curettes such as the After Fives are sharpened in exactly the same manner as the standard Gracey curettes. Although the terminal shank is 3 mm longer, the blade size and shape are

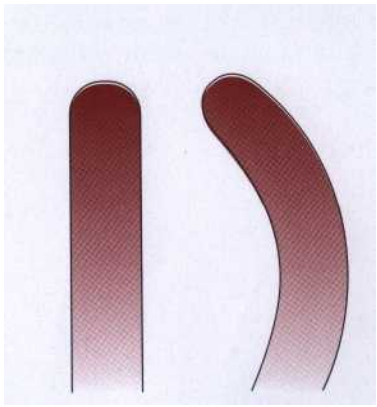

Fig. 41-69 The cutting edges of a universal curette extend straight from shank to toe. The cutting edges of a Gracey curette gently curve from shank to toe. Only the larger, outer cutting edge at the right is used for scaling and needs to be sharpened.

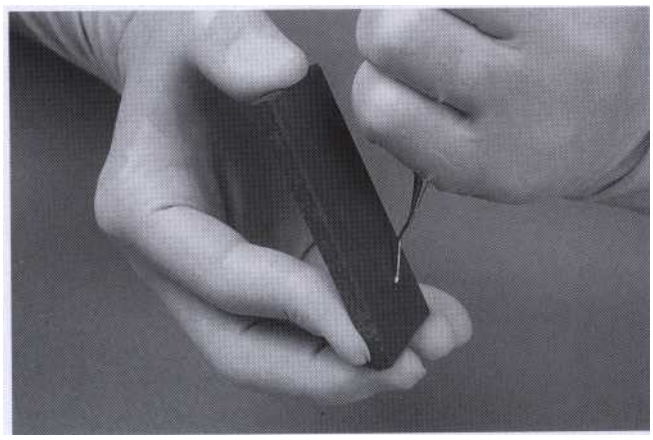

Fig. 41-70 Note that when a Gracey curette is held in proper sharpening position, its shank is not perpendicular to the floor, owing to its offset blade angle. The stone meets the blade at an angle of 100 to 110 degrees. Compare this position with the sharpening position of a universal curette, as shown in Fig. 41-65.

very similar, and therefore, there is no difference in the sharpening technique.

Mini-bladed Gracey curettes such as the Mini Fives or Gracey Curvettes are also sharpened with the same technique. These blades are only half the length of a standard Gracey blade, but the angle between the face and the lateral surface of the blade is still 70 to 80 degrees. However, sharpening too heavily or too often around the toe of a mini-bladed curette should be avoided to prevent excessive shortening of the blade.

Sickle Scalers. The two types of sickle scalers are the straight sickle and curved sickle. On a straight sickle, the face of the blade is flat from shank to tip, whereas on a curved sickle, the face of the blade forms a gentle curve (Fig. 41-72). The straight and curved sickles have similar cross-sectional designs, however. As in the curette, the angle between the face of the blade and the lateral surface of a sickle is 70 to 80 degrees (Fig. 41-73). When a sharpening stone is correctly applied to the lateral surface to preserve this angle, the angle between the face of the blade and the surface of the stone is 100 to 110 degrees. With this in mind, the sickle scaler can be sharpened in a manner much like that described for the curette except that the sickle has a sharp, pointed toe that must not be rounded.

A large, flat stone may also be used to sharpen sickles (Fig. 41-74). The stone is stabilized on a table or cabinet with the left hand. The sickle is held in the right hand with a modified pen grasp and applied to the stone so that the angle between the face of the blade and the stone is 100 to 110 degrees. The fourth finger is placed on the right-hand edge of the stone to stabilize and guide the sharpening movement. The right hand then pushes and pulls the sickle across the surface of the stone. To avoid a wire edge, finish with a pull stroke, being sure that the proper angulation is always maintained.

Chisels and Hoes. Chisels have a single, straight cutting edge that is perpendicular to the shank. The face of the blade is continuous with the shank of the instrument, which may be directly in line with the handle or slightly curved. The end of the blade is beveled at 45 degrees to form the cutting edge.

To sharpen a chisel, stabilize a flat sharpening stone on a flat surface. Grasp the instrument with a modified

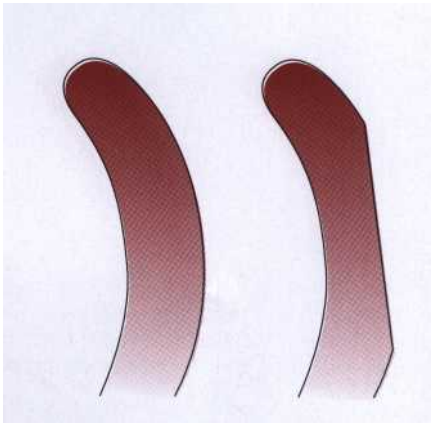

Fig. 41-71 The Gracey curette on the left has been properly sharpened to maintain a symmetric curve on its outer cutting edge. For the curette on the right, the sharpening stone was activated too long in one place, thereby flattening the blade.

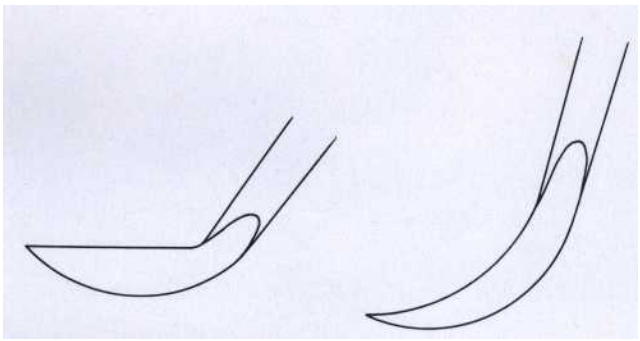

Fig. 41-72 The face of the blade on a straight sickle is flat from shank to tip, whereas on the curved sickle the blade face forms a gentle arc.

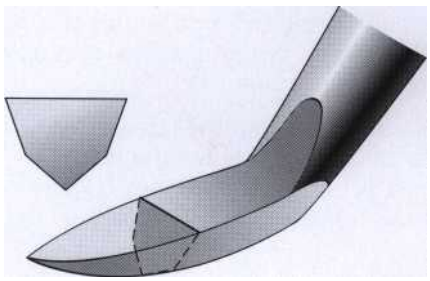

Fig. 41-73 Like the curette, the sickle has an angle of 70 to 80 degrees between the face of the blade and the lateral surface.

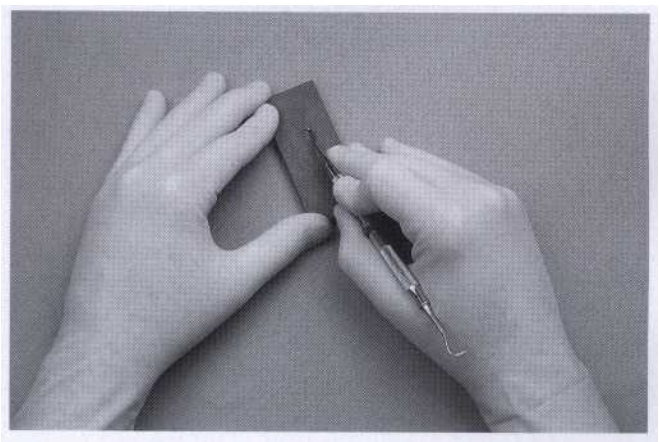

Fig. 41-74 A large, flat stone may also be used to sharpen the sickle. The stone is stabilized on a flat surface. The fourth finger of the right hand guides the sharpening stroke as the instrument is pulled across the face of the stone toward the operator.

pen grasp. Establish a finger rest with the pads of the third and fourth fingers against the straight edge of the sharpening stone. Apply the flat beveled surface of the chisel to the surface of the stone. If the entire surface of the bevel is contacting the stone, then the 45-degree angle between the beveled surface and the face of the blade will be maintained and the design of the instrument will not be altered (Figs. 41-75 and 41-76).

Using moderate, steady pressure, with the hand and arm acting as a unit and the finger resting on the edge of the stone as a guide, push the instrument across the surface of the sharpening stone. Release pressure slightly and draw the instrument back to its starting point. Repeat the sharpening stroke until a sharp edge has been obtained. Remember to finish with a push stroke to prevent the formation of a wire edge. Check for sharpness as previously described. Examine the instrument carefully to be sure that its design has not been inadvertently altered.

Back-action surgical chisels and hoe scalers are sharpened with exactly the same technique described for chisels except that a pull stroke is used rather than a push stroke (Fig. 41-77).

Periodontal Knives. There are two general types of periodontal knives. The first type includes the disposable scalpel blades that come prepackaged. They are presharpened and sterilized by the manufacturer. These are not resharpened when they become dull but are discarded and replaced.

The second type of periodontal knives is reusable and must be sharpened when they become dull. The most commonly used knives in this group are the flat-bladed gingivectomy knives (e.g., the Kirkland knives #15K and 16K) and the narrow, pointed interproximal knives.

FLAT-BLADED GINGIVECTOMY KNIVES. These knives have broad, flat blades that are nearly perpendicular to the lower shank of the instrument. The curved cutting edge extends around the entire outer edge of the blade and is formed by bevels on both the front and back surfaces of the blade (Fig. 41-78).

When sharpening these instruments, only the bevel on the back surface of the instrument needs be ground. This can be done by drawing the blade across a stationary flat sharpening stone or by holding the instrument stationary and drawing the stone across its blade.

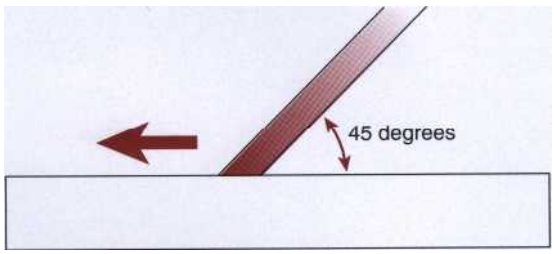

Fig. 41-75 When the entire bevel on a chisel contacts the sharpening stone, the angle between the instrument and the stone is 45 degrees. The cutting edge will be properly sharpened if this angle is maintained as the instrument is pushed across the stone.

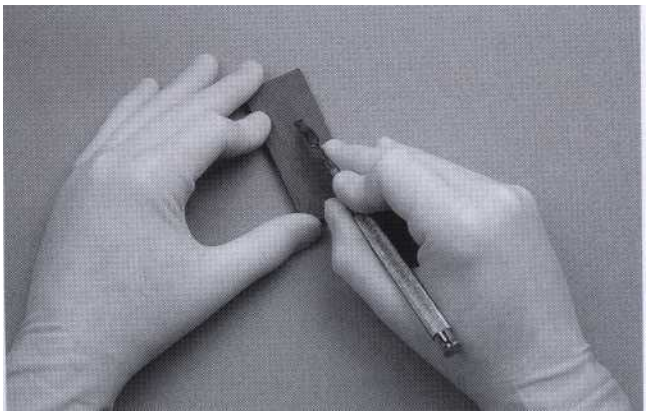

Fig. 41-76 The chisel is also sharpened on a stationary flat sharpening stone.

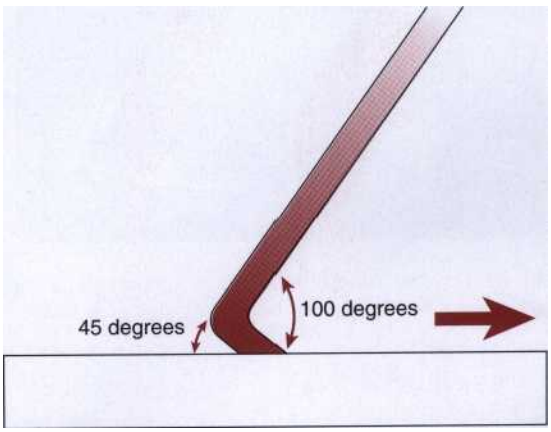

Fig. 41-77 Back-action chisels and hoes are sharpened with a pull stroke.

Fig. 41-78 Flat-bladed gingivectomy knives such as this Kirkland knife have a cutting edge that extends around the entire blade. The entire cutting edge must be sharpened.

INTERPROXIMAL KNIVES. The blades of interproximal knives have two long, straight cutting edges that come together at the sharply pointed tip of the instrument. The cutting edges are formed by bevels on the front and back surfaces of the blade. The entire blade is roughly perpendicular to the lower shank of the instrument (Fig. 41-79).

As with the flat-bladed gingivectomy knives, only the bevels on the back surface of the interproximal knives need to be sharpened. Again, this can be accomplished by drawing the instrument across a stationary stone or by holding the instrument stationary and moving the stone across it.

Stationary Stone Technique. Stabilize a flat sharpening stone on a flat surface. Grasp the handle of the instrument with a modified pen grasp, and apply the bevel on the back surface of the blade to the flat surface of the sharpening stone. With moderate pressure, pull the instrument toward you (Fig. 41-80 and Fig. 41-81). Release pressure slightly and return to the starting point. Begin at one end of the cutting edge and continue around the blade by rolling the handle of the instrument slightly between the thumb and the first and second fingers. Finish each section of the blade with a pull stroke to prevent formation of a wire edge. Check for sharpness as described previously.

Stationary Instrument Technique. Grasp the instrument with the palm. Apply the flat surface of a hand-held sharpening stone to the bevel on the back surface of the blade (Fig. 41-82). Begin at one end of the cutting edge and, with moderate pressure, draw the stone back and forth across the instrument. To prevent the formation of a wire edge, finish each section with a stroke into or toward the cutting edge. Proceed around the entire length of the cutting edge by gradually rotating the instrument and the stone in relation to one another.

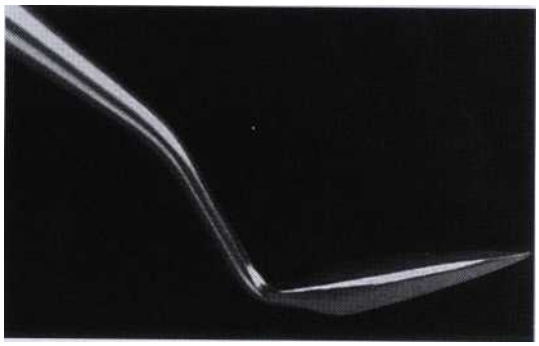

Fig. 41-79 The two cutting edges of an interproximal knife are formed by bevels on the front and back surfaces of the blade.

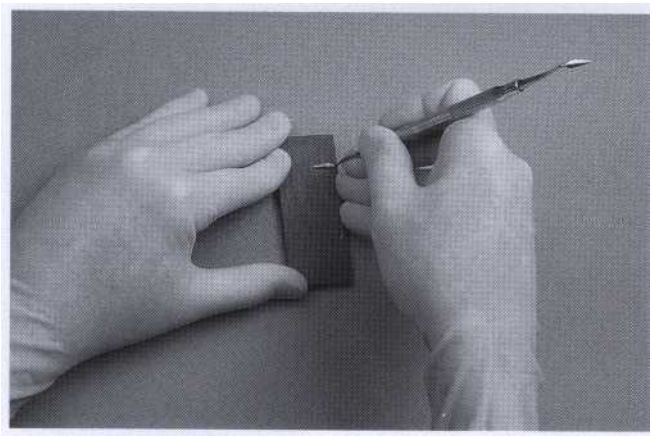

Fig. 41-81 The interproximal knife may be sharpened on a flat stationary stone. The blade is drawn toward the operator.

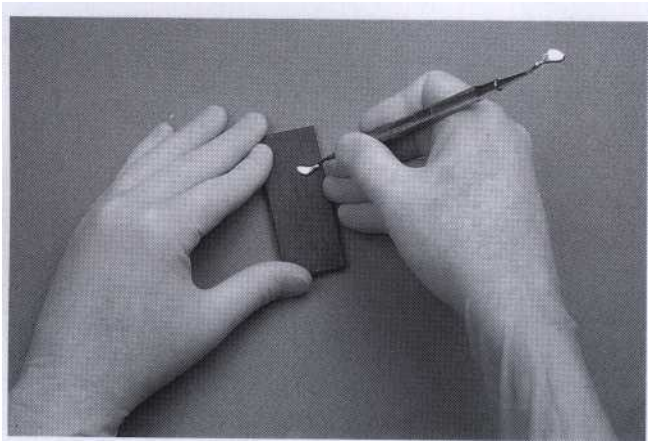

Fig. 41-80 The gingivectomy knife may be sharpened on a stationary flat stone. The instrument is held with a modified pen grasp. The fourth finger guides the sharpening stroke as the instrument is rolled between the fingers so that all sections of the blade are sharpened.

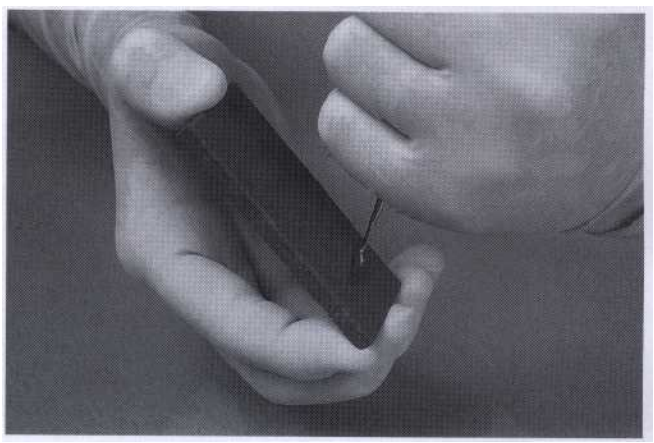

Fig. 41-82 The interproximal knife may also be sharpened with a hand-held stone. The instrument is held with a palm grasp, and the stone is applied to the entire cutting edge.

CHAPTER OUTLINE

GENERAL PRINCIPLES OF INSTRUMENTATION
- **Accessibility (Positioning of Patient and Operator)**
- **Visibility, Illumination, and Retraction**
- **Condition of Instruments (Sharpness)**
- **Maintaining a Clean Field**
- **Instrument Stabilization**
- **Instrument Activation**
- **Instruments for Scaling and Root Planing**

GENERAL PRINCIPLES OF INSTRUMENTATION

Effective instrumentation is governed by a number of general principles that are common to all periodontal instruments. Proper position of the patient and the operator, illumination and retraction for optimal visibility, and sharp instruments are fundamental prerequisites. A constant awareness of tooth and root morphologic features and of the condition of the periodontal tissues is also essential. Knowledge of instrument design enables the clinician to efficiently select the proper instrument for the procedure and the area in which it will be performed. In addition to these principles, the basic concepts of grasp, finger rest, adaptation, angulation, and stroke must be understood before clinical instrument-handling skills can be mastered.

Accessibility (Positioning of Patient and Operator)

Accessibility facilitates thoroughness of instrumentation. The position of the patient and operator should provide maximal accessibility to the area of operation. Inadequate accessibility impedes thorough instrumentation, prematurely tires the operator, and diminishes his or her effectiveness.

The clinician should be seated on a comfortable operating stool that has been positioned so that his or her feet are flat on the floor with the thighs parallel to the floor. The clinician should be able to observe the field of operation while keeping the **back straight and the head erect.**

The patient should be in a supine position and placed so that the mouth is close to the resting elbow of the clinician. For instrumentation of the maxillary arch, the patient should be asked to raise his or her chin slightly to provide optimal visibility and accessibility. For instrumentation on the mandibular arch, it may be necessary to raise the back of the chair slightly and request that the patient lower his or her chin until the mandible is parallel to the floor. This will especially facilitate work on the lingual surfaces of the mandibular anterior teeth.

Visibility, Illumination, and Retraction

Whenever possible, direct vision with direct illumination from the dental light is most desirable (Fig. 42-1). If this is not possible, indirect vision may be obtained by using the mouth mirror (Fig. 42-2), and indirect illumination may be obtained by using the mirror to reflect light to where it is needed (Fig. 42-3). Indirect vision and indirect illumination are often used simultaneously (Fig. 42-4).

Retraction provides visibility, accessibility, and illumination. Depending on the location of the area of operation, the fingers and/or the mirror are used for retraction. The mirror may be used for retraction of the cheeks

or the tongue, the index finger is used for retraction of the lips or cheeks. The following methods are effective for retraction:

1. Use of the mirror to deflect the cheek while the fingers of the nonoperating hand retract the lips and protect the angle of the mouth from irritation by the mirror handle
2. Use of the mirror alone to retract the lips and cheek (Fig. 42-5)
3. Use of the fingers of the nonoperating hand to retract the lips (Fig. 42-6)
4. Use of the mirror to retract the tongue (Fig. 42-7)
5. Combinations of the preceding methods

When retracting, care should be taken to avoid irritation to the angles of the mouth. If the lips and skin are dry, softening the lips with petroleum jelly before instrumentation is begun is a helpful precaution against cracking and bleeding. Careful retraction is especially important for patients with a history of recurrent *herpes* labialis, because these patients may easily develop herpetic lesions after instrumentation.

Condition of Instruments (Sharpness)

Before any instrumentation, all instruments should be inspected to make sure that they are clean, sterile, and in good condition. The working ends of pointed or bladed

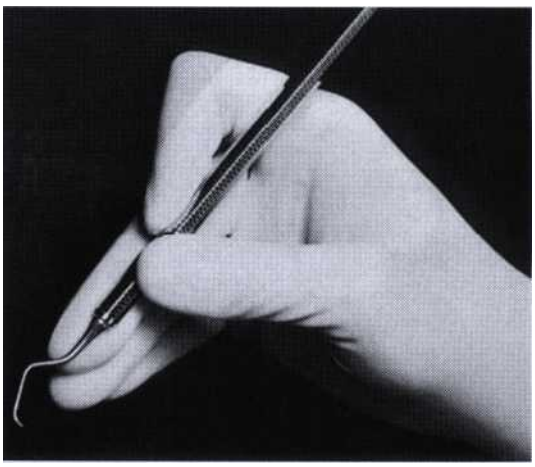

Fig. 42-8 Modified pen grasp. The pad of the middle finger rests on the shank.

instruments must be sharp to be effective. Sharp instruments enhance tactile sensitivity and allow the clinician to work more precisely and efficiently. Dull instruments may lead to incomplete calculus removal and unnecessary trauma because of the excess force usually applied to compensate for their ineffectiveness (see Chapter 41).

Maintaining a Clean Field

Despite good visibility, illumination, and retraction, instrumentation can be hampered if the operative field is obscured by saliva, blood, and debris. The pooling of saliva interferes with visibility during instrumentation and impedes control because a firm finger rest cannot be established on wet, slippery tooth surfaces. Adequate suction is essential and can be achieved with a saliva ejector or, if working with an assistant, an aspirator.

Gingival bleeding is an unavoidable consequence of subgingival instrumentation. In areas of inflammation this is not necessarily an indication of trauma from incorrect technique; instead, it indicates ulceration of the pocket epithelium. Blood and debris can be removed from the operative field with suction and by wiping or blotting with gauze squares. The operative field should also be flushed occasionally with water.

Compressed air and gauze squares can be used to facilitate visual inspection of tooth surfaces just below the gingival margin during instrumentation. A jet of air directed into the pocket deflects a retractable gingival margin. Retractable tissue can also be deflected away from the tooth by gently packing the edge of a gauze square into the pocket with the back of a curette. Immediately after the gauze is removed, the subgingival area should be clean, dry, and clearly visible for a brief interval.

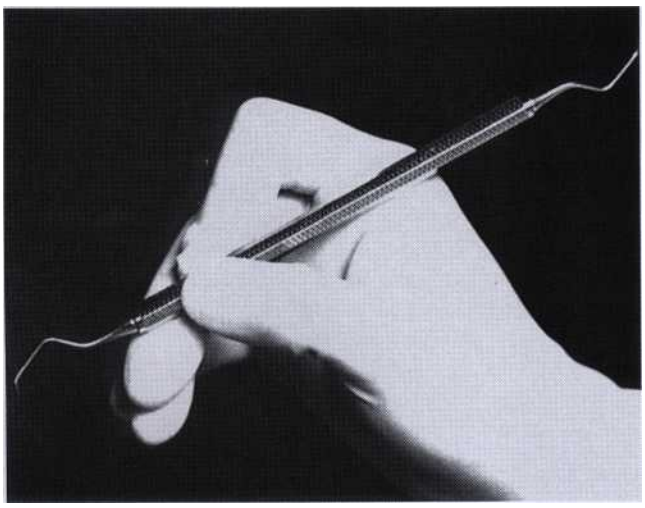

Fig. 42-9 **Standard pen grasp. The side of the middle finger rests on the shank.**

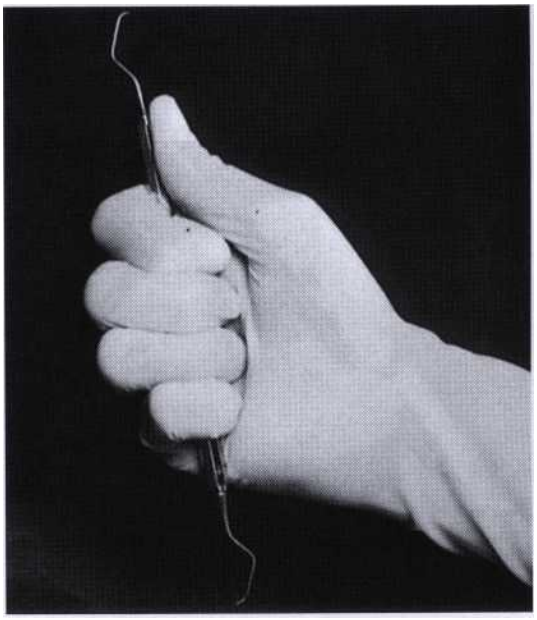

Fig. 42-10 **Palm and thumb grasp, used for stabilizing instruments during sharpening.**

Instrument Stabilization

Stability of the instrument and the hand is the primary requisite for controlled instrumentation. Stability and control are essential for effective instrumentation and avoidance of injury to the patient or clinician. The two factors of major importance in providing stability are the instrument grasp and the finger rest.

Instrument Grasp. A proper grasp is essential for precise control of movements made during periodontal instrumentation. The most effective and stable grasp for all periodontal instruments is the *modified pen grasp* (Fig. 42-8). Although other grasps are possible, this modification of the standard pen grasp (Fig. 42-9) ensures the greatest control in performing intraoral procedures.

The thumb, index finger, and middle finger are used to hold the instrument as a pen is held, but the middle finger is positioned so that the side of the pad next to the fingernail is resting on the instrument shank. The index finger is bent at the second joint from the finger tip and is positioned well above the middle finger on the same side of the handle.

The pad of the thumb is placed midway between the middle and index fingers on the opposite side of the handle. This creates a triangle of forces, or tripod effect, that enhances control because it counteracts the tendency of the instrument to turn uncontrollably between the fingers when scaling force is applied to the tooth. This stable modified pen grasp enhances control because it enables the clinician to roll the instrument in precise degrees with the thumb against the index and middle fingers to adapt the blade to the slightest changes in tooth contour. The modified pen grasp also enhances tactile sensitivity, because slight irregularities on the tooth surface are best perceived when the tactile-sensitive pad of the middle finger is placed on the shank of the instrument.

The *palm and thumb grasp* (Fig. 42-10) is useful for stabilizing instruments during sharpening and for manipulating air and water syringes, but it is not recommended for periodontal instrumentation. Maneuverability and tactile sensitivity are so inhibited by this grasp that it is unsuitable for the precise, controlled movements necessary during periodontal procedures.

Finger Rest. The finger rest serves to stabilize the hand and the instrument by providing a firm fulcrum as movements are made to activate the instrument. A good finger rest prevents injury and laceration of the gingiva and surrounding tissues by poorly controlled instruments. The fourth (ring) finger is preferred by most clinicians for the finger rest. Although it is possible to use the third (middle) finger for the finger rest, this is not recommended, because it restricts the arc of movement during the activation of strokes and severely curtails the use of the middle finger for both control and tactile sensitivity. Maximal control is achieved when the middle finger is kept between the instrument shank and the fourth finger. This "built-up" fulcrum is an integral part of the wrist-forearm action that activates the powerful working stroke for calculus removal. Whenever possible, these two fingers should be kept together to work as a one-unit fulcrum during scaling and root planing. Separation of the middle and fourth fingers during scaling strokes results in a loss of power and control because it forces the clinician to rely solely on finger flexing for activation of the instrument.

Finger rests may be generally classified as intraoral finger rests or extraoral fulcrums. Intraoral finger rests on tooth surfaces ideally are established close to the working area. Variations of intraoral finger rests and extraoral fulcrums are used whenever good angulation and a sufficient arc of movement cannot be achieved by a finger rest

close to the working area. The following examples illustrate the different variations of the intraoral finger rest:

1. Conventional: The finger rest is established on tooth surfaces immediately adjacent to the working area (Fig. 42-11).
2. Cross-arch: The finger rest is established on tooth surfaces on the other side of the same arch (Fig. 42-12).
3. Opposite-arch: The finger rest is established on tooth surfaces on the opposite arch (e.g., mandibular arch finger rest for instrumentation on the maxillary arch) (Fig. 42-13).
4. Finger-on-finger: The finger rest is established on the index finger or thumb of the nonoperating hand (Fig. 42-14).

Extraoral fulcrums are essential for effective instrumentation of some aspects of the maxillary posterior teeth. When properly established, they allow optimal access and angulation while providing adequate stabilization. Extraoral fulcrums are not finger rests in the literal sense, because the tips or pads of the fingers are not used for extraoral fulcrums as they are for intraoral finger rests. Instead, as much of the front or back surface of

Fig. 42-11 Intraoral conventional finger rest. The fourth finger rests on the occlusal surfaces of adjacent teeth.

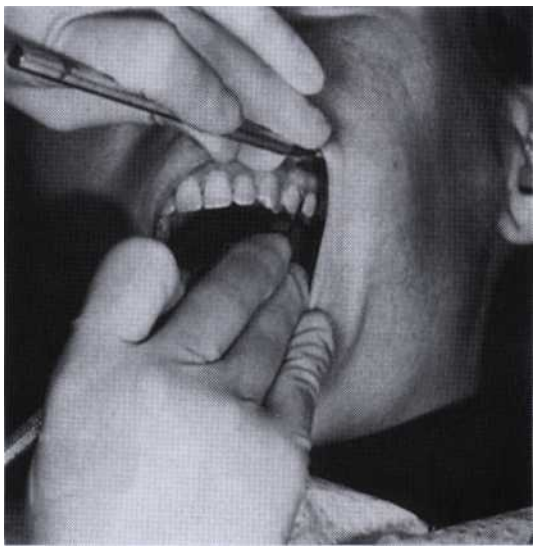

Fig. 42-13 Intraoral opposite-arch finger rest. The fourth finger rests on the mandibular teeth while the maxillary posterior teeth are instrumented.

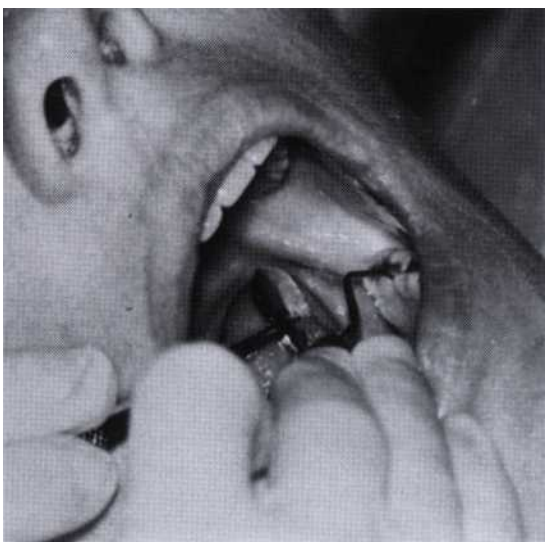

Fig. 42-12 Intraoral cross-arch finger rest. The fourth finger rests on the incisal surfaces of teeth on the opposite side of the same arch.

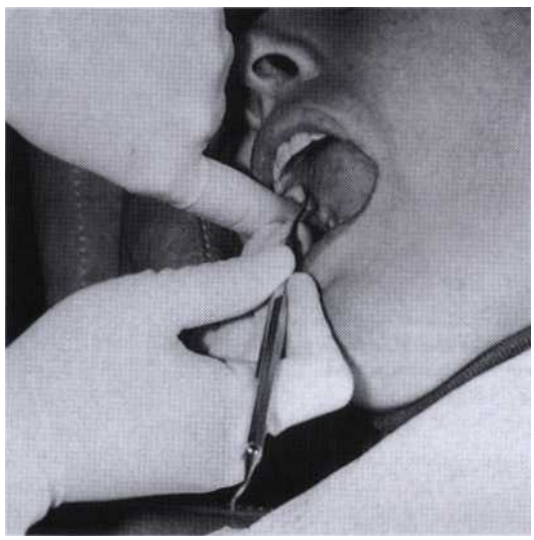

Fig. 42-14 Intraoral finger-on-finger rest. The fourth finger rests on the index finger of the nonoperating hand.

the fingers as possible is placed on the patient's face to provide the greatest degree of stability. The two most commonly used extraoral fulcrums are as follows:

1. *Palm-up:* The palm-up fulcrum is established by resting the backs of the middle and fourth fingers on the skin **overlying the lateral aspect of the mandible on the right side of the face (Fig.** 42-15).
2. *Palm-down:* The palm-down fulcrum is established by resting the front surfaces of the middle and fourth fingers on the skin overlying the lateral aspect of the mandible on the left side of the face (Fig. 42-16).

Both intraoral finger rests and extraoral fulcrums may be reinforced by applying the index finger or thumb of the nonoperating hand to the handle or shank of the instrument for added control and pressure against the tooth. The reinforcing finger is usually employed for opposite-arch or extraoral fulcrums when precise control and pressure are compromised by the longer distance between the fulcrum and the working end of the instrument. Fig. 42-17 shows the index finger-reinforced rest, and Fig. 42-18 shows the thumb-reinforced rest.

Instrument Activation

Adaptation. Adaptation refers to the manner in which the working end of a periodontal instrument is placed against the surface of a tooth. The objective of adaptation is to make the working end of the instrument conform to the contour of the tooth surface. Precise adaptation must be maintained with all instruments to avoid trauma to the soft tissues and root surfaces and to ensure maximum effectiveness of instrumentation.

Correct adaptation of the probe is quite simple. The tip and side of the probe should be flush against the tooth surface as vertical strokes are activated within the crevice. Bladed instruments such as curettes and sharp-pointed instruments such as explorers are more difficult to adapt. The ends of these instruments are sharp and can lacerate tissue, so adaptation in subgingival areas becomes especially important. The lower third of the working end, which is the last few millimeters adjacent to the toe or tip, must be kept in constant contact with the tooth while it is moving over varying tooth contours (Fig. 42-19). Precise adaptation is maintained by carefully rolling the handle of the instrument against the index and middle fingers with the thumb. This rotates the instrument in slight degrees so that the toe or tip leads into concavities and around convexities. On convex surfaces such as line angles, it is not possible to adapt more than 1 or 2 mm of the working end against the tooth. Even on what appear to be broader, flatter surfaces, no more than 1 or 2 mm of the working end can be adapted, because the tooth surface, although it may seem flat, is actually slightly curved.

If only the middle third of the working end is adapted on a convex surface so that the blade contacts the tooth at a tangent, the toe or sharp tip will jut out into soft tissue, causing trauma and discomfort (Fig. 42-20). If the instrument is adapted so that only the toe or tip is in contact, the soft tissue can be distended or compressed by the back of the working end, also causing trauma and discomfort. A curette that is improperly adapted in this manner can be particularly damaging, because the toe can gouge or groove the root surface.

Angulation. *Angulation* refers to the angle between the face of a bladed instrument and the tooth surface. It may also be called the tooth-blade relationship.

Correct angulation is essential for effective calculus removal. For subgingival insertion of a bladed instrument such as a curette, angulation should be as close to 0 degree as possible (Fig. 42-21). The end of the instrument can be inserted to the base of the pocket more easily with the face of the blade flush against the tooth. During scaling and root planing, optimal angulation is between 45 and 90 degrees (see Fig. 42-21). The exact blade angulation depends on the amount and nature of the calculus, the procedure being performed, and the condition of the tissue. Blade angulation is diminished or closed by tilting the lower shank of the instrument toward the tooth. It is increased or opened by tilting the lower shank away from the tooth. During scaling strokes on heavy, tenacious calculus, angulation should be just less than 90 degrees so that the cutting edge "bites" into the calculus. With angulation of less than 45 degrees, the cutting edge will not bite into or engage the calculus properly (see Fig. 42-21). Instead, it will slide over the calculus, smoothing or "burnishing" it. If angulation is more than 90 degrees, the lateral surface of the blade, rather than the cutting edge, will be against the tooth, and the calculus will not be removed and may become burnished (see Fig. 42-21). After the calculus has been removed, angulation of just less than 90 degrees may be maintained, or the angle may be slightly closed as the root surface is smoothed with light root planing strokes.

When gingival curettage is indicated, angulation greater than 90 degrees is deliberately established so that the cutting edge will engage and remove the pocket lining (see Fig. 42-21).

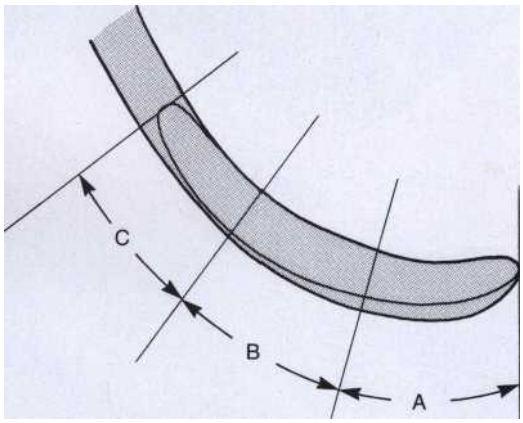

Fig. 42-19 Gracey curette blade divided into three segments: the lower one third of the blade, consisting of the terminal few millimeters adjacent to the toe (A); the middle one third (B); and the upper one third, which is adjacent to the shank (C).

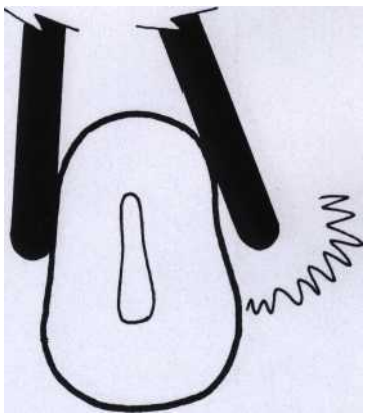

Fig. 42-20 glade adaptation. The curette on the left is properly adapted to the root surface. The curette on the right is incorrectly adapted; the toe juts out, lacerating the soft tissues.

Lateral Pressure. *Lateral pressure* refers to the pressure created when force is applied against the surface of a tooth with the cutting edge of a bladed instrument. The exact amount of pressure applied must be varied according to the nature of the calculus and according to whether the stroke is intended for initial scaling to remove calculus or for root planing to smooth the root surface.

Lateral pressure may be firm, moderate, or light. When removing calculus, lateral pressure is applied firmly or moderately initially and is progressively diminished until light lateral pressure is applied for the final root planing strokes. When insufficient lateral pressure is applied for the removal of heavy calculus, rough ledges or lumps may be shaved to thin, smooth sheets of burnished calculus that are difficult to detect and remove. This burnishing effect often occurs in areas of developmental depressions and along the cementoenamel junction (CEJ).

Although firm lateral pressure is necessary for the thorough removal of calculus, indiscriminate, unwarranted, or uncontrolled application of heavy forces during instrumentation should be avoided. Repeated application of excessively heavy strokes often nicks or gouges the root surface.

The careful application of varied and controlled amounts of lateral pressure during instrumentation is an integral part of effective scaling and root planing techniques and is absolutely critical to the success of both of these procedures.

Strokes. Three basic types of strokes are used during instrumentation: the exploratory stroke, the scaling stroke, and the root planing stroke. Any of these basic strokes may be activated by a pull or a push motion in a vertical, oblique, or horizontal direction (Fig. 42-22). Vertical and oblique strokes are used most frequently. Horizontal strokes are used selectively on line angles or deep pockets that cannot be negotiated with vertical or oblique strokes. The direction, length, pressure, and number of strokes necessary for either scaling or root planing are determined by four major factors: gingival position and tone, pocket depth and shape, tooth contour, and the amount and nature of the calculus or roughness.

The exploratory stroke is a light, "feeling" stroke that is used with probes and explorers to evaluate the dimensions of the pocket and to detect calculus and irregularities of the tooth surface. With bladed instruments such as the curette, the exploratory stroke is alternated with scaling and root planing strokes for these same purposes of evaluation and detection. The instrument is grasped lightly and adapted with light pressure against the tooth to achieve maximal tactile sensitivity.

The scaling stroke is a short, powerful pull stroke that is used with bladed instruments for the removal of both supragingival and subgingival calculus. The muscles of the fingers and hands are tensed to establish a secure grasp, and lateral pressure is firmly applied against the tooth surface. The cutting edge engages the apical border of the calculus and dislodges it with a firm movement in a coronal direction. The scaling motion should be initiated in the forearm and transmitted from the wrist to the hand with a slight flexing of the fingers. Rotation of the wrist is synchronized with movement of the forearm. The scaling stroke is not initiated in the wrist or fingers, nor is it carried out independently without the use of the forearm.

It is possible to initiate the scaling motion by rotating the wrist and forearm or by flexing the fingers. The use of wrist and forearm action versus finger motion has long been debated among clinicians. Perhaps the strong opinions on both sides should be the most valid indication that there is a time and a place for each. Neither method can be advocated exclusively, because a careful analysis of effective scaling and root planing technique

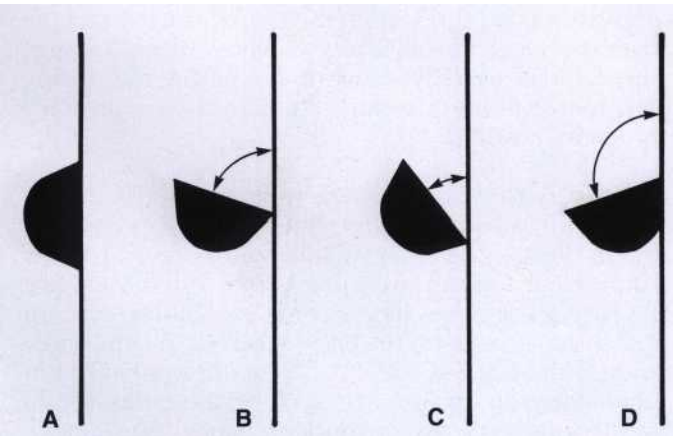

Fig. 42-21 Blade angulation. A, 0 degrees: correct angulation for blade insertion. B, 45 to 90 degrees: correct angulation for scaling and root planing. C, Less than 45 degrees: incorrect angulation for scaling and root planing. D, More than 90 degrees: incorrect angulation for scaling and root planing, correct angulation for gingival curettage.

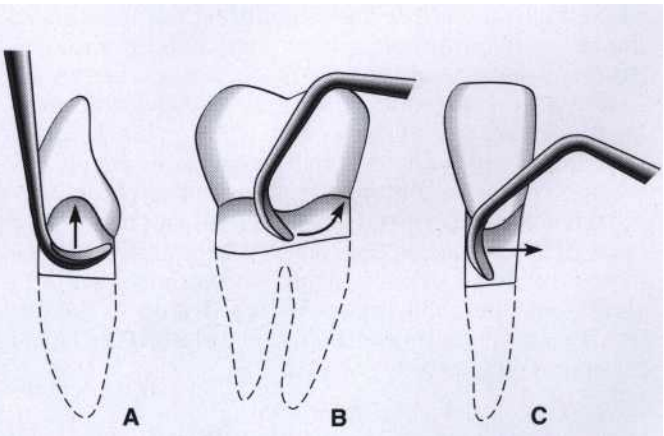

Fig. 42-22 Three basic stroke directions. A, Vertical; B, oblique; C, horizontal.

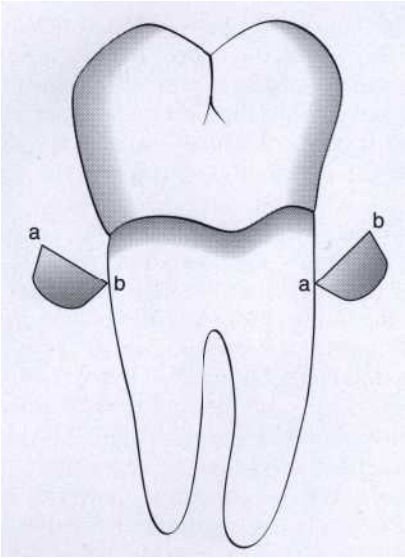

Fig. 42-23 Adaptation of the universal curette on a posterior tooth. Cross-sectional representations of the same universal curette blade as its cutting edges (a and b) are adapted to the mesial and distal surfaces of a posterior tooth.

reveals that, indeed, both types of **stroke activation are necessary for complete instrumentation.** The wrist and forearm motion, pivoting in an arc on the finger rest, produces a more powerful stroke and is therefore preferred for scaling. Finger flexing is indicated for precise control over stroke length in areas such as line angles and when horizontal strokes are used on the lingual or facial aspects of narrow-rooted teeth.

The push scaling motion has been advocated by some clinicians. In the push stroke, the instrument engages the lateral or coronal border of the calculus, and the fingers provide a thrust motion that dislodges the deposit. Because the push stroke may force calculus into the supporting tissues, its use, especially in an apical direction, is not recommended.

The root planing stroke is a moderate to light pull stroke that is used for final smoothing and planing of the root surface. Although hoes, files, and ultrasonic instruments have been used for root planing, curettes are widely acknowledged to be the most effective and versatile instruments for this procedure.[1-6,8,12-15] The design of the curette, which allows it to be more easily adapted to subgingival tooth contours, makes curettes particularly suitable for root planing in periodontal patients. With a moderately firm grasp, the curette is kept adapted to the tooth with even, lateral pressure. A continuous series of long, overlapping shaving strokes is activated. As the surface becomes smoother and resistance diminishes, lateral pressure is progressively reduced.

Instruments for Scaling and Root Planing

Universal Curettes. The working ends of the universal curette are designed in pairs so that all surfaces of the teeth can be treated with one double-ended instrument or a matched pair of single-ended instruments (see Fig. 42-16).

In any given quadrant, when approaching the tooth from the facial aspect, one end of the universal curette adapts to the mesial surfaces and the other end adapts to the distal surfaces. When approaching from the lingual aspect in the same quadrant, the double-ended universal curette must be turned end for end, because the blades are mirror images. This means that the end that adapts to the mesial surfaces on the facial aspect also adapts to the distal surfaces on the lingual aspect, and vice versa. Both ends of the universal curette are used to instrument the anterior teeth. On posterior teeth, however, owing to the limited access to distal surfaces, a single working end can be used to treat both mesial and distal surfaces by using both of its cutting edges. To do this, the instrument is first adapted to the mesial surface with the handle nearly parallel to the mesial surface. Because the face of the universal curette blade is honed at 90 degrees to the lower shank, if the lower shank is positioned so that it is absolutely parallel to the surface being instrumented, the tooth-blade angulation is 90 degrees. To close this angle and thus obtain proper working angulation, the lower shank must be tilted slightly toward the tooth. The distal surface of the same posterior tooth can be instrumented with the opposite cutting edge of the same blade. This cutting edge can be adapted at proper working angulation by positioning the handle so that it *is perpendicular* to the distal surface (Fig. 42-23).

When adapting the universal curette blade, as much of the cutting edge as possible should be in contact with the tooth surface, except on narrow convex surfaces such as line angles. Although the entire cutting edge should contact the tooth, pressure should be concentrated on the lower third of the blade during scaling strokes. During root planing strokes, however, lateral pressure should be distributed evenly along the cutting edge.

The primary advantage of these curettes is that they are designed to be used universally on all tooth surfaces, in all regions of the mouth. However, universal curettes have limited adaptability for the treatment of deep pockets in which apical migration of the attachment has exposed furcations, root convexities, and developmental depressions. For this reason, the Gracey curettes and the new modifications of Gracey curettes, which are area specific and specially designed for subgingival scaling and root planing in periodontal patients, are preferred by many clinicians.

Gracey Curettes. Gracey curettes (see Fig. 42-18) are a set of area-specific instruments that were designed by Dr. Clayton H. Gracey of Michigan in the mid-1930s. Four design features make the Gracey curettes unique: (1) they are area specific, (2) only one cutting edge on each blade is used, (3) the blade is curved in two planes, and (4) the blade is "offset." (These features have been summarized in Table 41-1.) Each of these features directly influences the manner in which the Gracey curettes are used and should be discussed individually.

AREA SPECIFICITY. There are seven pairs of curettes in the set. The Gracey curettes #1-2 and 3-4 are used on anterior teeth. The Gracey #5-6 may be used on both anterior and premolar teeth. The facial and lingual surfaces of posterior teeth are instrumented with Gracey

curettes #7-8 and 9-10. The Gracey #11-12 is designed for mesial surfaces of posterior teeth, and the #13-14 adapts to the distal surfaces of posterior teeth. Although these guidelines for areas of use were originally established by Dr. Clayton H. Gracey, it is possible to use a Gracey curette in an area of the mouth other than the one for which it was specifically designed if the general principles regarding these curettes are understood and applied. Gracey curettes need not be reserved exclusively for periodontal patients. In fact, many clinicians prefer Gracey curettes for general scaling because of their excellent adaptability.

SINGLE CUTTING EDGE USED. Like a universal curette, the Gracey curette has a blade with two cutting edges. Unlike the universal curette, however, the Gracey instrument is designed so that only one cutting edge is used. To determine which of the two is the correct cutting edge to adapt to the tooth, the blade should be held face up and parallel to the floor. When viewed from this angle, the blade can be seen to curve to the side. One cutting edge forms a larger outer curve and the other forms a shorter, small inner curve. The larger outer curve, which has also been described as the inferior cutting edge or as the cutting edge farther away from the handle, is the correct cutting edge (Fig. 42-24).

BLADE CURVES IN TWO PLANES. Like the toe of the universal curette, the toe of the Gracey curette curves upward. However, the toe of the Gracey curette also curves to the side, as mentioned in the preceding discussion. This unique curvature enhances the blade's adaptation to convexities and concavities as the working end is advanced around the tooth. Only the lower third or half of the Gracey blade is in contact with the tooth during instrumentation. The cutting edge of a universal curette blade, on the other hand, is straight and does not curve to the side. This makes it less adaptable to root concavities.

OFFSET BLADE. Gracey curette blades are honed at an offset angle, which means that the face of the blade is not perpendicular to the lower shank as it is on a universal curette. Instead, Gracey curettes are designed so that the tooth-blade working angulation is 60 to 70 degrees when the lower shank is held parallel to the tooth surface. Gracey curettes were originally designed to be used with push strokes and were beveled to provide a tooth-blade angulation of 40 degrees when the lower shank was parallel to the tooth surface; for many years, Gracey curettes were available only in this form. Currently Gracey curettes are available not only in the original push design, but also in a modified version to be used with pull strokes. It is important to understand this when purchasing Gracey curettes to avoid obtaining instruments that are not properly designed for pull strokes. If Gracey curettes that are designed to be used with push strokes are used with pull strokes instead, they are likely to burnish calculus rather than completely remove it. The design of the Gracey curette was modified in response to requests from clinicians who liked the shank design and adaptability of the original Gracey instruments but were opposed to the use of push strokes for scaling and root planing. The push stroke is not recommended, especially for the novice clinician, because it is likely to cause undue trauma to the junctional epithelium and to embed fragments of dislodged calculus in the soft tissues.

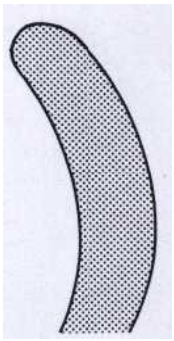

Fig. 42-24 Determining the correct cutting edge of a Gracey curette. When viewed from directly above the face of the blade, the correct cutting edge is the one forming the larger, outer curve on the right.

PRINCIPLES OF USE. The following general principles of use of the Gracey curettes are essentially the same as those for the universal curette; italicized principles apply only to Gracey curettes:

1. *Determine the correct cutting edge.* The correct cutting edge should be determined by visually inspecting the blade and confirmed by lightly adapting the chosen cutting edge to the tooth with the lower shank parallel to the surface of the tooth. With the toe pointed in the direction to be scaled (e.g., mesially with a #7-8 curette), only the back of the blade can be seen if the correct cutting edge has been selected (Fig. 42-25). If the wrong cutting edge has been adopted, the flat, shiny face of the blade will be seen instead (Fig. 42-26).
2. *Make sure the lower shank is parallel to the surface to be instrumented.* The lower shank of a Gracey curette is that portion of the shank between the blade and the first bend in the shank. Parallelism of the handle or upper shank is not an acceptable guide with Gracey curettes, because the angulations of the shanks vary. On anterior teeth, the lower shank of the Gracey #1-2, 3-4, or 5-6 should be parallel to the mesial, distal, facial, or lingual surfaces of the teeth (Fig. 42-27). On posterior teeth the lower shank of the #7-8 or 9-10 should be parallel to the facial or lingual surfaces of the teeth (Fig. 42-28); the lower shank of the #11-12 should be parallel to the mesial surfaces of the teeth (Fig. 42-29); and the lower shank of the #13-14 should be parallel to the distal surfaces of the teeth (Fig. 42-30).
3. When using intraoral finger rests, keep the fourth and middle fingers together in a built-up fulcrum for maximum control and wrist-arm action.
4. Use extraoral fulcrums or mandibular finger rests for optimal angulation when working on the maxillary posterior teeth.
5. Concentrate on using the lower third of the cutting edge for calculus removal, especially on line angles or when attempting to remove a calculus ledge by breaking it away in sections, beginning at the lateral edge.
6. Allow the wrist and forearm to carry the burden of the stroke, rather than flexing the fingers.

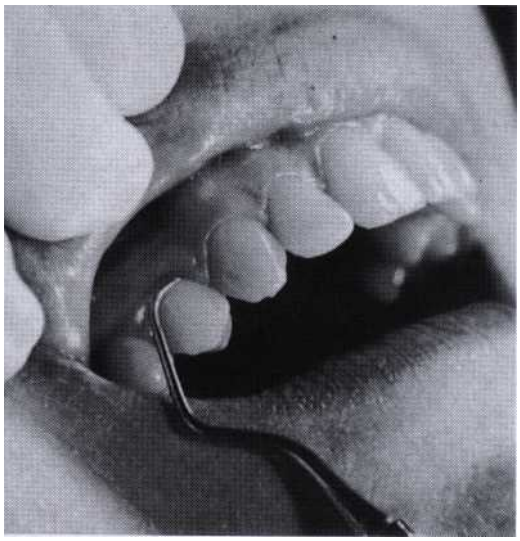

Fig. 42-25 Correct cutting edge of a Gracey curette adapted to the tooth.

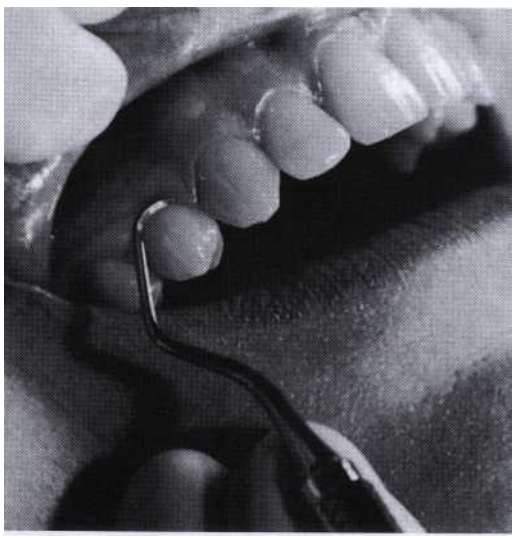

Fig. 42-26 Incorrect cutting edge of a Gracey curette adapted to the tooth.

7. Roll the handle slightly between the thumb and fingers to keep the blade adapted as the working end is advanced around line angles and into concavities.
8. Modulate lateral pressure from firm to moderate to light depending on the nature of the calculus, and reduce pressure as the transition is made from scaling to root planing strokes.

EXTENDED SHANK GRACEY CURETTES. Extended shank Gracey curettes such as the After Five curettes are 3 mm longer in the terminal shank than the standard Gracey curettes but are used with the same technique (see Fig. 41-23). They are most useful for deep pockets on maxillary and mandibular posterior teeth, where the longer terminal shank allows better access, especially to deep mesial and distal pockets (see Fig. 41-24). Although the longer lower shank makes access easier while using a conventional intraoral finger rest, the use of an extraoral fulcrum allows better access and adaptation to all of the maxillary posterior teeth. After Five curettes with rigid shanks should be used for scaling of heavy calculus; those with regular, finishing shanks should be used for periodontal maintenance patients with deep residual pockets.

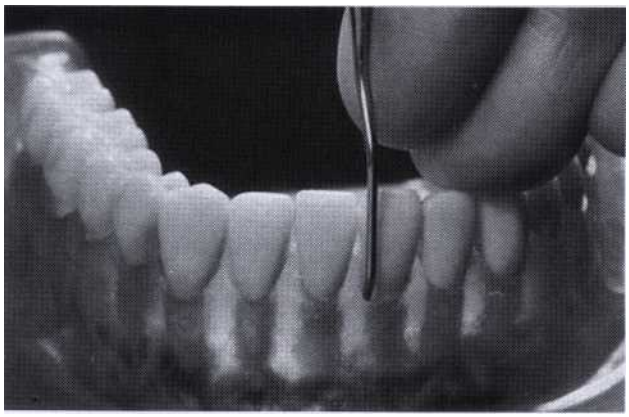

Fig. 42-27 Gracey #5-6 curette adapted to an anterior tooth.

MINI-BLADED GRACEY CURETTES. Mini-bladed Gracey curettes such as the Mini Five curettes and the Gracey Curvette curettes have a terminal shank that is 3 mm longer than the standard Gracey curettes and a blade that is 50% shorter (see Fig. 42-26 and Fig. 42-27). These mini-bladed instruments are generally used in the same manner as the Gracey curettes except for the following specific differences:

1. Mini-bladed curettes should not be used routinely in place of standard Gracey or After Five curettes. Instead, they should be used to supplement conventional curettes and ultrasonic instruments in areas of difficult access such as furcations; line angles, and deep, tight, or narrow pockets.
2. Large #4 handles are recommended for any mini-bladed instruments, because the larger diameter of the handles allows better control of the small blades.
3. Mini-bladed curettes can be used to scale with the toe directed either mesially or distally. In fact, the Mini Five curettes often adapt more effectively to the root curvatures of many posterior teeth when the blade is inserted with the toe pointed distally and strokes are activated from the mesial toward the distal line angle (Fig. 42-31).
4. Use rigid shank mini-bladed curettes for calculus removal. Use the thinner, standard shank mini-bladed curettes for deplaquing during maintenance.
5. When using mini-bladed curettes for calculus removal, use intraoral finger rests close to the working area. When performing light root planing or deplaquing, either intraoral or extraoral rests may be used. Extraoral rests are usually necessary to gain access to deep pockets on maxillary second and third molars.

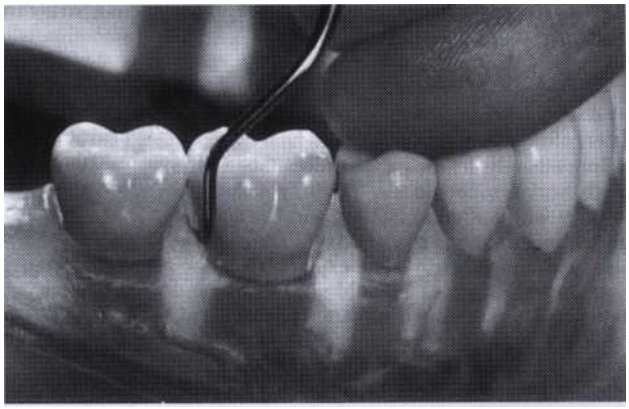

Fig. 42-30 Gracey #13-14 curette adapted to the distal surface of a posterior tooth.

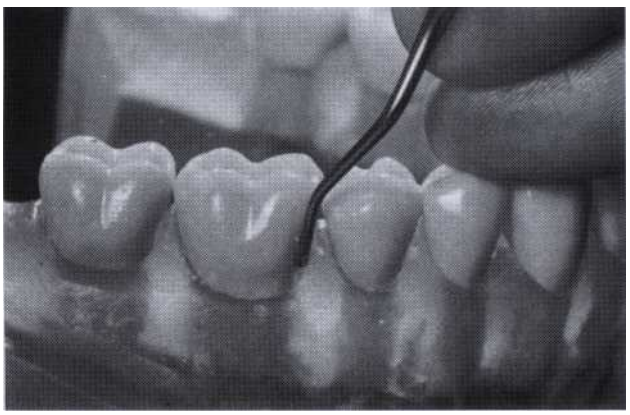

Fig. 42-29 Gracey #11-12 curette adapted to the mesial surface of a posterior tooth.

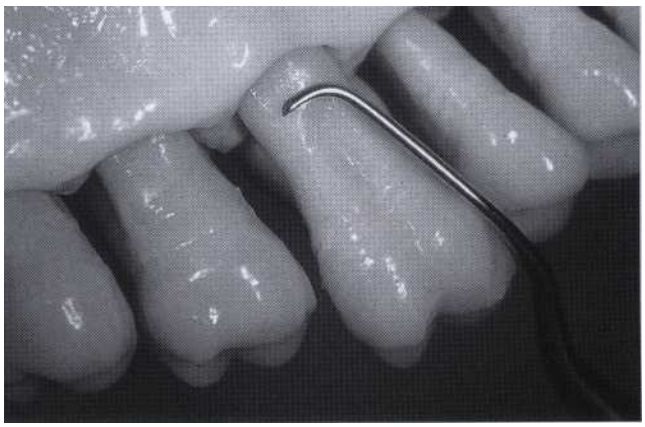

Fig. 42-31 Mini Five 13/14 curette adapted to the palatal surface of a maxillary molar with the toe directed distally.

6. Mini Fives are generally used with straight vertical strokes. They may also be used with oblique or horizontal strokes but due to the shortness of the blade, these strokes might not extend far enough subgingivally unless the tissue is very retractable. Horizontal strokes with the Mini Fives are most effective when used in the CEJ or in developmental depressions just below it.

When properly used, mini-bladed Gracey curettes allow unprecedented access and effectiveness for both nonsurgical and surgical root debridement. One study has shown that Gracey Curvette curettes performed better than standard Gracey curettes in deep anterior pockets.' In areas such as line angles; furcations; and narrow, curved, facial, or palatal root surfaces, these miniature curettes provide excellent adaptation with better tactile sensitivity than modified slim ultrasonic tips. Studies have shown that Gracey Curvette curettes performed better than ultrasonic slim tips on deep mandibular anterior pockets, furcations and furcation entrances.[9,10] No comparison of hand instruments and modified slim ultrasonic tips can be made unless mini-bladed curettes have been fully employed. To date, some research has been done to compare the effectiveness of mini-bladed instruments with the modified slim ultrasonic tips. There is a need for more of these studies to be performed in vivo to guide clinicians in the optimal utilization of these new types of instruments."

Systematic Approach

One of the central components of periodontal therapy is the removal of the subgingival bacterial biofilm and calculus that act as reservoirs for periodontopathogenic microrganisms. Traditionally, root surface debridement has been carried out with hand instruments such as curettes. Hand instrumentation is technically demanding, time consuming, tiring, and uncomfortable for both the operator and the patient, and as a result, numerous power-driven scalers have been developed during the last decades. Until recently, their use was mostly limited to supragingival debridement due to bulky working tips. Technologic advances and new designs of ultrasonic and sonic scalers have transformed the role of power-driven oscillating instruments in periodontal therapy. The probelike, slender instrument tips allow efficient instrumentation of deep periodontal pockets with increased patient comfort and less operator fatigue[10,12,25,54] (Fig. 43-1). Consequently, power-driven instrumentation has now become an accepted treatment modality in periodontal therapy.

SONIC SCALERS AND MAGNETOSTRICTIVE AND PIEZOELECTRIC ULTRASONIC SCALERS

Oscillating scaler systems can be divided into sonic scalers and magnetostrictive and piezoelectric ultrasonic scalers. Sonic scaler hand-pieces were invented during the 1960s (e.g., Densonic scaler, Titan S, KaVo Sonicflex)[62] and operate by compressed air from the dental unit. A rotating cam within the instrument hand-piece generates vibrations with frequencies in the range of 6000 Hz to 9000 Hz (Fig. 43-2). The vibrations are conducted to the scaler tip, which then oscillates, depending on the air pressure input, with an amplitude of up to 1000 j,m in an almost circular motion[20,29,34,59] (Fig. 43-3). Due to this oscillation pattern, irrespective of the adaptation of the tip to the root surface (i.e., mesial, distal, or buccal), plaque and calculus are removed by a tapping motion, which is one of the major advantages of the sonic scalers over the ultrasonic scalers (Fig. 43-4).

Magnetostrictive ultrasonic scalers (e.g., Dentsply Cavitron, Odontosson) were introduced in the 19505[62] and are either driven by a metal stack consisting of nickel-iron alloy strips or a Ferrite Insert inserted into a hand-piece (Figs. 43-5 and 43-6). Inside the hand-piece a live coil generates an alternating electromagnetic field that leads to expansion or contraction of the ferromagnetic material. The resulting vibrations are conducted to the scaler tip, causing oscillations with amplitudes of 13 to 72 Am and an elliptical motion pattern at frequencies of 20,000 Hz to 45,000 Hz.[34] Thus depending on the angulation of the scaler tip in relation to the root surface, a

Fig. 43-2 Sonic staler hand-piece fitted with slim staler tip (Type KaVo Sonicflex Lux 2000).

more or less pronounced hammering or scraping motion pattern will result (Fig. 43-4).

Piezoelectric scalers (e.g., Amdent, EMS Piezon Master, Satellec Suprasson) also oscillate with frequencies of 20,000 to 45,000 Hz (Fig. 43-7). The vibration is generated by changes in the dimension of a quartz crystal caused by the application of an alternating current. The resulting oscillation mode of the piezoelectric staler tip is strictly linear with amplitudes up to 72 /_Lm.34 The mode of action of the tip is either of a tapping or a scraping nature, depending on the direction of the sealer tip toward the root surface (see Fig. 43-4). Instrument power setting of magnetostrictive and piezoelectric ultrasonic scalers can be adjusted by the operator. A higher power setting increases the amplitude of tip oscillation, however, with a constant and stable tip oscillation frequency and motion pattern.

Safety and Efficacy of Oscillating Sealers

It is imperative to adjust the amount of substance removal and, consequently, the use of sonic and ultrasonic staler tips, according to the appropriate phase of periodontal therapy. In initial periodontal therapy an instrument needs to efficiently and rapidly remove tenacious calculus, whereas in maintenance therapy the instruments should efficiently remove bacterial biofilms while minimizing root substance removal .[9-35,12] In particular, during repeated maintenance visits, even minimal substance loss may accumulate over time and may lead to severe root damage. Factors influencing the amount of root substance removed during hand instrumentation have been well evaluated.[11,61] Assuming a correct angulation of the curette, the number of scaling strokes and the lateral force applied represent the two main parameters influencing the efficacy of hand instruments. However, using power-driven oscillating scalers, the instruments' efficacy and safety also depends on instrumentation time, lateral force, sealer tip angulation, and instrument power setting. In addition, the interactions of the working parameters create a highly complex pattern of substance removal. More detailed information regarding the influence of certain working parameters root substance loss for different oscillating sealer systems was gained by in vitro studies.[17-19] For sonic scalers (KaVo Sonicflex Lux 2000, KaVo, Biberach, Germany), lateral force showed the same impact on substance loss as staler tip angulation. Assuming that a defect depth of 0.5 mm, resulting from repeated subgingival scaling over 10 years of maintenance, is clinically acceptable and the same surfaces are always scaled, the average defect depth per year should not exceed 50 p,m. With respect to instrument safety, a resulting defect depth of 50 p,m after 40-second instrumentation time (average time spent for debridement of a root surface during maintenance within 1

year)' may be acceptable. Thus these instruments can be used safely if the scaler tip is angulated parallel to the root surface and the forces applied do not exceed 2N (Fig. 43-8). However, all other parameter combinations can lead to severe root damage.

In magnetostrictive ultrasonic scalers, tip angulation and lateral force also have an almost identical influence on substance removal. For all instrument power settings, assessed higher angulations and lateral forces resulted in greater defect depths. By contrast, an increasing instrument power setting does not lead to a pronounced increase in defect depth. The critical defect depth of 50 p,m can only be maintained if the scaler tip is angulated absolutely parallel to the root surface and the forces used do not exceed 1N (see Fig. 43-8).

As piezoelectric ultrasonic scalers show a linear oscillation pattern, root substance removal from these

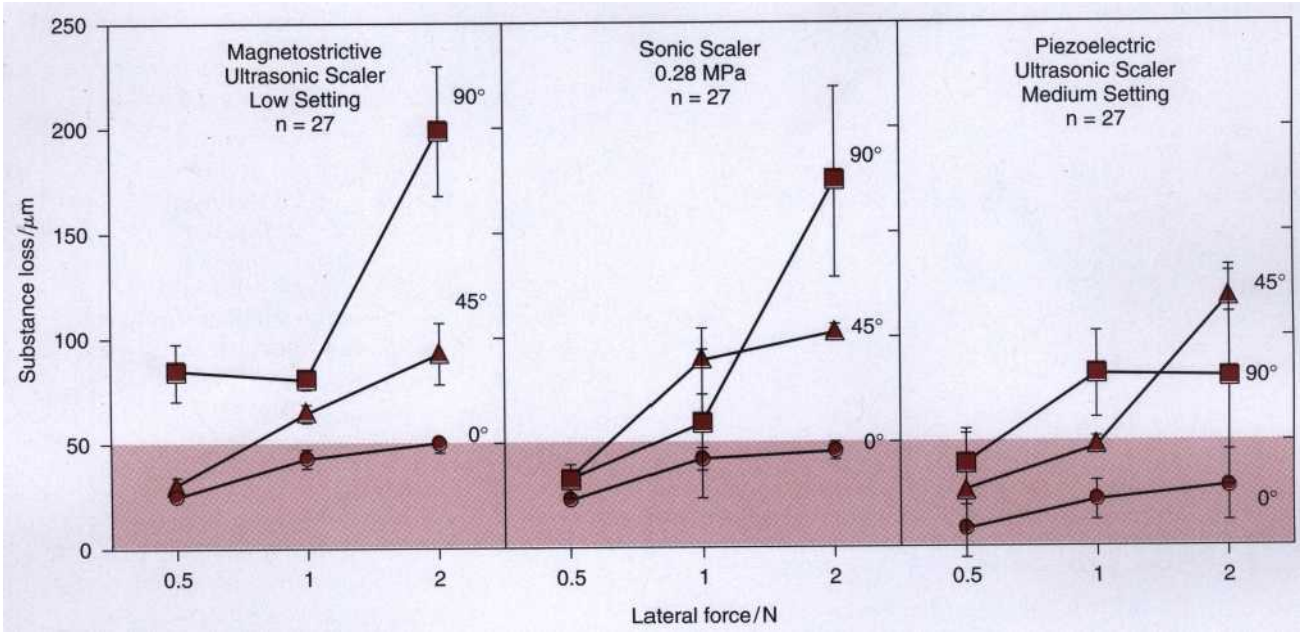

Fig. 43-8 Defect depth after 40-s instrumentation time with a piezoelectric scaler *(right),* **sonic scaler** *(center)* **and magnetostrictive ultrasonic scaler** *(left).* **The critical defect depth of 50 Am is marked by the shaded area. (From Flemmig T, Petersilka G, Mehl A, et al: Working parameters of a sonic scaler influencing root substance removal in vitro. Clin Oral Invest 1997; 1:55.)**

instruments is mostly influenced by scaler tip angulation. The greatest increment in defect depth was found with increasing tip angulation from 45 degrees to 90 degrees. In contrast, lateral force and the instrument power setting do not substantially influence substance loss. However, if the tip is angulated parallel to the root surface, the critical defect depth can be maintained below 50 gym, even if higher application forces up to 2N are used (Fig. 43-9).

Comparing the efficacy of oscillating scalers revealed that magnetostrictive ultrasonic scalers remove a larger amount of root substance at all power settings than the piezoelectric ultrasonic scaler. The efficacy of the sonic scaler is comparable to the efficacy of a magnetostrictive scaler at low power setting or to the efficacy of the piezoelectric scaler at medium power settings .[44]

Principles of Sonic and Ultrasonic Instrumentation

Indications. Indications and contraindications for sonic and ultrasonic scaling do not substantially differ from those given for the use of hand instruments in initial and supportive periodontal therapy. Clinical studies have shown that achievable attachment gain and pocket probing depth reduction after the use of hand instruments and sonic or different types of ultrasonic scalers are identical.[2-31,33] Numerous attempts have been made to investigate the quality-that is, the degree of roughness or root substance after different scaling modalities.[1,14,23,24,26,32,36,41,48,55] However, results are equivocal and difficult to compare as study designs and results vary greatly.

In addition, the quality of root surfaces after debridement is of reduced importance, as are the clinical results of root surface instrumentation. Subgingival root surface roughness does not seem to interfere with healing after scaling and root planing.[39,56] Thus it does not appear useful to reinstrument root surfaces with hand instruments after a clinically detectable smooth surface has been created with sonic or ultrasonic scalers. Complete instrumentation of molar furcational aspects is difficult to achieve either with hand or power-driven scalers.[16,28,42,43,16] This may be due to the fact that the average width of molar furcational entrances is smaller than the working end of conventional curets.[5] Additionally, even if access with small hand instruments is possible, it is difficult to implement proper working strokes within a furcation in the limited space available. Slim sonic or ultrasonic scaler tips allow access to the furcation and have been shown to be superior to hand instruments in cleaning furcation areas in vitro.[31,40]

Sonic and ultrasonic scalers should not be used when treating patients with transmissible diseases, since aerosol and splatter caused by sonic and ultrasonic scalers[21] are a potential health hazard to the operating dental staff.[4,22] Although the amount of microbial content in an aerosol generated during supragingival ultrasonic scaling may be reduced by using a preprocedural antiseptics rinse,[15,21] subgingival scaling procedures always result in the dispersion of blood. Thus splatter and aerosol still might be contaminated with pathogenic microorganisms. A careful operative technique and the use of high volume evacuators aid in minimizing the aerosol dispersion[47] and therefore are of high importance for infection control. Since magnetostrictive ultrasonic scalers

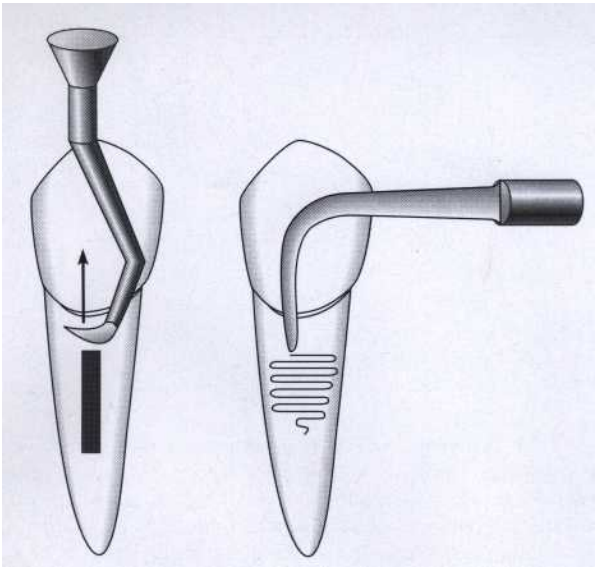

Fig. 43-9 Schematic drawing of the different patterns of the cleaning action of hand instruments versus power-driven oscillating scalers. Left, Using a hand curette allows a sectionwide cleaning of contaminated root surfaces. Right, Complete root surface debridement with oscillating scalers is achieved by carrying out serpentine-like, overlapping horizontal strokes in corono-apical direction. (Modified from Petersilka GJ, Flemmig TF: Subgingival root surface treatment using sonic and ultrasonic scalers. Parodontologie, 1999; 3:233.)

may interfere with some cardiac pacemakers, their use is also not recommended in affected patients due to health concerns.

Patient and Operator Positioning

Patient and operator positioning for sonic and ultrasonic instrumentation follow the same principles as for hand instrumentation. For instrumentation of the upper arch, the patient is seated in a supine position with the chin slightly lifted up. The backrest of the dental chair should be in approximately 45-degree angulation to the floor if treatment is carried out in the mandible. A slight lowering of the patient's chin allows good visibility to the lingual aspects of the lower front teeth. Good patient positioning should allow the operator to be seated upright; whenever necessary, indirect view or illumination by the use of dental mirrors should be used.

Site Evaluation

Before each scaling procedure, the clinician should carry out a thorough evaluation of the sites to be treated. This includes evaluation of pocket probing depth, root surface anatomy, and morphology (i.e., detection of surface irregularities such as calculus, furcations, or invaginations), as well as an adequate interpretation of radiographic findings. In combination with detailed anatomic knowledge, the operator should be able to develop a three dimensional picture of the periodontal pocket topography.

The Role of Coolant in Subgingival Sonic and Ultrasonic Scaling

The high frequency oscillation of sonic and ultrasonic scaler tips generates heat which necessitates the application of a cooling irrigation fluid to keep the tissues surrounding the scaler tip within a physiologic temperature range.[37] A flow rate of at least 14 ml/min to 23 ml/min cooling agent[22] appears to be sufficient to prevent thermal damages in periodontal pockets as the penetration of the coolant used correlates well with the depth of the pocket treated.[38] However, positioning of high volume evacuators close to the tip reduces the amount of coolant reaching the site being scaled and may lead to excessive heat generation.

Since only little lateral dispersion of the irrigation fluid from the scaler tip occurs, bacterial biofilm removal *in vivo is* most likely caused by mechanical disruption due to the oscillating tip. Possible cleaning mechanisms due to microstreaming effects or cavitation caused by collapsing microbubbles formed within the coolant surrounding the oscillating ultrasonic scalers tip have been detected *in vitro*.[27,57-60] In addition, cell disruption due to ultrasonic scaling has been shown in filamentous and rod-shaped bacteria.[3] However, these effects have not been proven to occur subgingivally, and cavitation is not likely to have an *in vitro* antimicrobial effect on periodontopathogenic bacteria such as *Actinobacillus actinomycetemcomitans* or *Porphyromonas gingivalis*.[50]

Several studies have evaluated the possible advantageous effects of the use of antimicrobials as a coolant. Although povidone-iodine solutions used as adjunctive irrigation liquid during ultrasonic scaling have been reported to have favorable clinical and microbiologic effects, there is a lack of clinically relevant attachment gain.[49] In addition, delivery of low concentration (0.1% to 0.2 %) chlorhexidine digluconate solutions as an irrigant during ultrasonic or sonic scaling does not appear to have relevant long-term benefits.[7,46,51,53] Therefore the use of antimicrobials cannot be considered as scientifically warranted at this time.

Instrument Power Setting

The power setting of sonic and ultrasonic scalers influences the amplitude of tip oscillation. Therefore a high instrument setting may generate pronounced aerosol and splatter formation and might reduce the volume of cooling agent that is delivered into the periodontal pocket. As treatment outcome is not significantly altered by instrument power setting' and high instrument power setting might facilitate unnecessary root substance removal,[17-19] power setting should be reduced to a low or medium level whenever possible.

Instrument Grasp and Finger Rest

To allow maximum instrument stabilization the instrument hand-piece should be held using a modified pen

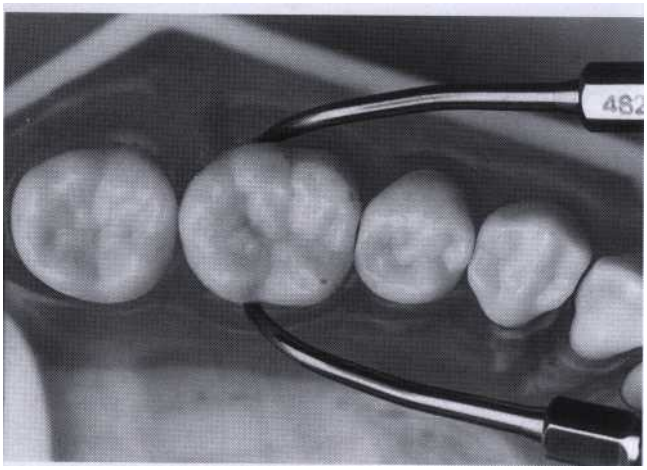

Fig. 43-10 Sample of scaler tip systems showing a left and right offset angulation. Note the correct application of the scaler tips to the root surface as the convex part is applied to the root surface only.

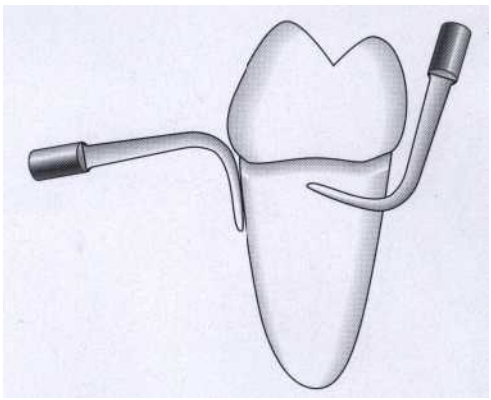

Fig. 43-11 Systematic approach of cleaning a root surface with slim scaler tips. The tip is applied parallel to the long axis of the tooth. Additionally, an oblique insertion of the tip for cleaning the contralateral interdental surface is recommended. Irrespective of the orientation to the long axis of the tooth, the tip needs to be applied parallel to the root surface treated to avoid root surface damage. (Modified from Petersilka GJ, Flemmig TF: Subgingival root surface treatment using sonic and ultrasonic scalers. Parodontologie 1999; 3:233.)

grasp. With hand instrumentation an intraoral finger rest is recommended for instrumentation of teeth in the lower arch and in the upper front segment. An extraoral palm rest should be chosen while instrumenting maxillary posterior teeth, with the back of the hand in the right maxillary area or with the palm of the hand in the left area respectively.

Systematic Approach

Studies to date have failed to confirm that power-driven root instrumentation is much more rapid than hand instrumentation [2,30,55] Experienced operators have been shown to instrument root surfaces more thoroughly, [6,13,16,28] so a systematic approach in learning the use of power-driven instruments is necessary to achieve the best clinical results. The application and implementation of sonic and ultrasonic instruments is different from that required for hand instrumentation. Plaque and calculus removal with hand instruments is achieved by carrying out a series of overlapping vertical strokes around the circumference of the tooth. Because the contact surface between a rounded power-driven scaler tip and the spherical root surface is rather small, thorough mechanical debridement can only be attained by a series of overlapping horizontal serpentine-like strokes in a coronal-apical direction (Fig 43-10). Using the appropriate working parameters and instrument settings, roots should be instrumented with the scaler tip in constant motion until the surface feels smooth and clean. The use of an explorer helps detect residual calculus and prevents inadvertent root overinstrumentation. To allow sufficient access to all tooth surfaces within the whole dentition, most sonic and ultrasonic scaler systems operate with two different working tips showing a left and right offset angulation (Fig. 43-10). For the use of these slim instruments it is of utmost importance that they be inserted into the pocket in a manner in which the convex working surface of the tip is in contact to the root (Fig. 43-11).[41] Using the concave side as a working surface bears the risk that the instrument tip will be applied perpendicular to the root surface leading to unnecessary gauging and root surface damage. The left bent tip is used for the instrumentation of **the maxillary** right posterior facial aspect, the maxillary front teeth palatal aspect and the maxillary left palatal aspect (Fig. 43-12). In addition, the contralateral approximal tooth surfaces may be cleaned with the same left offset tip inserted in an almost oblique/horizontal position (see Fig. 43-11). The right offset tip is used to instrument the remaining areas to be treated (see Fig. 43-12). For instrumentation in the mandible the left offset tip should be used for the right lingual molar area, the lower buccal frontal segment, and the lower left buccal posterior area. As in the maxilla, the right bent tip is used for the instrumentation of the corresponding sites remaining to be treated (see Fig. 43-11).

By using this systematic approach, a complete and efficient instrumentation of the entire dentition is attainable and both patient and operator will benefit from the use of sonic and ultrasonic scalers.

SUPRAGINGIVAL IRRIGATION
Supragingival Irrigation as a Monotherapy
Supragingival Water Irrigation and Toothbrushing
Antimicrobial Agents and Toothbrushing
SUBGINGIVAL IRRIGATION
Subgingival Irrigation as a Monotherapy for Periodontitis
Antimicrobial Agents and Scaling and Root Planing
SAFETY OF IRRIGATION

In the treatment of periodontal diseases, irrigation is used as a lavage to flush away the bacteria that are in contact with the periodontal tissues. Irrigation is a nonspecific reduction of plaque bacteria. The two types of irrigation are supragingival and subgingival irrigation. They vary by the depth to which the irrigant is projected into the gingival or periodontal pocket. In supragingival irrigation, the irrigant penetrates 29% to 71% of shallow pockets, and 44% to 68% of moderately deep and deep pockets[9,21] compared with 75% to 93% of the periodontal pocket that is penetrated by subgingival irrigation.[9,12,30] Mouth rinses penetrate only 4% of the pocket depth and are therefore largely restricted to the supragingival area[55] (Fig. 44-1).

IRRIGATOR DEVICES

A number of irrigators offered today vary by irrigation pressure, water stream characteristics, and jet type design. A syringe can also be used for delivering a solution to irrigate the pocket (Fig. 44-2). Monojet or multistreamed jet tips are available for supragingival irrigation, as well as blunted cannulae with end or side parts for subgingival irrigation. In most units the irrigation pressure is produced by an electrical pump and is delivered in a continuous or pulsating stream. The alternating compression and decompression phases in pulsating irrigators may facilitate the displacement of plaque bacteria.[7] A continuous flow of water during irrigation causes constant tissue compression and may impair removal of bacteria. The majority of information available on the therapeutic effects of supragingival irrigation are based on studies using pulsating monojet irrigators, and multistreamed irrigators have been insufficiently examined to date. For this reason, pulsating monojet irrigators are preferred for supragingival irrigation.

SUPRAGINGIVAL IRRIGATION

Supragingival irrigation is usually performed once or twice daily by the patient as an adjunct to toothbrushing and flossing. The irrigator's nozzle should be positioned at some distance from the gingival margin and the jet stream lined perpendicular to the long axis of the teeth to achieve optimal subgingival penetration of an irrigant" (Fig. 44-3). Irrigation pressures of 540 kPa to 620 kPa (80 psi to 90 psi) can be tolerated without adverse effects.[8,9] No histologic alteration of the gingiva has been observed after supragingival irrigation at a pressure of 410 kPa (60 psi).[6]

Supragingival Irrigation as a Monotherapy

Supragingival irrigation with water alone does not sufficiently prevent plaque accumulation nor gingivitis. In this respect, supragingival irrigation is clearly inferior to mechanical plaque control such as using conventional oral hygiene measures.[33] Thus supragingival irrigation

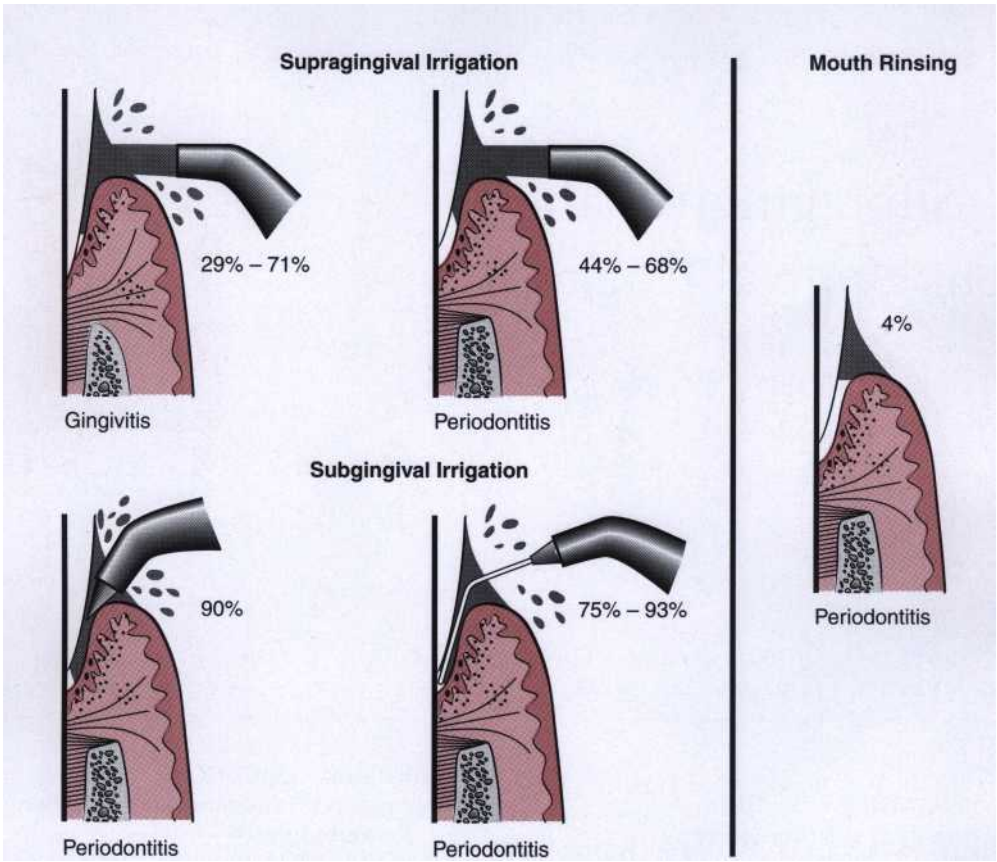

Fig. 44-1 Subgingival penetration of solutions delivered by supragingival or subgingival irrigation and rinsing in percent of pocket depth.

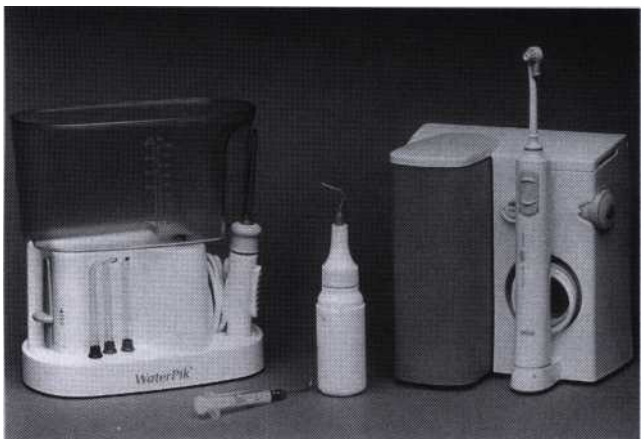

Fig. 44-2 Devices for supra- and subgingival irrigation.

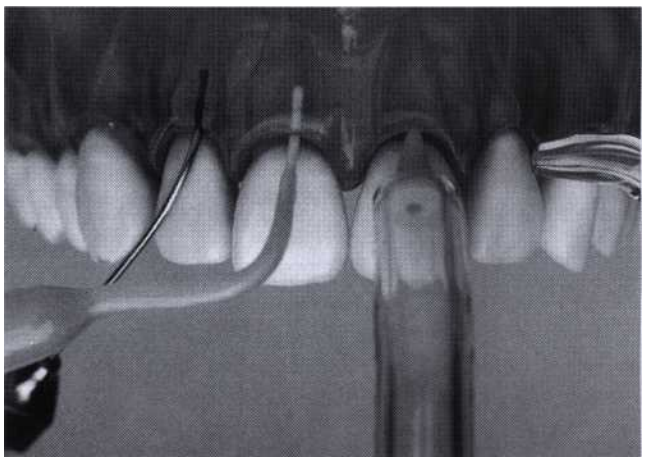

Fig. 44-3 Positioning of various irrigator tips for supragingival *(extreme right)* **and subgingival irrigation** *(others).*

cannot replace toothbrushing and should only be used as an adjunct to toothbrushing and interdental cleaning.

Supragingival Water Irrigation and Toothbrushing

Although earlier studies concerning supragingival water irrigation as an adjunct to toothbrushing yielded controversial results,[18,22,32,33] recent studies have clearly demonstrated that this method in conjunction with toothbrushing can improve the periodontal health in patients with gingivitis and/or periodontitis, particularly for patients with clinical signs of gingival inflammation and/or poor oral hygiene[13,25,26,34,49] (Fig. 44-4). However, patients with low plaque scores (i.e., good oral hygiene) have no additional benefit from supragingival irrigation",[33] (Fig. 44-5).

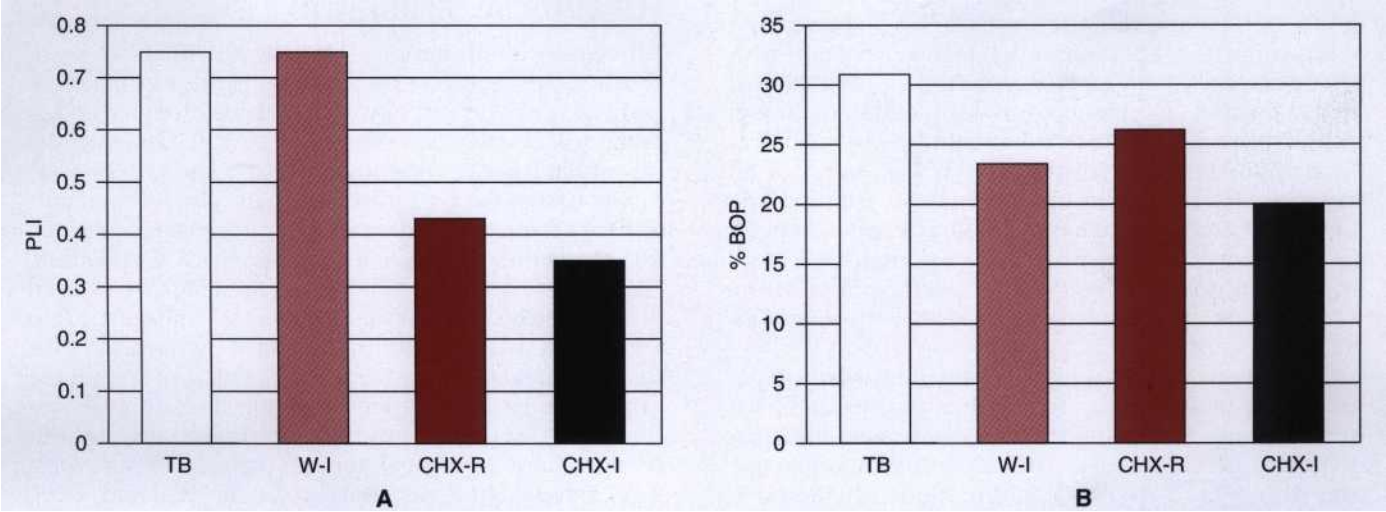

Fig. 44-4 Covariance adjusted mean plaque index scores (PLI) and percent of sites with bleeding on probing (BOP) in patients with naturally occurring gingivitis after 6 months of adjunctive irrigation. Supragingival irrigation was performed with 500 ml water (W-I) or 300 ml of water immediately followed by irrigation of 200 ml 0.06% chlorhexidine digluconate (CHX-I). Adjunctive rinsing with 15 ml of 0.12% chlorhexidine digluconate for 30 seconds twice daily (CHX-R) and toothbrushing alone (TB) were used as positive and negative controls, respectively. All groups performed regular tooth brushing.[25]

The therapeutic effects of supragingival irrigation with water on gingival inflammation is considerable and has been shown to be equivalent to twice daily mouth rinsing with 0.12% chlorhexidine digluconate solution in patients with gingivitis[25] (see Fig. 44-4). Daily supragingival irrigation with water after initial therapy may also improve gingival health among patients with periodontitis.[3] In patients receiving regular supportive periodontal therapy, daily supragingival irrigation with water can significantly reduce gingival inflammation and bleeding on probing.[26,49] Interestingly, supragingival irrigation with water has only limited effects on plaque scores-that is, supragingival plaque mass or the composition of the subgingival microflora.[17,20,25,26,48]

Earlier reports of direct bactericidal effects from irrigation resulting in the reduction of bacterial cell contents" have not been confirmed. Thus it may be possible that supragingival irrigation reduces gingival inflammation without altering the supra- and subgingival plaque. Although the responsible mechanism for the antiinflammatory effect is not clearly known, it can be assumed that through supragingival irrigation, there is a dilution or a removal of bacterial toxins, an interference with plaque maturation, or a possibility that the unattached plaque may be washed away. One may also speculate that the additional bacteremia caused by supragingival irrigation[23,57] may stimulate the production of specific antibodies directed against periodontal pathogens.[62] Such antibodies have been shown to be protective and reduce periodontal disease progression.[5,29]

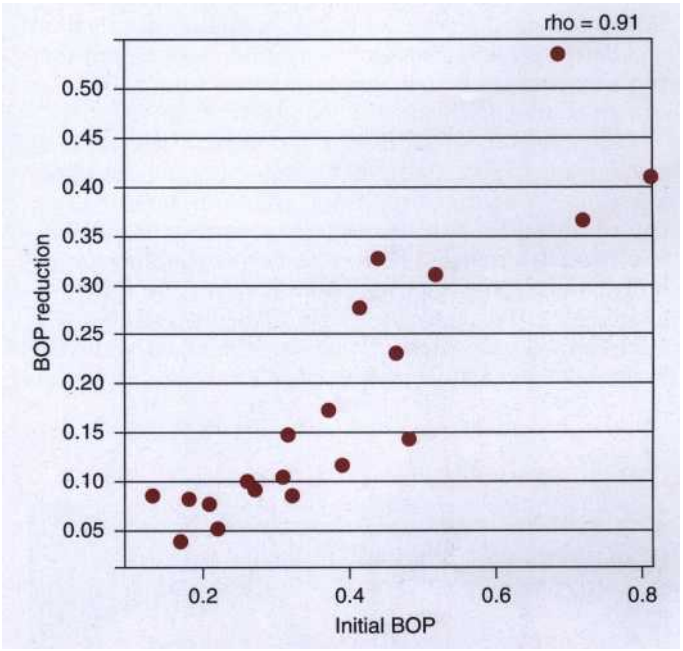

Fig. 44-5 Correlation between the reduction of bleeding on probing by adjunctive supragingival irrigation with water and initial bleeding on probing score.

Antimicrobial Agents and Toothbrushing

Enhanced penetration of antimicrobials into the periodontal pocket delivered by supragingival irrigation has been speculated to better control the subgingival microflora compared to mouth rinsing.[9,21,55] The minimal effective dosage for once daily supragingival irrigation with chlorhexidine digluconate has been established to be 400 ml of a 0.02% solution.[39]

In patients with gingivitis using antimicrobials with supragingival irrigation (e.g., 200 ml of 0.06% chlorhexidine digluconate), there is a greater reduction of gingival inflammation compared to irrigation with only water",[11]

or mouth rinsing with antimicrobials.[25,38,54] The superior antiinflammatory effects of supragingival irrigation with 0.06% chlorhexidine digluconate is also accompanied by a reduction of supragingival plaque and black-pigmented bacteria, as well as other gram negative anaerobic rods in the subgingival plaque .48 However, not all antimicrobial agents are beneficial as an irrigant. The use of 0.00225% sanguinaria solution or a solution of thymol, menthol, eucalyptus, and methylsalicilate as an irrigant did not improve the therapeutic effects of the supragingival irrigation when compared with water or a placebo irrigant.[16,54]

Gingival health, was significantly improved in patients with periodontitis after scaling and supragingival irrigation with 0.2% chlorhexidine digluconate or 0.02% stannous fluoride compared to only supragingival irrigation with water.[8,70] Lower concentrations of chlorhexidine digluconate (0.02%) or metronidazole (0.05%) solution used over 4 weeks after initial therapy in patients with periodontitis demonstrated no differences in reducing gingival inflammation compared with supragingival irrigation with water.'

The relatively high daily dosage of chlorhexidine digluconate needed for supragingival irrigation is also financially more costly compared with mouth rinsing.[2,28,44] Thus the incremental benefit of using an antimicrobial agent versus water for supragingival irrigation and delivering an antimicrobial agent by supragingival irrigation compared with application by mouth rinsing should be weighed against the long-term costs.

It is noteworthy that there is a significant elevation of calculus formation, tooth and tongue staining, and taste impairment that occurs from the long-term use of chlorhexidine digluconate[25,40] (Fig. 44-6). In addition, few patients tolerate the esthetically compromising brown teeth stains that may appear over time with prolonged use. Although chlorhexidine digluconate may be safely applied long term ,44 its side effects have usually limited its use to short periods.

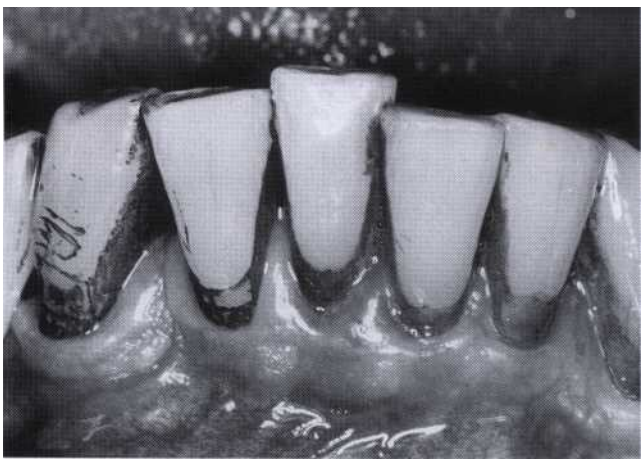

Fig. 44-6 **Extrinsic tooth staining after long-term application of chlorhexidine digluconate.**

SUBGINGIVAL IRRIGATION

Numerous studies have assessed the potential benefit of subgingival irrigation using various irrigants in the treatment of periodontitis; however, its benefit remains questionable due to controversial results .[27,59] To penetrate the periodontal pocket near its base by 75% to 93%,[9,12,30] rubber tip nozzles are positioned at the gingival margin 12 or blunted cannulas with an end or side port are inserted into the periodontal pocket[30] (see Fig. 44-3). Ejection site pressures at the opening of various tip designs have been demonstrated to range from 0.7 kPa to 35 kPa (0.1 psi to 5 psi) and were lowest in side port systems .[9,41] Care should be taken not to block the opening of the canula to prevent excessive pressure buildup. Irrigating devices similar to those employed for supragingival irrigation or syringes have been used for the delivery of solutions. Similar subgingival penetration can be achieved using the side or end port cannulas .[41]

Several factors limit the irrigant from reaching the base of the pocket. The lateral dispersion of the subgingivally irrigated solution [51] and the presence of calculus deposits impair the subgingival penetration into deep pockets of 7 to 10 mm.[41] To bring the irrigant into contact with all root surfaces, scaling and root planing should precede subgingival irrigation, and irrigation should be performed circumferentially. Practical considerations, as well as patient dexterity and compliance, dictate that the use of cannulas be limited to professionals, whereas rubber tip irrigators can be applied by the patient. However, it has been reported that some instructed patients may be able to successfully use a blunted canula for subgingival irrigation. 1,74 Patient-applied subgingival irrigation can be performed on a daily basis, whereas professionally performed irrigation requires the patient to visit the dentist and is therefore limited to several applications per year.

Subgingival Irrigation as a Monotherapy for Periodontitis

Several studies have demonstrated that subgingival irrigation with antimicrobial agents (e.g., 0.2% chlorhexidine digluconate solution, 1% chlorhexidine digluconate gel, 0.4% or 1.6% stannous fluoride, 0.5% tetracycline HCI, 7% tetrapotassium peroxydiphosphate, 3% hydrogen peroxide, or 0.5% metronidazole) resulted in a transient reduction of spirochetes, motile bacteria, and/or black-pigmented anaerobic rods in subgingival plaque. However, a rebound to pretreatment levels occurred within 1 to *8* weeks.[31,37,42,43,47,58,60,72,73] Clinically, supragingival plaque scores were reduced and periodontal health was somewhat improved after subgingival irrigation.[10,24,31,37,42,43,47,58,60,63,71,73] However, no difference was found between an antimicrobial agent or saline as the subgingival irrigant.[31,35,37,43,71,73] When compared with scaling and root planing, subgingival irrigation as a monotherapy had only limited effects on the subgingival microflora with low clinical benefits .[42,43,58,71,73] Therefore applying subgingival irrigation with water or antimicrobial agents as the sole therapeutic method is insufficient to treat periodontitis and should not be performed in lieu of scaling and root planing.

Antimicrobial Agents and Scaling and Root Planing

It is well documented that mechanical debridement of deep pockets is often incomplete with residual subgingival plaque and/or calculus remaining in the pocket.[14,56,66] The rationale for subgingival irrigation with an antimicrobial agent after scaling and root planing is based on the assumption that bacteria left behind during mechanical debridement could be killed by the so-applied antimicrobial solution. However, several factors impede the efficacy of antimicrobial agents delivered into the periodontal pocket.

Due to the outwardly directed gingival crevicular fluid flow, antimicrobial agents irrigated subgingivally may not be in contact with the subgingival microflora long enough to be effective. The half-life time of subgingivally injected agents has been shown to be approximately 13 minutes.[53] After subgingival irrigation for 5 minutes with 0.12% chlorhexidine, no chlorhexidine at antimicrobially effective levels remained in the periodontal pocket.[64]

Chlorhexidine digluconate inhibits the majority of subgingival bacteria in vitro at concentrations attainable in vivo[4,61] and may be inactivated when in contact with blood components in the periodontal pocket.[52] A 0.5% chlorhexidine digluconate solution required a longer contact time to eliminate periodontal pathogens in the presence of serum.[52] Considering the biofilm structure of subgingival plaque[61] and its effect on the activity of antimicrobial agents, it becomes rather unlikely that subgingivally irrigated solutions have a profound effect on the subgingival microflora. For example, when Streptococcus sanguis was exposed to 0.2% chlorhexidine digluconate or 0.05% cetylpyridinium chloride, no viable bacteria were detected after 5 minutes of exposure of planktonic cells. However, the same bacterium was shown to survive in biofilms even after exposure to chlorhexidine digluconate or cetylpyridinium chloride for 4 hours.75 Also, 50 to 5000 times higher concentrations of antimicrobials are needed to kill bacteria that are embeded in a biofilm compared with planktonic bacteria.[36,5°] These considerations may explain why Subgingival irrigation with 0.12% chlorhexidine digluconate is of limited benefit as an adjunct to scaling and root planing.[10,46,65,71,72]

Only subgingival irrigation with 50 mg/ml to 100 mg/ml tetracycline HCl for 5 minutes per tooth after scaling and root planing results in an effective release of tetracycline HCl from root surfaces at antimicrobial concentrations over 4 to 7 days due to the binding of tetracycline to the root surface.[15,64] Some improvements in clinical attachment gain over scaling and root planing alone have also been reported.

The preponderance of information available to date, however, gives little evidence that suggests that adjunctive subgingival irrigation has a substantial long-term benefit beyond its use in scaling and root planing.

SAFETY OF IRRIGATION

Supragingival irrigation appears to be a safe method of treatment. Daily supragingival irrigation with water has shown no clinically significant adverse effects over longer observation periods.[25,26,49] In addition, no micromorphologic changes of periodontal tissues after supragingival irrigation have been found.' There has only been one recent report on extensive tissue necrosis and permanent loss of alveolar bone after subgingival irrigation with 2% stannous fluoride.[62]

It is important to know that the use of irrigators like toothbrushing and subgingival scaling[23,57] can cause transient bacteremia. Although the incidence of transient bacteremia after toothbrushing or subgingival scaling is not significantly increased by supragingival irrigation[67,69] or subgingival irrigation,[45] it may be prudent not to recommend irrigation for patients requiring premedication for bacterial endocarditis.[19]

CHAPTER OUTLINE

TREATMENT OF ACUTE NECROTIZING ULCERATIVE GINGIVITIS
Treatment
Gingival Changes with Healing
Additional Treatment Considerations
Sequelae of Inadequate Treatment

TREATMENT OF ACUTE PERICORONITIS
Pericoronitis and Necrotizing Ulcerative Gingivitis
TREATMENT OF ACUTE HERPETIC GINGIVOSTOMATITIS
Supportive Treatment

The treatment of acute gingival disease entails the alleviation of the acute symptoms and elimination of all other periodontal disease, chronic and acute, throughout the oral cavity. Treatment is not complete as long as periodontal pathologic changes or factors capable of causing them are present.

TREATMENT OF ACUTE NECROTIZING ULCERATIVE GINGIVITIS

Necrotizing ulcerative gingivitis (NUG) can occur in a mouth essentially free of any other gingival involvement or be superimposed on underlying chronic gingival disease. Treatment should include the alleviation of the acute symptoms and the correction of the underlying chronic gingival disease. The former is the simplest part of the treatment, whereas the latter requires more comprehensive procedures.

The treatment of NUG consists of (1) alleviation of the acute inflammation plus treatment of chronic disease either underlying the acute involvement or elsewhere in the oral cavity, (2) alleviation of generalized toxic symptoms such as fever and malaise, and (3) correction of systemic conditions that contribute to the initiation or progress of the gingival changes. Chapter 51 provides further information on the management and treatment of NUG in patients with acquired immunodeficiency syndrome (AIDS).

Treatment

Treatment of NUG should follow an orderly sequence, as described in the following paragraphs.

First Visit. At the first visit, the clinician should obtain a general impression of the patient's background, including information regarding recent illness, living conditions, dietary background, type of employment, hours of rest, and mental stress. The patient's general appearance should be observed, as well as apparent nutritional status and responsiveness or lassitude, and his or her temperature should be taken. The submaxillary and

submental areas should be palpated to detect enlarged lymph glands.

The oral cavity is examined for the characteristic lesion of NUG (see Chapters 19 and 27), its distribution, and the possible involvement of the oropharyngeal region. Oral hygiene is evaluated; the presence of pericoronal flaps, periodontal pockets, and local irritants is determined. A bacterial smear may be made from the material in the involved areas, but this is merely corroboratory and is not to be relied on for diagnosis.

The patient is questioned regarding the history of the acute disease and its onset and duration. Is it recurrent? Are the recurrences associated with specific factors such as menstruation, particular foods, exhaustion, or mental stress? Has there been any previous treatment? When and for how long? One should also inquire as to the type of treatment received and the patient's impression regarding its effect.

Treatment during this initial visit is confined to the acutely involved areas, which are isolated with cotton rolls and dried. A topical anesthesia is applied, and after 2 or 3 minutes the areas are gently swabbed with a cotton pellet to remove the pseudomembrane and nonattached surface debris. Each cotton pellet is used in a small area and is then discarded; sweeping motions over large areas with a single pellet are not recommended. After the area is cleansed with warm water, the superficial calculus is removed. Ultrasonic scalers are very useful for this purpose, since they do not elicit pain, and the water jet aids in the lavage of the area.

Subgingival scaling and curettage are contraindicated at this time because of the possibility of extending the infection to deeper tissues, and also of causing a bacteremia. *Unless an emergency exists, procedures such as extractions or periodontal surgery are postponed until the patient has been symptom free for a period of 4 weeks, to minimize the likelihood of exacerbating the acute symptoms.*

The patient is also told to rinse the mouth every 2 hours with a glassful of an equal mixture of warm water and 3% hydrogen peroxide. Twice-daily rinses with 0.12% chlorhexidine are also very effective.

Patients with moderate or severe NUG and local lymphadenopathy or other systemic symptoms are placed on an antibiotic regimen of penicillin, 500 mg orally every 6 hours. For penicillin-sensitive patients, other antibiotics, such as erythromycin (500 mg every 6 hours) are prescribed. Metronidazole (500 mg twice times daily for 7 days), is also effective. Antibiotics are continued until the systemic complications or the local lymphadenopathy have subsided.

Patients are told to report back to the clinician in 1 to 2 days. The patient should be advised of the extent of total treatment the condition requires and warned that treatment is not complete when pain stops. He or she should be informed of the presence of chronic gingival or periodontal disease, which must be eliminated to prevent recurrence of the acute symptoms.

INSTRUCTIONS TO THE PATIENT. The patient is discharged with the following instructions:

1. Avoid tobacco, alcohol, and condiments.
2. Rinse with a glassful of an equal mixture of 3% hydrogen peroxide and warm water every 2 hours and/or twice daily with 0.12 % chlorhexidine solution.
3. Pursue usual activities, but avoid excessive physical exertion or prolonged exposure to the sun as required in golf, tennis, swimming, or sunbathing.
4. Confine toothbrushing to the removal of surface debris with a bland dentifrice; overzealous brushing and the use of dental floss or interdental cleaners will be painful. Chlorhexidine mouth rinses are also very helpful in controlling plaque throughout the mouth.

Second Visit. At the second visit, 1 to 2 days later, the patient's condition is usually improved; the pain is diminished or no longer present. The gingival margins of the involved areas are erythematous, but without a superficial pseudomembrane.

Scaling is performed if sensitivity permits. Shrinkage of the gingiva may expose previously covered calculus, which is gently removed. The instructions to the patient are the same as those given previously.

Third Visit. At the next visit, 1 to 2 days after the second, the patient should be essentially symptom free. There may still be some erythema in the involved areas, and the gingiva may be slightly painful on tactile stimulation (Fig. 45-1). Scaling and root planing are repeated. The patient is instructed in plaque control procedures (see Chapter 49), which are essential for the success of the treatment and the maintenance of periodontal health. The hydrogen peroxide rinses are discontinued, but chlorhexidine rinses can be maintained for two or three weeks.

Subsequent Visits. In subsequent visits, the tooth surfaces in the involved areas are scaled and smoothed, and plaque control by the patient is checked and corrected if necessary.

Unfortunately, treatment is often stopped at this time because the acute condition has subsided, but this is when comprehensive treatment of the patient's chronic periodontal problem should start. Appointments are scheduled for the treatment of chronic gingivitis, periodontal pockets, and pericoronal flaps, as well as for the elimination of all forms of local irritation.

Patients without gingival disease other than the treated acute involvement are dismissed for 1 week. If the condition is satisfactory at that time, the patient is dismissed for 1 month, at which time the schedule for subsequent recall visits is determined according to the patient's needs.

Gingival Changes with Healing

The characteristic lesion of NUG undergoes the following changes in the course of healing in response to treatment:

1. Removal of the surface pseudomembrane exposes the underlying red, hemorrhagic, craterlike depressions in the gingiva.

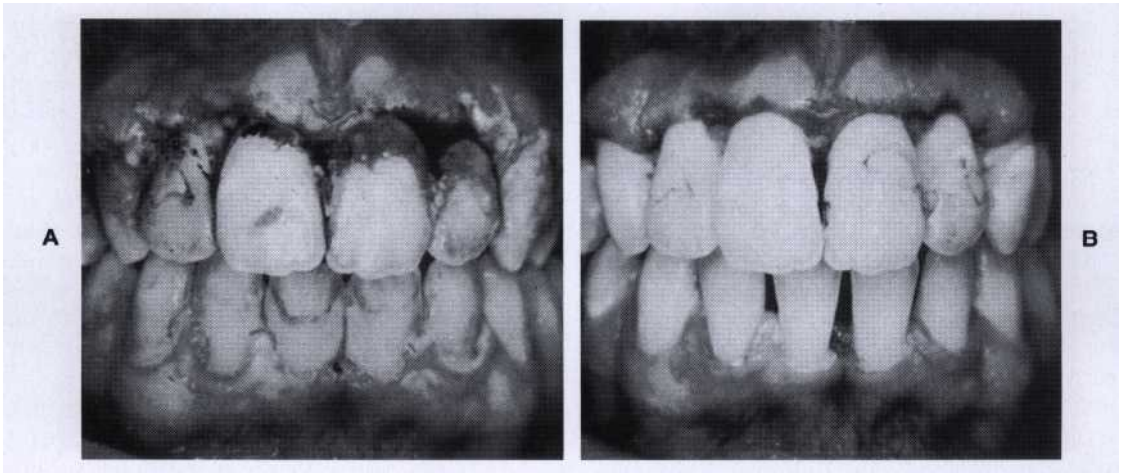

Fig. 45-1 Initial response to treatment of acute necrotizing ulcerative gingivitis (NUG). A, Severe acute necrotizing ulcerative gingivitis. B, Third day after treatment. There is still some erythema, but the condition is markedly improved.

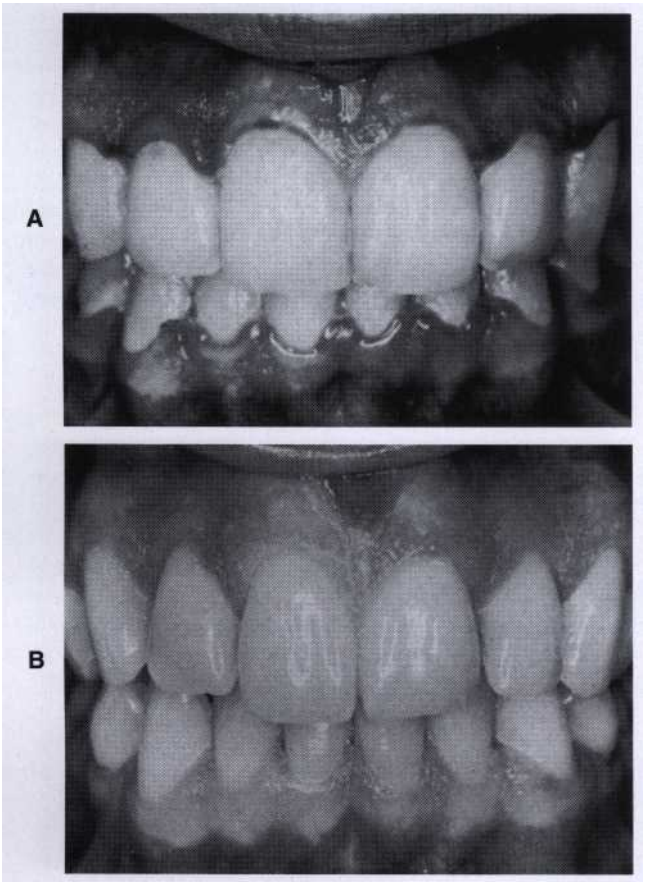

Fig. 45-2 Treatment of acute NUG. A, Before treatment. Note the characteristic interdental lesions. B, **After treatment, showing restoration of healthy gingival contour.**

2. In the next stage the bulk and redness of the crater margins are reduced, but the surface remains shiny (see Fig. 45-1).
3. This is followed by the early signs of restoration of normal gingival contour and color.
4. In the final stage the normal gingival color, consistency, surface texture, and contour are restored. Portions of the root exposed by the acute disease are covered by healthy gingiva (Figs. 45-2 and 45-3). When the menstrual period occurs in the course of treatment, there is a tendency toward exacerbation of the acute signs and symptoms, giving the appearance of a relapse. Patients should be informed of this possibility and spared unnecessary anxiety regarding their oral condition.

Additional Treatment Considerations

Contouring of the Gingiva as an Adjunctive Procedure. Even in cases of severe gingival necrosis, healing ordinarily leads to restoration of the normal gingival contour (Fig. 45-4). However, if the teeth are irregularly aligned, healing sometimes results in the formation of a shelflike gingival margin, which favors the retention of plaque and the recurrence of gingival inflammation. This can be corrected by reshaping the gingiva surgically or with electrosurgery (Fig. 45-5). Effective plaque control by the patient is particularly important to establish and maintain the normal gingival contour in areas of tooth irregularity.

Surgical Procedures. Tooth extraction or periodontal surgery should be postponed until 4 weeks after the acute signs and symptoms of NUG have subsided. If emergency surgery is required in the presence of acute symptoms, prophylactic chemotherapy with systemic penicillin or other antibiotics is indicated to prevent worsening or spreading of the acute disease.

Role of Drugs. A large variety of drugs have been used topically in the treatment of NUG.2 Topical drug therapy is only an adjunctive measure; *no drug, when used alone, can be considered complete therapy*.

Escharotic drugs such as phenol, silver nitrate, and chromic acid should not be used. They are necrotizing agents that alleviate the painful symptoms by destroying

the nerve endings in the gingiva. They also destroy the young cells necessary for repair and delay healing. Their repeated use results in the loss of gingival tissue, which is not restored when the disease subsides.'

SYSTEMIC ANTIBIOTICS. *Antibiotics are administered systemically only in patients with toxic systemic complications or local adenopathy.* They are not recommended in NUG patients who do not have these complications.

When used, systemic antibiotics also reduce the oral bacterial flora and alleviate the oral symptoms,[10,11] but they are only an adjunct to the complete local treatment the disease requires. Patients treated by systemic antibiotics alone should be cautioned that the acute painful symptoms may recur after the drug is discontinued.

SUPPORTIVE SYSTEMIC TREATMENT. In addition to systemic antibiotics, supportive treatment consists of copious fluid consumption and administration of analgesics for relief of pain. Bed rest is necessary for patients with toxic systemic complications such as high fever, malaise, anorexia, and general debility.

NUTRITIONAL SUPPLEMENTS. The rationale for nutritional supplements in the treatment of NUG is based on the following:

1. Lesions resembling those of NUG have been produced experimentally in animals with certain nutritional deficiencies (see Chapter 12).
2. It is possible that difficulty in chewing raw fruits and vegetables in a painful condition such as NUG could lead to the selection of a diet inadequate in vitamins B and C.
3. Isolated clinical studies[4,6] report fewer recurrences when local treatment of NUG is supplemented with vitamin B or vitamin C.

When the intake of water-soluble vitamins B and C has been severely curtailed because of pain in NUG, nutritional supplements may be indicated along with local treatment to ward off deficiencies of the aforementioned vitamins. Under such circumstances the patient may be given a standard multivitamin preparation combined with a therapeutic dose of vitamins B and C.

The patient should be placed on a natural diet with the required detergent action and nutritional content as soon as the oral condition permits. Nutritional supplements may be discontinued after 2 months.

Local procedures are the keystone of the treatment of necrotizing ulcerative gingivitis. Inflammation is a local conditioning factor that impairs the nutrition of the gingiva regardless of the systemic nutritional status. Local irritants should be eliminated to foster normal metabolic and reparative processes in the gingiva. Persistent or recurrent NUG is more likely to be caused by the failure to remove local irritants and by inadequate plaque control than by nutritional deficiency.

Sequelae of Inadequate Treatment

Persistent or "Unresponsive" Cases. If the clinician finds it necessary to change from drug to drug in

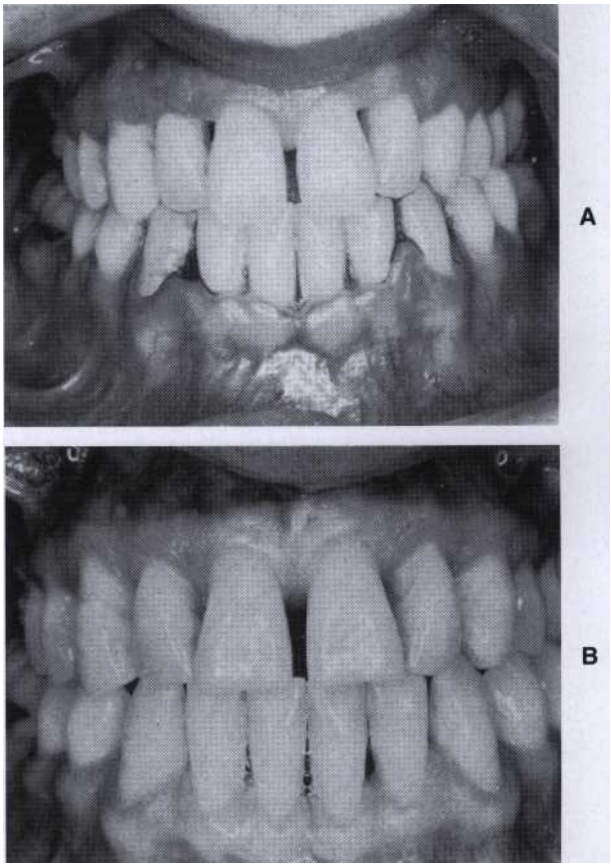

Fig. 45-3 Physiologic contour and new attachment of gingiva after treatment of acute NUG. A, Acute NUG showing the characteristic punched-out eroded gingival margin with surface pseudomembrane. B, After treatment. Note the restoration of physiologic gingival contour and reattachment of the gingiva to the surfaces of the mandibular teeth, which had been exposed by the disease.

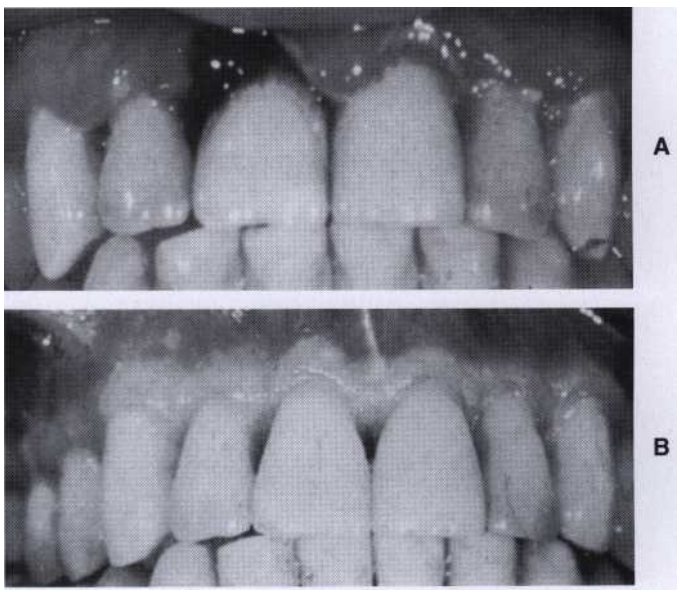

Fig. 45-4 Gingival healing after treatment. A, Before treatment. Severe acute necrotizing ulcerative gingivitis with crater formation. B, After treatment. Note the restored gingival contour.

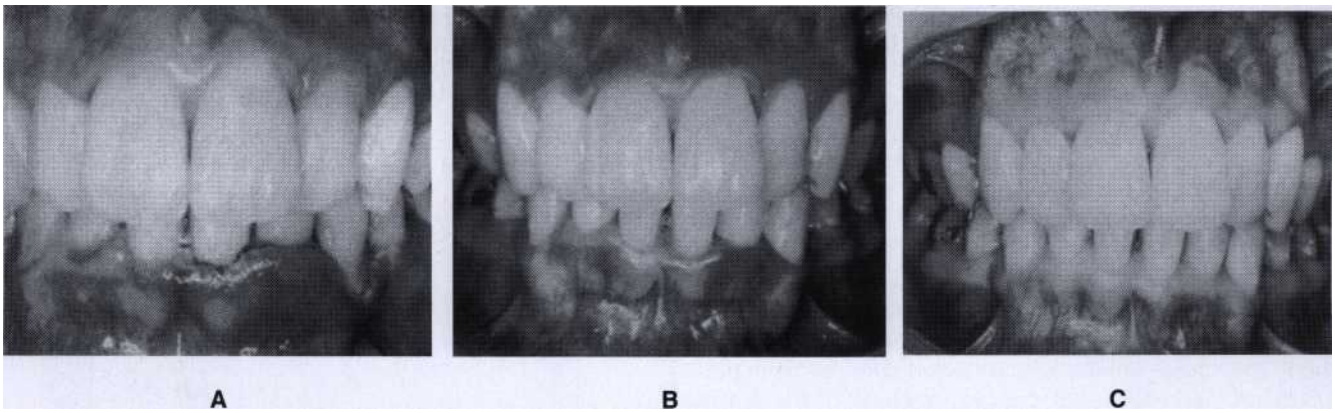

Fig. 45-5 Reshaping the gingiva in the treatment of acute NUG. A, Before treatment, showing bulbous gingiva and interdental necrosis in the mandibular anterior area. B, After treatment. Gingival contours still undesirable. C, Final result. Physiologic contours obtained by reshaping the gingiva.

an effort to relieve a "stubborn" case of NUG, something is wrong with the overall treatment regimen that is not likely to be corrected by changing drugs. When confronted with such a problem, the following should be completed:

1. All local drug therapy should be discontinued so that the condition may be studied in an uncomplicated state.
2. Careful differential diagnosis is undertaken to rule out diseases that resemble NUG (see Chapter 12).
3. A search is made for contributing local and systemic etiologic factors that may have been overlooked.
4. Special attention is given to instructing the patient in plaque control before undertaking comprehensive local treatment.

Recurrent Necrotizing Ulcerative Gingivitis. The following factors should be explored in patients with recurrent NUG:

1. *Inadequate local therapy*. *Too* often, treatment is discontinued when the symptoms have subsided, without eliminating the chronic gingival disease and periodontal pockets that remain after the superficial acute condition is relieved. Persistent chronic inflammation causes degenerative changes that predispose the gingiva to recurrence of acute involvement.
2. *Pericoronal flap.* Recurrent acute involvement in the mandibular anterior area is often associated with persistent pericoronal inflammation arising from difficult eruption of third molars.' The anterior involvement is less likely to recur after the third molar situation is corrected.
3. *Anterior overbite.* Marked overbite is often a contributing factor in the recurrence of disease in the anterior region. When the incisal edges of the maxillary teeth impinge on the labial gingival margin or the mandibular teeth strike the palatal gingiva, the resultant tissue injury predisposes the gingiva to recurrent acute disease. Less severe overbite produces food impaction and gingival trauma. Correction of the overbite is necessary for the complete treatment of NUG.

Inadequate plaque control and *heavy use of tobacco* are also common causes of recurrent disease.

TREATMENT OF ACUTE PERICORONITIS

The treatment of pericoronitis depends on the severity of the inflammation, the systemic complications, and the advisability of retaining the involved tooth. All pericoronal flaps should be viewed with suspicion. Persistent symptom-free pericoronal flaps should be removed as a preventive measure against subsequent acute involvement.

The treatment of acute pericoronitis consists of (1) gently flushing the area with warm water to remove debris and exudate and (2) swabbing with antiseptic after elevating the flap gently from the tooth with a scaler. The underlying debris is removed, and the area is flushed with warm water (Fig. *45-6).* Antibiotics can be prescribed in severe cases. If the gingival flap is swollen and fluctuant, an anteroposterior incision to establish drainage is made with a #15 blade.

After the acute symptoms have subsided, a determination is made as to whether the tooth is to be retained or extracted. The decision is governed by the likelihood of further eruption into a good functional position. Bone loss on the distal surface of the second molars is a hazard following the extraction of partially or completely impacted third molars,' and the problem is significantly greater if the third molars are extracted after the roots are formed or in patients older than their early twenties. To reduce the risk of bone loss around second molars, partially or completely impacted third molars should be extracted as early as possible in their development.

If it is decided to retain the tooth, the pericoronal flap is removed using periodontal knives or electrosurgery (Fig. *44-6).* It is necessary to remove the tissue distal to the tooth, as well as the flap on the occlusal surface. Incising only the occlusal portion of the flap leaves a deep distal pocket, which invites recurrence of acute pericoronal involvement.

After the tissue is removed, a periodontal pack is applied. The pack may be retained by bringing it forward

along the facial and lingual surfaces into the interproximal space between the second and third molars. The pack is removed after 1 week.

Pericoronitis and Necrotizing Ulcerative Gingivitis

Pericoronitis and NUG pericoronal flaps that are chronically inflamed may become the sites of NUG. The disease is treated in the same manner as elsewhere in the mouth; after the acute symptoms have subsided, the flap is removed. Pericoronal flaps are often referred to as *primary incubation zones* in NUG; their elimination is one of many measures required to minimize the likelihood of recurrent disease.

TREATMENT OF ACUTE HERPETIC GINGIVOSTOMATITIS

Primary infection with herpes simplex virus in the oral cavity results in a condition known as acute herpetic gingivostomatitis, which is an oral infection often, accompanied by systemic symptoms (see Chapter 19). This infection typically occurs in children, but it can and does occur in adults as well. It runs a 7- to 10-day course and heals without scars. A recurrent herpetic episode may be precipitated in individuals with a history of herpes virus infections and by respiratory infections, sunlight exposure fever, trauma, exposure to chemicals, and emotional stress.

Various medications have been used to treat herpes gingivostomatitis with little success; these have included local applications of escharotics, vitamins, radiation and antibiotics. Limited success was initially reported with the use of herpesvirus-specific drugs, such as acyclovir ointment.$ However, a recent clinical report has suggested good results using systemic acyclovir to prevent (or lessen the severity of) recurrent herpes virus infection associated with dental treatment." The patient, who was known to have recurrent infections after dental treatment, did not experience any recurrence when treated with acyclovir. Most strains of herpes virus are susceptible to acyclovir, and it has been suggested that topical application of acyclovir is useful in decreasing the spread and severity of the infection.

Treatment consists of palliative measures to make the patient comfortable until the disease runs its course. Plaque, food debris and superficial calculus are removed to reduce gingival inflammation, which complicates the acute herpetic involvement. Extensive periodontal therapy should be postponed until the acute symptoms subside to avoid the possibility of exacerbation (Fig. 45-7). For symptomatic relief, especially before meals, topical local anesthetic, such as lidocaine hydrochloride viscous solution can be applied to the affected areas. Before each meal the patient should rinse with 1 tablespoon of this solution. If the patient is experiencing pain of longer duration, aspirin or a nonsteroidal antiinflammatory agent can be given systemically.

Local or systemic application of antibiotics is sometimes advised to prevent opportunistic infection of ulceration'. This is especially true in the immune compromised individual. If the condition does not resolve within a 2-week period, the patient should be referred to a physician for medical consultation.'

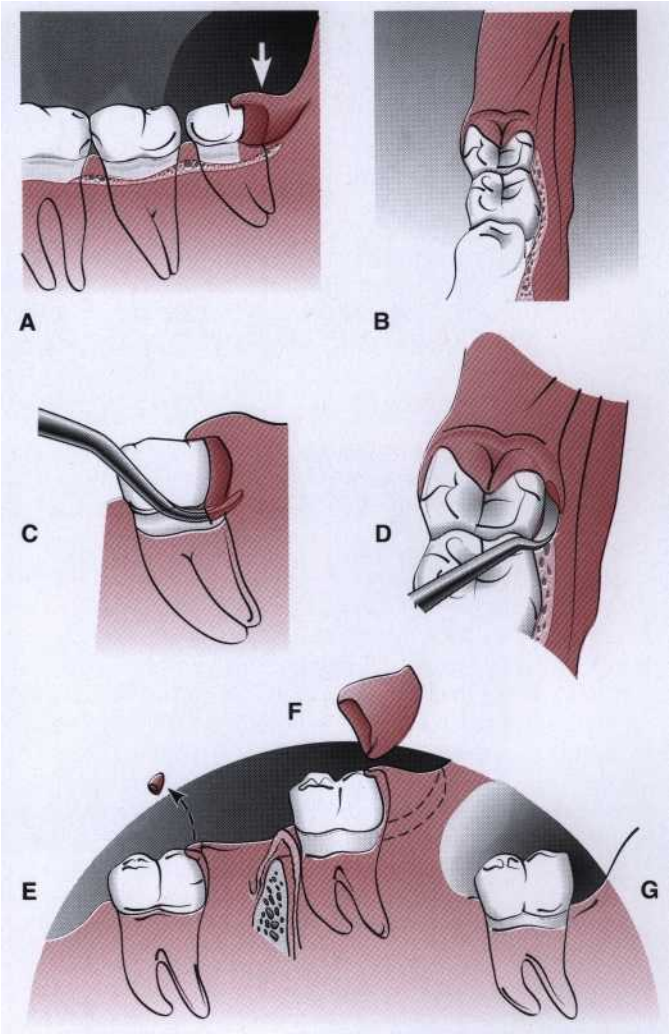

Fig. 45-6 Treatment of acute pericoronitis. A, Inflamed pericoronal flap (arrow) in relation to the mandibular third molar. B, Anterior view of third molar and flap. C, Lateral view with staler in position to gently remove debris under flap. D, Anterior view of staler in position. E, Removal of section of the gingiva distal to the third molar, after the acute symptoms subside. The line of incision is indicated by the broken line. F, Appearance of the healed area. G, Incorrect removal of the tip of the flap, permitting the deep pocket to remain distal to the molar.

The patient should be informed that the disease is contagious at certain stages such as when vesicles are present (highest viral titer). All individuals exposed to an infected patient should take precautions. Herpetic infection of a clinician's finger, referred to as *herpetic whitlow*, can occur if a seronegative clinician becomes infected with a patient's herpetic lesions.8,9

Supportive Treatment

Supportive measures include copious fluid intake and systemic antibiotic therapy for the management of toxic systemic complications. For the relief of pain, aspirin is usually sufficient. A dosage of 325 mg to 650 mg every 4 hours may be prescribed for adults, with smaller doses used for children.

Treatment of the Periodontal Abscess

Henry H. Takei

CHAPTER

CHAPTER OUTLINE

THE ACUTE PERIODONTAL ABSCESS
Treatment
THE GINGIVAL ABSCESS
THE CHRONIC PERIODONTAL ABSCESS

Periodontal abscesses are commonly encountered in patients with deep pockets. They are an acute exacerbation of a preexisting pocket resulting from exudates and purulent material being entrapped in the pocket with no pathway for drainage. Abscesses may be acute or chronic. *Acute abscesses* are painful, edematous, red, shiny ovoid elevations of the gingival margin, the attached gingiva, or both. After their purulent content is partially exuded, they become chronic. *Chronic abscesses* may produce a dull pain and may at times become acute (see Chapter 30).

THE ACUTE PERIODONTAL ABSCESS

To undertake the proper course of therapy, it is essential to establish the differential diagnosis between a periodontal and a pulpal abscess. Box 46-1 compares the symptoms associated with the two lesions.

Treatment

The purpose of treatment of an acute abscess is to alleviate the pain, control the spread of infection, and establish drainage! The patient's general systemic response should be evaluated. Rise in temperature, feverish appearance, and a feeling of malaise should be noted and a proper antibiotic regimen started if necessary.

Drainage can be established through the pocket or by means of an incision from the outer surface. The former is preferable.

Drainage through the Pocket. The area is anesthetized topically and, if necessary, local anesthesia is injected around the periphery of the abscess. Care is taken not to inject into the swelling itself. A flat instrument or a probe is carefully introduced into the pocket in an attempt to distend the pocket wall for drainage. A curette can then be gently inserted into the pocket to further drain and gently curette the mass of tissue internally.

Drainage through an External Incision. The abscess is isolated and dried with gauze sponges. After the application of topical anesthesia, local anesthesia is injected around the periphery of the abscess.

A #15 blade is used to make a vertical incision through the most fluctuant part of the swelling, extending to an area just apical to the abscess (Fig. 46-1). A curette or periosteal elevator is used to gently elevate the tissue to create drainage and curette the granulomatous tissue in the internal aspect of the abscess. The external aspect of the abscess is gently pushed to drain the remaining purulent material and approximate the wound edges. Sutures are usually not required.

After the drainage stops, the area is dried and painted with an antiseptic. Patients without systemic complications are instructed to rinse often with a solution of 1 tsp salt in a glass of warm water and to return for follow-up evaluation the next day. In addition to the rinses, penicillin or other antibiotics are prescribed for patients with elevated temperatures. The patient is also instructed to avoid exertion and is placed on a copious fluid diet.

BOX 46-1

Differences between Periodontal and Pulpal Abscesses

Periodontal Abscess	*Pulpal Abscess*
The abscess is associated with a preexisting periodontal pocket, caries, or both.	The abscess is associated with deep restoration.
A pulp test may be vital.	A pulp test may be nonvital.
Swelling is generalized and located around the involved tooth and gingival margin, seldom with a fistulous tract.	Swelling is localized, often with a fistulous opening in the apical area. This may be located away from the offending tooth.
Pain is usually dull, constant, and less severe than in a periapical abscess. The pain is localized and the patient usually can locate the offending tooth.	Pain is usually severe, throbbing, and may last for days. The patient may not be able to locate the offending tooth.
Pain associated with the movement or percussion is not as severe as with a pulpal abscess.	Pain associated with tooth movement or percussion can be severe.

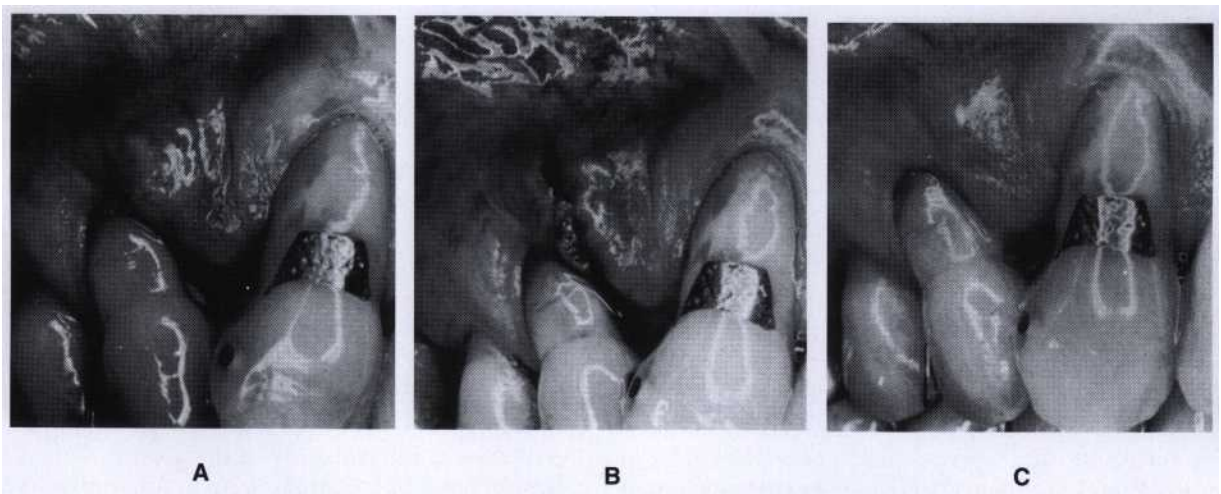

Fig. 46-1 Incision of an acute periodontal abscess. A, Fluctuant acute periodontal abscess. B, Abscess incised. C, After acute signs subside.

If necessary, bed rest is recommended. Analgesics are prescribed for pain.

The next day, the swelling is generally markedly reduced or absent and the symptoms should have subsided. If acute symptoms persist, the patient is instructed to continue the regimen prescribed the previous day and to return in 24 hours. The symptoms invariably disappear by this time, and the lesion is ready for the usual treatment of a chronic periodontal abscess.

THE GINGIVAL ABSCESS

In contrast to the periodontal abscess, which involves the supporting tissues, the gingival abscess is a lesion of the marginal or interdental gingiva, usually produced by an impacted foreign object. It is treated as follows:

Under topical and local infiltrative anesthesia, the fluctuant area of the lesion is incised with a #15 blade, and the incision is gently widened to permit drainage. The area is cleansed with warm water and covered with a gauze pad. After bleeding stops, the patient is dismissed for 24 hours and instructed to rinse every 2 hours with a glassful of warm water.

When the patient returns, the lesion is generally reduced in size and free of symptoms. A topical anesthetic is applied, and the area is scaled. If the residual size of the lesion is too great, it is removed surgically.

THE CHRONIC PERIODONTAL ABSCESS

After adequate drainage, antibiotic treatment, or both, the acute abscess becomes chronic. Some cases have drained spontaneously and the patient is then diagnosed as having a chronic abscess. Further treatment is similar to that of a periodontal pocket.

PRINCIPLES OF SCALING AND ROOT PLANING

Definitions and Rationale

Scaling is the process by which plaque and calculus are removed from both supragingival and subgingival tooth surfaces. No deliberate attempt is made to remove tooth substance along with the calculus. Root *planing is* the process by which residual embedded calculus and portions of cementum are removed from the roots to produce a smooth, hard, clean surface.

The primary objective of scaling and root planing is to restore gingival health by completely removing elements that provoke gingival inflammation (i.e., plaque, calculus, and endotoxin) from the tooth surface (see Color Fig. 48-1). Instrumentation has been shown to dramatically reduce the numbers of subgingival microorganisms and produce a shift in the composition of subgingival plaque from one with high numbers of gram-negative anaerobes to one dominated by gram-positive facultative bacteria that are compatible with health.[16,68,77,97,100,108,110] After thorough scaling and root planing, a profound reduction of spirochetes, motile rods, and putative pathogens such as *Actinobacillus actinomycetemcomitans, Porphyromonas gingivalis,* and *Prevotella intermedia* and an increase in coccoid cells occur.[68,97,103,108,120,127] These changes in the microbiota are accompanied by a reduction or elimination of inflammation clinically.[9,31,37,49,52,67,92,93] This positive microbial change must be sustained by the periodic scaling and root planing performed during supportive periodontal therapy.',[14,64,67,90,108,124]

Scaling and root planing are not separate procedures. All the principles of scaling apply equally to root planing. The difference between scaling and root planing is only a matter of degree. The nature of the tooth surface determines the degree to which the surface must be scaled or planed.

Plaque and calculus on enamel surfaces provoke gingival inflammation. Unless they are grooved or pitted, enamel surfaces are relatively smooth and uniform. When plaque and calculus form on enamel, the deposits are usually superficially attached to the surface and are not locked into irregularities. Scaling alone is sufficient to completely remove plaque and calculus from enamel, leaving a smooth, clean surface.

Root surfaces exposed to plaque and calculus pose a

* **Material in this chapter was drawn freely from Pattison AM, Pattison GL: Periodontal Instrumentation, ed 2. Upper Saddle River, NJ. Prentice Hall, 1992.**

different problem. *Deposits of calculus on root surfaces are frequently embedded in cemental irregularities.* [1,17,76,105,128] *When dentin is exposed, plaque bacteria may invade dentinal tubules.' Therefore scaling alone is insufficient to remove them, and a portion of the root surface must be removed to eliminate these deposits.* Furthermore, when the root surface is exposed to plaque and the pocket environment, its surface is contaminated by toxic substances, notably endotoxins.[2,1,44] Recent evidence suggests that these toxic substances are only superficially attached to the root and do not permeate it deeply.'",'[9,47,48,75,79,80,111] Removal of extensive amounts of dentin and cementum is not necessary to render the roots free of toxins and should be avoided.[35,67,90] However, where cementum is thin, instrumentation may expose dentin. Although this is not the aim of treatment, it may be unavoidable.[104,119]

Scaling and root planing should not be thought of as separate procedures unrelated to the rest of the treatment plan. They belong in the initial phase of an orderly sequence of treatment. After careful analysis of a case, the number of appointments needed to complete this phase of treatment is estimated. Patients with small amounts of calculus and relatively healthy tissues can be treated in one appointment. Most other patients require several treatment sessions. The dentist should estimate the number of appointments needed on the basis of the number of teeth in the mouth, severity of inflammation, amount and location of calculus, depth and activity of pockets, presence of furcation invasions, patient's comprehension of and compliance with oral hygiene instructions, and need for local anesthesia. Recent research indicates that completing initial scaling and root planing in one or two long appointments rather than four shorter quadrant scaling appointments may be advantageous.[74,94,95] This removes pathogens from the entire mouth as quickly as possible so that they are not present to reinfect previously instrumented areas.

When the rationale for scaling and root planing is thoroughly understood, it becomes apparent that mastery of these skills is essential to the ultimate success of any course of periodontal therapy. Of all clinical dental procedures, subgingival scaling and root planing in deep pockets are the most difficult and exacting skills to master. It has been argued that such proficiency in instrumentation cannot be attained; therefore periodontal surgery is necessary to gain access to root surfaces. Others have argued that although proficiency is possible, it need not be developed because access to the roots can be gained more easily with surgery. However, without mastering subgingival scaling and root planing skills, the clinician will be severely hampered and unable to treat adequately those patients for whom surgery is contraindicated.

Detection Skills

Good visual and tactile detection skills are required for the accurate initial assessment of the extent and nature of deposits and root irregularities before scaling and root planing. Valid evaluation of results of instrumentation depends on these detection skills.

Visual examination of supragingival and subgingival calculus just below the gingival margin is not difficult with good lighting and a clean field. Light deposits of supragingival calculus are often difficult to see when they are wet with saliva. Compressed air may be used to dry supragingival calculus until it is chalky white and readily visible. Air also may be directed into the pocket in a steady stream to deflect the marginal gingiva away from the tooth so that subgingival deposits near the surface can be seen.

Tactile exploration of the tooth surfaces in **subgingival areas** of pocket depth, furcations, and developmental depressions is much more difficult than visual examination of supragingival areas and requires the skilled use of a fine-pointed explorer or probe. The explorer or probe is held with a light but stable modified pen grasp. This provides maximal tactile sensitivity for detection of subgingival calculus and other irregularities. The pads of the thumb and fingers, especially the middle finger, should perceive the slight vibrations conducted through the instrument shank and handle as irregularities in the tooth surface are encountered.

After a stable finger rest is established, the tip of the instrument is carefully inserted subgingivally to the base of the pocket. Light exploratory strokes are activated vertically on the root surface. When calculus is encountered, the tip of the instrument should be advanced apically over the deposit until the termination of the calculus on the root is felt. The distance between the apical edge of the calculus and the bottom of the pocket usually ranges from 0.2 to 1.0 mm. The tip is adapted closely to the tooth to ensure the greatest degree of tactile sensitivity and avoid tissue trauma. When a proximal surface is being explored, strokes must be extended at least halfway across that surface past the contact area to ensure complete detection of interproximal deposits. When an explorer is used at line angles, convexities, and concavities, the handle of the instrument must be rolled slightly between the thumb and fingers to keep the tip constantly adapted to the changes in tooth contour.

Although exploration technique and good tactile sensitivity are important, interpreting various degrees of roughness and making clinical judgments based on these interpretations also require much expertise. The beginning student usually has difficulty detecting fine calculus and altered cementum. Such detection must begin with the recognition of ledges, lumps, or spurs of calculus, then smaller spicules, then slight roughness, and finally a slight graininess that feels like a sticky coating or film covering the tooth surface. Overhanging or deficient margins of dental restorations, caries, decalcification, and root roughness caused by previous instrumentation are all commonly found during exploration. These and other irregularities must be recognized and differentiated from subgingival calculus. Because this requires a great deal of experience and a high degree of tactile sensitivity, many clinicians agree that the development of detection skills is as important as the mastery of scaling and root planing technique.

Supragingival Scaling Technique

Supragingival calculus is generally less tenacious and less calcified than subgingival calculus. Because instrumenta-

tion is performed coronal to the gingival margin, scaling strokes are not confined by the surrounding tissues. This makes adaptation and angulation easier. It also allows direct visibility as well as a freedom of movement not possible during subgingival scaling.

Sickles, curettes, and ultrasonic and sonic instruments are most commonly used for the removal of supragingival calculus. Hoes and chisels are less frequently used. To perform supragingival scaling, the sickle or curette is held with a modified pen grasp, and a firm finger rest is established on the teeth adjacent to the working area. The blade is adapted with an angulation of slightly less than 90 degrees to the surface being scaled. The cutting edge should engage the apical margin of the supragingival calculus while short, powerful, overlapping scaling strokes are activated coronally in a vertical or an oblique direction. The sharply pointed tip of the sickle can easily lacerate marginal tissue or gouge exposed root surfaces, so careful adaptation is especially important when this instrument is being used. The tooth surface is instrumented until it is visually and tactilely free of all supragingival deposits. If the tissue is retractable enough to allow easy insertion of the bulky blade, the sickle may be used slightly below the free gingival margin. If the sickle is used in this manner, final scaling and root planing with the curette should always follow.

Subgingival Scaling and Root Planing Technique

Subgingival scaling and root planing are far more complex and difficult to perform than supragingival scaling, Subgingival calculus is usually harder than supragingival calculus and is often locked into root irregularities, making it more tenacious and therefore more difficult to remove.[17,76,105,128] The overlying tissue creates significant problems in subgingival instrumentation. Vision is obscured by the bleeding that inevitably occurs during instrumentation and by the tissue itself. The clinician must rely heavily on tactile sensitivity to detect calculus and irregularities, guide the instrument blade during scaling and root planing, and evaluate the results of instrumentation.

In addition, the adjacent pocket wall limits the direction and length of the strokes. The confines of the soft tissue make careful adaptation to tooth contours imperative to avoid trauma. Such precise adaptation cannot be accomplished without a thorough knowledge of tooth morphologic features. The clinician must form a mental image of the tooth surface to anticipate variations in contour, continually confirming or modifying the image in response to tactile sensations and visual cues such as the position of the instrument handle and shank. The clinician then must instantaneously adjust the adaptation and angulation of the working end to the tooth. It is this complex and precise coordination of visual, mental, and manual skills that makes subgingival instrumentation one of the most difficult of all dental skills. *The curette is preferred by most clinicians for subgingival scaling and root planing because of the advantages afforded by its design.* Its curved blade, rounded toe, and curved back allow the curette to be inserted to the base of the pocket and adapted to variations in tooth contour with minimal tissue displacement and trauma.

Sickles, hoes, files, and ultrasonic instruments also are used for subgingival scaling of heavy calculus. Some small files such as the Hirschfeld file may be inserted to the base of the pocket to crush or initially fracture tenacious deposits. Larger files, hoes, sickles, and standard ultrasonic tips for supragingival use are too bulky and cannot easily be inserted into deep pockets or areas where tissue is firm and fibrotic. Hoes and files are not able to produce as smooth a surface as curettes.[12,104] Hoes, files, and standard large ultrasonic tips are all more hazardous than the curette in terms of trauma to the root surface and surrounding tissues.[12,85,104] Although thin ultrasonic tips designed for scaling of deep pockets and furcations can be inserted more easily subgingivally, they must be used on low power.[31,32,45] When low-power scaling is performed on heavy calculus or tenacious sheets of calculus, thin ultrasonic tips are likely to burnish the calculus rather than thoroughly remove it. Therefore ultrasonic scaling should be followed by careful assessment with an explorer and further instrumentation with curettes when necessary.

Subgingival scaling and root planing are accomplished with either universal or area-specific (Gracey) curettes using the following basic procedure: The curette is held with a modified pen grasp, and a stable finger rest is established. The correct cutting edge is slightly adapted to the tooth, with the lower shank kept parallel to the tooth surface. The lower shank is moved toward the tooth so that the face of the blade is nearly flush with the tooth surface. The blade is then inserted under the gingiva and advanced to the base of the pocket by a light exploratory stroke. When the cutting edge reaches the base of the pocket, a working angulation of between 45 and 90 degrees is established, and pressure is applied laterally against the tooth surface. Calculus is removed by a series of controlled, overlapping, short, powerful strokes primarily using wrist-arm motion (Fig. 47-1). As calculus is removed, resistance to the passage of the cutting edge diminishes until only a slight roughness remains. Longer, lighter root planing strokes are then activated with less lateral pressure until the root surface is completely smooth and hard. The instrument handle must be rolled carefully between the thumb and fingers to keep the blade adapted closely to the tooth surface as line angles, developmental depressions, and other changes in tooth contour are followed. Scaling and root planing strokes should be confined to the portion of the tooth where calculus or altered cementum is found. This zone is known as the *instrumentation zone.* Sweeping the instrument over the crown where it is not needed wastes operating time, dulls the instrument, and causes loss of control.

The amount of lateral pressure applied to the tooth surface depends on the nature of the calculus and whether the strokes are for initial calculus removal or final root planing. If heavy lateral pressure is continued after the bulk of calculus has been removed and the blade is repeatedly readapted with short, choppy strokes, the result will be a root surface roughened by numerous nicks and gouges, resembling the rippled surface of a washboard.89 If heavy lateral pressure is continued with long, even strokes, the result will be excessive removal of root structure, producing a smooth but "ditched" or "riffled" root surface. To avoid these hazards of overinstrumentation,

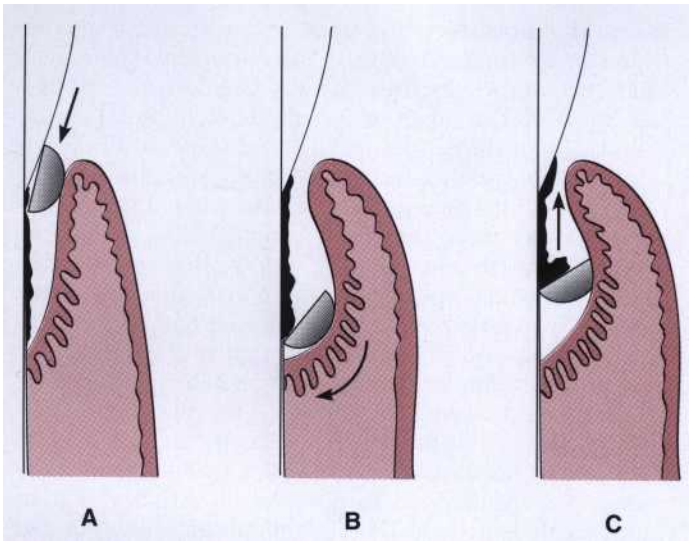

Fig. 47-1 Subgingival scaling procedure. A, Curette inserted with the face of the blade flush against the tooth. B, Working angulation (45 to 90 degrees) is established at the base of the pocket. C, Lateral pressure is applied, and the scaling stroke is activated in the coronal direction.

a deliberate transition from short, powerful scaling strokes to longer, lighter root planing strokes must be made as soon as the calculus and initial roughness have been eliminated.

When scaling strokes are used to remove calculus, force can be maximized by concentrating lateral pressure onto the lower third of the blade (see Fig. 42-19). This small section, the terminal few millimeters of the blade, is positioned slightly apical to the lateral edge of the deposit, and a short vertical or oblique stroke is used to split the calculus from the tooth surface. Without withdrawing the instrument from the pocket, the lower third of the blade is advanced laterally and repositioned to engage the next portion of the remaining deposit. Another vertical or oblique stroke is made, slightly overlapping the previous stroke. This process is repeated in a series of powerful scaling strokes until the entire deposit has been removed. The overlapping of these pathways or "channels" of instrumentation[89] ensures that the entire instrumentation zone is covered (Fig. 47-2).

Engaging a large, tenacious ledge or piece of calculus with the entire length of the cutting edge is not recommended because the force is distributed through a longer section of the cutting edge rather than concentrated. Far more lateral pressure is required to dislodge the entire deposit in one stroke. Although some clinicians may possess the strength to remove calculus completely in this manner, the heavier forces required diminish tactile sensitivity and contribute to a loss of control that results in tissue trauma. A single heavy stroke usually is not sufficient to remove calculus entirely. Instead, the blade skips over or skims the surface of the deposit. Subsequent strokes made with the entire cutting edge tend to shave the deposit down layer by layer. When a series of these repeated whittling strokes is applied, the calculus may be reduced to a thin, smooth, burnished sheet that is difficult to distinguish from the surrounding root surface.

A common error in instrumenting proximal surfaces is failing to reach the midproximal region apical to the contact. This area is relatively inaccessible, and the technique requires more skill than instrumentation of buccal or lingual surfaces. It is extremely important to extend strokes at least halfway across the proximal surface so that no calculus or roughness remains in the interproximal area. With properly designed curettes, this can be accomplished by keeping the lower shank of the curette parallel with the long axis of the tooth (Fig. 47-3). With the lower shank parallel to the long axis, the blade of the curette will reach the base of the pocket and the toe will extend beyond the midline as strokes are advanced across the proximal surface. This extension of strokes beyond the midline ensures thorough exploration and instrumentation of these surfaces. If the lower shank is angled or tilted away from the tooth, the toe will move toward the contact area. Because this prevents the blade from reaching the base of the pocket, calculus apical to the contact will not be detected or removed. Strokes will be hampered because the toe tends to become lodged in the contact. If the instrument is angled or tilted too far toward the tooth, the lower shank will hit the tooth or the contact area, preventing extension of strokes to the mid-proximal region (see Fig. 47-3).

The relationship between the location of the finger rest and the working area is important for two reasons. First, the finger rest or fulcrum must be positioned to allow the lower shank of the instrument to be parallel or nearly parallel to the tooth surface being treated. This parallelism is a fundamental requirement for optimal working angulation. Second, the finger rest must be positioned to enable the operator to use wrist-arm motion to activate strokes. On some aspects of the maxillary posterior teeth, these requirements can be met only with the use of extraoral or opposite-arch fulcrums. When intraoral finger rests are used in other regions of the mouth, the finger rest must be close enough to the working area to fulfill these two requirements. A finger rest that is established too far from the working area forces the clinician to separate the middle finger from the fourth finger in an effort to obtain parallelism and proper angulation. Effective wrist-arm motion is possible only when these two fingers are kept together in a built-up fulcrum. Separation of the fingers commits the clinician to the exclusive use of finger flexing for the activation of strokes.

As instrumentation proceeds from one tooth to the next, the body position of the operator and the location of the finger rest must be frequently adjusted or changed to allow parallelism and wrist-arm motion. Various approaches to instrumentation in different areas of the mouth are illustrated here. The examples shown provide maximal efficiency for the clinician and comfort for the patient. For most areas, more than one approach is presented. Other approaches are possible and are acceptable if they provide equal efficiency and comfort. The following approaches may be used:

Ultrasonic Scaling

Ultrasonic Scaling Instruments. Ultrasonic instruments have been used as a valuable adjunct to conventional hand instrumentation for many years, Until relatively recently, all ultrasonic tips were large and bulky, making them generally suitable only for supragingival scaling or subgingival scaling where tissue was inflamed and retractable. However, newly designed, thin ultrasonic tips have allowed better access to subgingival areas previously accessible only with hand instruments.[20] It is important to understand this historical perspective when attempting to interpret the literature comparing the effects of hand and ultrasonic instruments on root surfaces. Earlier studies using older tip designs generally showed that ultrasonic instruments left a rougher, more damaged surface than curettes.[4,22,35,36,51,53,114,119,126] More recent studies, especially those using the newer, thinner tips, show that ultrasonic instruments can produce root surfaces as smooth or smoother than can be produced by curettes.[30,31,34,98] Whether these relative degrees of smoothness are important has not been clearly established.[35,45,54,61,81,107] It is evident, however, that both methods of instrumentation are able to provide satisfactory clinical results as measured by removal of plaque and calculus, reduction of bacteria, reduction of inflammation and pocket depth, and gain in clinical attachment.[6-10,28,37,65,83,92,114,1v] Ultrasonic instruments have been shown to be more effective than hand instruments at reducing spirochetes and motile rods in class II and III furcations.[62] Recently, two in vitro studies found that ultrasonic and sonic scalers do not kill periodontopathic bacteria by vibrational energy but rather suggest an antimicrobial effect from an increase in temperature.[82,106] Other in vitro studies found that Gracey Curvette curets were more effective than slim ultrasonic inserts in de-

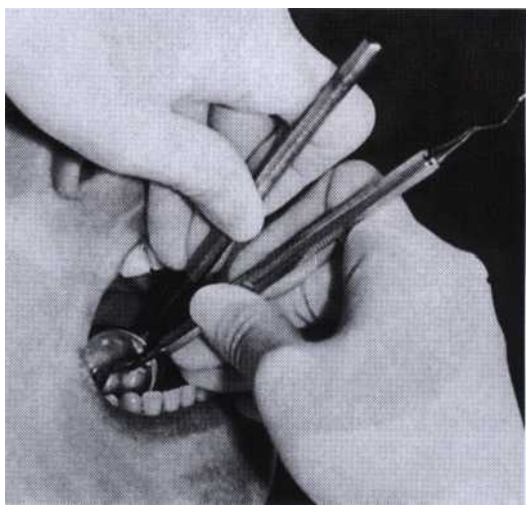

Fig. 47-23 Mandibular right posterior sextant: lingual aspect.

bridging root trunks, furcation entrances, and furcation areas of mandibular first molars .[86,87]

The selection of either ultrasonic or hand instrumentation should be determined by the clinician's preference and experience and the needs of each patient. The success of either treatment method is determined by the time devoted to the procedure and the thoroughness of root debridement. In practice, clinicians commonly use a combination of both ultrasonic and hand instrumentation to achieve thorough debridement.

The vibrational energy produced by the ultrasonic instrument makes it useful for removing heavy, tenacious deposits of calculus and stain. Such deposits can be removed more quickly and with less effort ultrasonically than manually. When ultrasonic instruments are properly manipulated, less tissue trauma and therefore less postoperative discomfort occur. This makes ultrasonic instrumentation useful for initial debridement in patients with acute painful conditions such as necrotizing ulcerative gingivitis. This same quality can be used to advantage with the new, thin ultrasonic tips for subgingival root debridement and deplaquing in maintenance patients with residual pocket depth. Ultrasonic scaling devices also have been used for gingival curettage and to remove overhangs and excess cement after cementing orthodontic appliances. Opinions differ regarding the effectiveness of ultrasonic instruments for removing stain compared with conventional polishing methods.', 16

Some definite contraindications to the use of ultrasonic and sonic scaling devices exist. No one with a cardiac pacemaker should be exposed to ultrasonic instruments.'° Patients with known communicable diseases that can be transmitted by aerosols should not be treated with ultrasonic or sonic scaling devices. The water spray creates a contaminated aerosol that fills the operating area, exposing personnel and surfaces. [58,78] Even when treating patients without known communicable diseases, it is especially important that proper infection control measures be observed (i.e., use of protective clothing, eyewear, masks, and gloves) and proper surface decontamination be performed afterward. Prerinsing for 1 minute with an antimicrobial mouthwash such as 0.12% chlorhexidine significantly reduces the number of bacteria in the aerosol for approximately 1 hour. 121 Patients at risk for respiratory disease should not be treated with ultrasonic or sonic devices; these include patients who are immunosuppressed or suffer from chronic pulmonary disorders. [109,115] Finally, metal ultrasonic and sonic inserts are contraindicated for titanium implants, which can be etched or gouged, and for porcelain or bonded restorations, which can be fractured or removed. [15,29,59,96,122] Plastic-tipped ultrasonic and sonic inserts that do not cause damage to titanium implants are available." Also, Teflon-coated sonic scaler tips have been developed for titanium implants and for deplaqueing and subgingival polishing of root surfaces .[55,56,102]

Ultrasonic Scaling Technique. Ultrasonic instrumentation is accomplished with a light touch and light pressure, keeping the tip parallel to the tooth surface and constantly in motion. [31,45,91] Leaving the tip in one place for too long or using the point of the tip against the tooth can produce gouging and roughening of the root surface or overheating of the tooth.[30] Using a lower-power setting and applying only slight pressure reduces the volume and depth of tooth structure removal .[22,91] The working end of the ultrasonic instrument must come in contact with the calculus deposit to fracture and remove it. As with hand instruments, instrument adaptation to the tooth is critical to success. The working tip must contact all aspects of the root surface to thoroughly remove plaque and toxins. Although as much as 10 mm or more of the length of the ultrasonic tip vibrates, only a small portion of it can be adapted to contact the curved root surface at any one time or point. As with hand instruments, a series of rapid, overlapping strokes must be activated to ensure complete root coverage .[45] However, these rapid, light strokes with a blunt, vibrating working end impair tactile sensitivity, and the constant water spray necessary for the operation of the instrument hampers visibility. For these reasons, during ultrasonic instrumentation, the tooth surface should be frequently examined with an explorer to evaluate the completeness of debridement.

The aerosol produced by sonic and ultrasonic instrumentation may contain potentially infectious bloodborne and airborne pathogens. [5,31-40,46,58,72,73,99,118] Pneumococci, staphylococci, alpha hemolytic streptococci, and *Mycobacterium tuberculosis* are among the bacteria that have been found in dental aerosols .[50,63] Aerosols also subject dental personnel and patients to many viruses including herpes simplex virus, hepatitis virus, influenza virus, common cold viruses, Epstein-Barr virus, and cytomegalovirus.[20-26,69,116] Of additional concern are pathogens that do not originate from patients but are from the contaminated waterlines of the dental unit or the ultrasonic device .[27,33,88] Putative pathogens such as *Pseudomonas sp.* and *Legionella pneumophilia* have been isolated from dental unit water and can become aerosolized by an ultrasonic scaler. [27,33,38,84] Aerosol from ultrasonic instrumentation always contains blood[1,71] and lingers in the air for 30 minutes or longer in the entire operatory and in areas of the dental office outside the operatory.[58,60,72,73] Unprotected patients may be more susceptible to infection from the aerosol than dental personnel who are wearing protective barriers such as masks, gloves, eyewear and clinical clothing. [13,20,109] High-speed evacuation, preprocedural rinsing with chlorhexidine, flushing of the handpiece and waterlines or a self-contained sterile water source, thorough disinfection of environmental surfaces, and adequate ventilation and air filtration units with HEPA (High Efficiency Particulate Air) filters (Honeywell Environmental Air Control Inc., Hagerstown, MD) are all important precautions to minimize the potential hazards of ultrasonic aerosols .[41-43,101]

With these points in mind, the ultrasonic device is used in the following manner:

1. Thoroughly wipe the ultrasonic unit with a disinfectant. Use a sterile, autoclavable ultrasonic handpiece or wipe the handpiece with disinfectant. Cover the ultrasonic unit or control knobs and the handpiece with plastic or latex barriers. Flush the waterlines and handpiece for 2 minutes to decrease the number of microorganisms in the lines. 125 Use waterline filters or sterile water whenever possible.

2. Direct the patient to rinse for 1 minute with an antimicrobial mouthrinse such as 0.12% chlorhexidine to reduce the contaminated aerosol.[121,125]
3. The clinician and the assistant should wear protective eyewear and masks and use high-speed evacuation to minimize inhalation of the contaminated aerosol produced during instrumentation.[41-43]
4. Turn on the unit, select an insert, place it into the handpiece, and then adjust the water control knob to produce a light mist of water at the working tip. Adequate aspiration is necessary to remove this water as it accumulates in the mouth. The power setting should begin on low and be adjusted no higher than necessary to remove calculus. Medium- to high-power settings have been shown to cause damage to roots when the tip is not parallel to the root surface.
5. The instrument is grasped with a light pen or modified pen grasp, and a finger rest or extraoral fulcrum should be established to allow a very light, featherlike touch. Extraoral hand rests should be used for the maxillary teeth. For the mandibular teeth, either intraoral or extraoral fulcrums may be used.
6. Use short, light, vertical, horizontal, or oblique overlapping strokes. Keep the working tip adapted to the tooth surface as it is passed over the deposit. Heavy lateral pressure is unnecessary because the vibrational energy of the instrument dislodges the calculus. However, the working end must touch the deposit for this to occur.
7. The working end should be kept in constant motion, and the tip should be kept parallel to the tooth surface or at no more than a 15-degree angle to avoid etching or grooving the tooth surface."'
8. The instrument should be switched off periodically to allow for aspiration of water, and the tooth surface should be examined frequently with an explorer.
9. Any remaining irregularities of the root surface may be removed with sharp standard or mini-bladed curettes if necessary.

Evaluation

The adequacy of scaling and root planing is **evaluated when the** procedure is performed and again later, after a period of soft tissue healing.

Immediately after instrumentation, the tooth surfaces should be carefully inspected visually with optimal lighting and the aid of a mouth mirror and compressed air; they also should be examined with a fine explorer or probe. Subgingival surfaces should be hard and smooth. Although complete removal of calculus is definitely necessary for the health of the adjacent soft tissue,[123] little documented evidence that root smoothness is necessary is available.[35,37,117] Nevertheless, relative smoothness is still the best immediate clinical indication that calculus has been completely removed.35

Although smoothness is the criterion by which scaling and root planing are immediately evaluated, the ultimate evaluation is based on tissue response.[123] Clinical evaluation of the soft tissue response to scaling and root planing, including probing, should not be conducted earlier than 2 weeks postoperatively. Reepithelialization of the wounds created during instrumentation takes 1 to 2 weeks.[112,113] Until then, gingival bleeding on probing can be expected even when calculus has been completely removed because the soft tissue wound is not epithelialized. Any gingival bleeding on probing noted after this interval is more likely to be due to persistent inflammation produced by residual deposits that were not removed during the initial procedure or inadequate plaque control. Positive clinical changes after instrumentation often continue for weeks or months. For this reason, a longer period of evaluation may be indicated before deciding whether to intervene with further instrumentation or surgery.21

Occasionally the clinician may find that some slight root roughness remains after scaling and root planing.[53,114,126] If sound principles of instrumentation have been followed, the roughness may not be calculus. Because calculus removal, not root smoothness per se, has been shown to be necessary for tissue health, it might be more prudent in such a case to stop short of perfect smoothness and reevaluate the patient's tissue response after 2 to 4 weeks or longer. This avoids overinstrumentation and removal of excessive root structure in the pursuit of smoothness for its own sake. If the tissue is healthy after an interval of 2 to 4 weeks or longer, no further root planing is necessary. If the tissue is inflamed, the clinician must determine to what extent this is due to plaque accumulation or the presence of residual calculus and to what degree further root planing is necessary.

Phase I Periodontal Therapy

Dorothy A. Perry and Max O. Schmid

CHAPTER OUTLINE

RATIONALE
RESULTS
REEVALUATION
DECISION TO REFER FOR SPECIALIST TREATMENT

Phase I therapy is the first step in the chronologic sequence of procedures that constitute periodontal treatment. The objective of Phase I therapy is to alter or eliminate the microbial etiology and contributing factors for gingival and periodontal diseases. The result is the arresting of the progression of disease and preservation of the dentition in a state of health, comfort, and function with appropriate esthetics.' Phase I therapy is referred to by a number of names, including *initial therapy,' nonsurgical periodontal therapy,'' cause-related therapy,$* and the *etiotropic phase of therapy.16* All terms refer to the procedures performed to treat gingival and periodontal infections, up to and including tissue reevaluation.

RATIONALE

The reduction and elimination of etiologic and contributing factors in periodontal treatment is achieved by complete removal of calculus, correction of defective restorations, treatment of carious lesions, and institution of a comprehensive daily plaque control regimen .3.5,7,9,'4 The initial phase of therapy is provided to all patients with periodontal pockets who later will be evaluated for surgical intervention and those with gingivitis or mild chronic periodontitis who are unlikely to need surgical treatment. The procedures included in Phase I therapy may be the only procedures required to solve the patient's periodontal problems, or they may constitute the preparatory phase for surgical therapy. Color Fig. 48-1 shows the results of Phase I therapy for two different periodontal patients.

Phase I therapy is a critical aspect of periodontal treatment. Data from clinical research indicate that the long-term success of periodontal treatment depends predominantly on maintaining the results achieved with Phase I therapy and much less on any specific surgical procedures. In addition, Phase I therapy provides an opportunity for the dentist to evaluate tissue response and the patient's attitude toward periodontal care, both of which are crucial to the overall success of treatment.

Phase I therapy has many specific goals that go well beyond the control of inflammation and pocket reduction by mechanical means. The American Academy of Periodontology has included the following aspects in the Parameters of Care for Phase I Therapy':

1. Evaluation and alteration of patient systemic risk factors. These include, among others, systemic diseases and conditions, smoking, substance abuse, and use of medications. Consultation with the patient's physician may be a necessary part of Phase I therapy.
2. Plaque control performed by the patient (see Chapter 49).
3. Removal of microbial plaque and calculus from the surfaces of the teeth (see Chapters 42 and 43).
4. Appropriate use of antimicrobial agents and devices including necessary plaque sampling and antibiotic sensitivity testing (see Chapters 44 and 50).

5. Control or elimination of contributing local factors including the following:
   A. Treatment of poorly fitting restorations
   B. Correction of poorly fitting prosthetic devices
   C. Restoration of carious lesions
   D. Odontoplasty
   E. Tooth movement
   F. Treatment of food impaction areas
   G. Treatment of occlusal trauma
   H. Extraction of hopeless teeth

Based on the knowledge that microbial plaque harbors the primary pathogens of gingival inflammation, the specific aim of Phase I therapy for every patient is effective plaque control. This is accomplished by establishing an effective daily plaque control regimen for the patient, removing calculus, and eliminating rough and irregular tooth surfaces, including treating carious lesions. Effective plaque control is the key objective of every therapeutic periodontal procedure, but it is best accomplished if tooth surfaces are free of rough deposits and irregular contours so that they are readily accessible to oral hygiene aids.

Caries control and treatment of active carious lesions is an often-overlooked aspect of Phase I therapy. Caries is now recognized as an infection.' As such, carious must be temporized, with removal of the infectious process and improved tooth contours established to maximize the healing achieved during the scaling and root planing treatment. Frank carious lesions, particularly Class V lesions in the cervical areas of teeth and those on root surfaces, provide a reservoir for bacteria and can contribute to the repopulation of the periodontal plaque. The cavities themselves are receptacles where plaque is sheltered from even the most energetic mechanical plaque removal. For these reasons it is imperative that caries control and at least temporization of carious lesions be completed during Phase I therapy.

After careful analysis of the case and diagnosis of the specific periodontal condition presented, the dentist determines the treatment plan for the scaling and root planing portion of Phase I therapy. This is an estimate of the procedures and number of appointments needed to complete the initial phase of therapy after carious lesions are controlled. Patients with small amounts of calculus and relatively healthy tissues can be treated in one appointment. Most patients require several treatment sessions to complete debridement of tooth surfaces. The dentist should estimate the number of appointments needed on the basis of the conditions presented by each individual patient. In addition to the number of times the patient must be seen, some consideration should be given to control of infectious organisms during the period of active Phase I treatment. One option for scheduling appointments is one or two longer appointments on consecutive days, while the patient is on an aggressive prescribed regimen of antimicrobial agents, then follow-up appointments during healing. This treatment sequence has been referred to as anti-enfective or disinfection treatment.lo,10,13 Data from these studies indicated that improvements in probing depths and reduction of periodontal pathogens were somewhat greater for the group using antimicrobial adjuncts. As our understanding of the best use of antimicrobial agents increases, treatment plans undoubtedly will evolve to maximize therapeutic results.

A number of specific conditions need to be considered in formulating the treatment plan for each patient. The individual patient considerations relating to the development of the Phase I therapy treatment plan and sequence include the following"15

- General health and tolerance of treatment
- Number of teeth present
- Amount of supragingival calculus
- Amount of subgingival calculus
- Probing pocket depths (amount of attachment loss is less significant than depth of pockets for determining the treatment plan)
- Furcation involvement
- Alignment of teeth
- Margins of restorations
- Developmental anomalies
- Physical barriers to access (i.e., limited opening or tendency to gag)
- Patient cooperation
- Patient sensitivity (requiring use of anesthesia or analgesia)

RESULTS

Phase I therapy is a complex and individualized treatment. It requires detailed analysis of each patient's disease and contributing factors and customized therapy. The treatments common to all Phase I therapy are patient plaque control, caries control, and scaling and root planing to remove supragingival calculus, subgingival calculus, and plaque deposits. Plaque control performed by the patient at home is complex and requires changing lifelong habits. It is difficult to achieve and varies among individual patients, but strategies for success exist. Plaque control education and motivation are presented in Chapter 49.

Scaling and root planing therapy has been studied extensively to evaluate its effects on periodontal disease. A review of studies evaluating the effects of scaling and root planing indicate that the treatment is both effective and reliable.6 Studies ranging from 1 month to 2 years in length demonstrate up to 80% reductions in bleeding on probing and mean probing depth reductions in the range of 2 to 3 mm. Others have demonstrated that the number of pockets 4 mm in depth or greater was reduced by 52% to 80%. Several of these studies also compared the relative healing result using hand instrumentation and ultrasonic or sonic instruments for scaling and root planing. No difference in healing was identified based on the type of instruments used to provide the treatmennt6 Additional individual treatment such as caries control and correction of ill-fitting restorations only augment the positive results of healing gained through good plaque control and scaling and root planing. Fig. 48-1 shows the effects of an overhanging amalgam restoration on the gingiva. Maximal healing from scaling and root planing is not possible with local

D, Clinical appearance of recontoured restoration (arrow).**

conditions that retain plaque and provide reservoirs for repopulation of periodontal pathogens.

REEVALUATION

Reevaluation of the periodontal case should occur about 4 weeks after the completion of the scaling and root planing procedures. This permits time for both epithelial and connective tissue healing, correction of conditions such as overhanging margins, and sufficient practice with oral hygiene skills so that the dentist can accurately assess the periodontal condition at the end of Phase I therapy.

Gingival inflammation is usually substantially reduced or eliminated within 3 to 4 weeks after removal of calculus and local irritants. Healing consists of the formation of a long junctional epithelium rather than new connective tissue attachment to the root surfaces. The attachment epithelium reappears within 1 to 2 weeks. Gradual reductions in inflammatory cell population, crevicular fluid flow, and repair of connective tissue result in reduction of the clinical signs of inflammation, with less redness and swelling.'

Transient root hypersensitivity and recession of the gingival margins frequently accompany the healing process. Patients should be warned at the outset of treatment that these results may happen, otherwise it may come as an unpleasant surprise. These unexpected and uncomfortable consequences may result in distrust and loss of motivation to continue therapy, so it is important that patients be educated about the consequences at the outset of treatment.

The periodontal tissues must be carefully reexamined to determine the need for further therapy. Pockets must be reprobed to decide whether surgical intervention in indicated. However, additional improvement through surgery can be expected only if Phase I therapy has been successful. Therefore surgical treatment of periodontal pockets should be attempted only if the patient is exercising effective plaque control and the gingiva is free of overt inflammation.

DECISION TO REFER FOR SPECIALIST TREATMENT

The goal of this textbook is to prepare general dentists to manage most periodontal care required in their practices. The preface to the 8th edition of this textbook states:

> *The periodontal care of the public is primarily the concern of the general dentist, and that the general dentist cannot disregard his or her responsibility to provide periodontal care for all patients. The extremely high incidence of* ***periodontal problems*** *in the* ***population makes it impossible*** *for the small number of specialists*

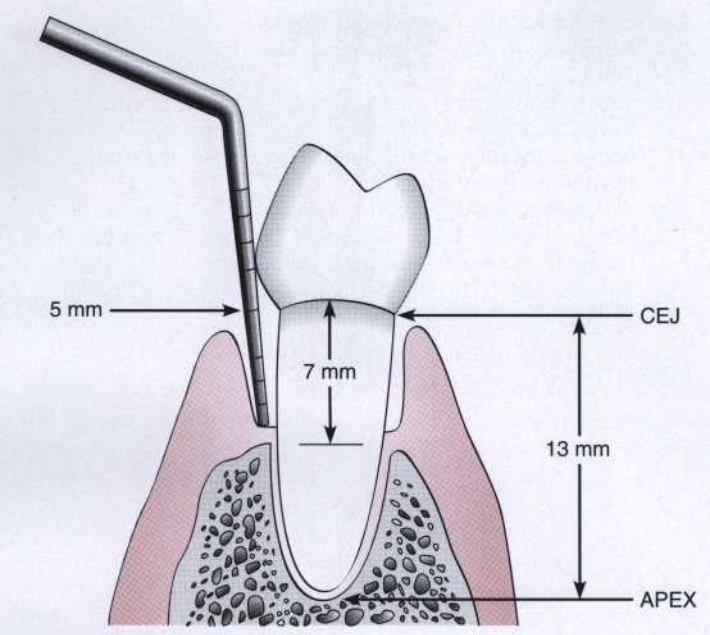

Fig. 48-2 The 5-mm standard for referral to a periodontist is based on root length, probing depth, and attachment loss. The **standard serves as a reasonable guideline to trigger further analysis of the case and possible need for specialist care.** (Redrawn from Armitage G (ed): Periodontal Maintenance Therapy. Berkeley, CA, Praxis, 1974.)

in periodontics to cope with them; in addition, the close relationship between periodontal and restorative dental therapies makes it very important for the general dentist to have a thorough knowledge of periodontics. A well-trained group of periodontists who specialized in the diagnosis and treatment of severe or unusual problems should serve only to supplement the general dental care available to our population.'

The question remains when to refer a patient for specialist periodontal care. With a few patients the disease is so severe or unusual in presentation that referral to a periodontist is obvious. Many cases are treatable in the general dentist's office and likely to heal sufficiently after Phase I therapy so that no further treatment intervention is required beyond routine maintenance. Any patient who does not clearly fall into either category has been called a *candidate for referral."* The 5-mm standard has been proposed as a guideline for referral. If the patient at reevaluation has apical migration of the epithelial attachment, probing depths of greater than 5 mm, or both, then referral should be considered. The 5-mm standard has been suggested because the typical root length is about 13 mm (Fig. 48-2). The probe, when inserted into the 5-mm pocket, rests near the epithelial attachment, which is normally about 1 mm thick. The crest of the bone supporting the tooth would then be 7 mm apical to the cementoenamel junction (CEJ), demonstrating loss of approximately half the bone support for the tooth. Specialist care could help preserve the tooth in this situation by eliminating deep pockets and regenerating support for the tooth.

In addition to the 5-mm standard, other factors must be considered in the decision to refer. These include the following:

1. Extent of disease: The deeper the pockets, the stronger the indication for referral.
2. Root length: Short roots are more seriously jeopardized by 5 mm of clinical attachment loss than long roots.
3. Hypermobility, which suggests a more guarded prognosis.
4. Difficulty of scaling and root planing: The presence of deep pockets and furcations make local treatment much more difficult.
5. Restorative work: Long-term prognosis of the tooth is an important consideration in planning extensive restorative work.
6. Age of the patient: The younger the patient with extensive attachment loss, the more aggressive the disease process is likely to be.
7. Resolution by shrinkage: Some tissue such as thick, fibrotic gingiva do not resolve as well as thinner, edematous gingiva when edema subsides, leaving deeper probing depths.

The success in treating advanced periodontal disease generally occurs in patients with 6- to 8-mm probing depths and/or attachment loss. Specialists have limited success when depths are 9 mm or greater, so early referral of advanced cases is likely to provide the best results. Each patient is unique, and the decision process for each patient is complex. The considerations presented in this section should give the reader some guidance in making referral decisions.

SUMMARY

Plaque control is the removal of dental plaque on a regular basis and the prevention of its accumulation on the teeth and adjacent gingival surfaces. It is a critical component of dental practice, permitting long-term success of periodontal and dental care. This widely held view is reflected in the following policy statement adopted in 1998 European Workshop on Mechanical Plaque Control: "Forty years of experimental research, clinical trials, and demonstration projects in different geographical and social settings have confirmed that effective removal of dental plaque is essential to dental and periodontal health throughout life."[1]

In 1965, Loe and co-workers conducted the classic study demonstrating the relationship between plaque accumulation and the development of experimental gingivitis in humans. Dental plaque was allowed to accumulate in the absence of any plaque control procedures, resulting in the development of gingivitis in all subjects within 7 to 21 days. The composition of bacteria also shifted so that gram-negative organisms predominated in dental plaque associated with gingival inflammation. In addition, it was shown that the gingivitis was reversible. Daily removal of dental plaque led to resolution of the gingival inflammation in just a few days. Good supragingival plaque control has also been shown to retard calculus formation and affect the growth and composition of subgingival plaque.[121] Carefully performed daily home plaque control, combined with frequent professionally delivered plaque removal, has been demonstrated to reduce supragingival plaque, decrease the total number of microorganisms in moderately deep pockets, including furcation areas, and greatly reduce the number of subgingival sites with *Porphyromonas gingivalis,* a significant periodontal pathogen. Thus plaque control is

an effective way of treating and preventing gingivitis and is a critical part of all the procedures involved in the treatment and prevention of periodontal diseases .as

Although all patients need to adopt good plaque control practices, periodontal patients are considered more "at risk" than the general dental patient population. Their plaque control is critical because they have active infections or have had previously treated disease. In either case, periodontal patients have demonstrated susceptibility to periodontal infections. The tissue destruction they experience creates sites and defects susceptible to further breakdown.$$ The role of other risk factors for periodontal infections, such as smoking, genetic predisposition, or systemic disease, also are very important but not easily quantified. In reality, the control of these other risk factors is often beyond the control of the clinician, requiring the focus on this one well-established etiologic factor, dental plaque. Plaque control and preventive procedures can be relied upon to improve periodontal infections; however, the resolution of disease also depends on the type of periodontal infection and the presence of additional risk factors. 55

The dental profession relies on mechanical plaque control (i.e., daily cleaning with a toothbrush and other oral hygiene aids) as the most dependable way of achieving oral health benefits for all dental patients including periodontal patients. Plaque growth occurs within hours and must be completely removed at the very least every 48 hours in periodontally healthy subjects to prevent inflammation. 140 Toothbrushing is a completely accepted part of daily life and good oral hygiene practice. However, plaque control by toothbrushing alone is not sufficient to control gingival and periodontal diseases because periodontal lesions are predominantly interdental. 88 It has been demonstrated in healthy subjects that plaque formation begins on the interproximal surfaces where the toothbrush does not reach. Masses of plaque first develop in the molar and premolar areas, followed by the proximal surfaces of the anterior teeth and the facial surfaces of the molars and premolars. Lingual surfaces accumulate the least amount of plaque. In terms of removing plaque, subjects consistently leave more plaque on the posterior teeth than the anterior teeth, and interproximal surfaces retain the highest amounts of plaque. 140 The plaque control efforts of periodontal patients are further complicated by defects in gingival architecture and long, exposed root surfaces.

The optimal frequency for plaque removal by periodontal patients has not been determined, but it is reasonable to expect periodontal patients to completely remove plaque from the teeth at least once every 24 hours due to patient susceptibility to disease and complexity of the task.' Taken together, these findings suggest plaque control efforts must focus on more than simply improved toothbrushing. Periodontal patients must concentrate on cleaning interproximal areas and be encouraged to adopt significantly more difficult and time-consuming oral hygiene habits that must be performed daily.

Chemical inhibitors of plaque and calculus incorporated in mouthwashes or dentifrices also play an important role in plaque control. Fluorides are essential for caries control. These products have been highly marketed and are commonly used as adjunctive agents to mechanical techniques. These medicaments, as with any drug, should be recommended and prescribed according to the needs of individual patients. Chemical plaque control is a rapidly growing field and will become even more significant for periodontal patients and practices in the future as increasingly effective products become available.

Plaque control is one of the key elements of the practice of dentistry. It permits each patient to assume responsibility for his or her own oral health on a daily basis. Without it, optimal oral health through periodontal treatment cannot be attained or preserved. Every patient in every dental practice should be educated about plaque control and encouraged to perform a personalized program on a daily basis. Good plaque control facilitates the return to health for patients with gingival and periodontal diseases, prevents tooth decay, and preserves oral health for a lifetime.

THE TOOTHBRUSH

The bristle toothbrush appeared about the year *1600* in China, was first patented in America in 1857, and has since undergone little change. Generally, toothbrushes vary in size and design as well as in length, hardness, and arrangement of the bristles (Fig. 49-1).134 The American Dental Association has described the range of dimensions of acceptable brushes: a brushing surface 1 to 1.25 inches (25.4 to 31.8 mm) long and 5/16 to 3/8 inch (7.9 to 9.5 mm) wide, 2 to 4 rows of bristles, and 5 to 12 tufts per row.2 A toothbrush should be able to reach and efficiently clean most areas of the teeth.

Some toothbrush manufacturers claim superiority of design for such things as minor modifications of bristle placement, length, or stiffness. **These claims are primar**ily based on demonstrations of plaque removal that are shown to be statistically significantly superior to comparable toothbrushes in one or more clinical studies. However, the research does not show significant differences in gingivitis scores or bleeding indices, the more important measures of improved gingival health. It is questionable whether slight differences in measurements of plaque removal are in fact clinically significant because no toothbrush and few toothbrushers remove all plaque. A recent study of four different commercially available toothbrush designs compared plaque removal at a single brushing. All four toothbrushes removed plaque equally and the authors concluded that no one design was superior to others.33

In terms of recommending a particular toothbrush, superiority of clinical significance has not been demonstrated for any one type of toothbrush. Ease of manipulation by the patient is an important factor in brush selection, as is the patient's perception that the brush works well. The effectiveness of and potential injury from different types of brushes depend to a great degree on how the brushes are used.26 Data from in vitro studies of abrasion by different manual toothbrushes suggest that differences in the brush design permitting the bristles to carry more toothpaste while brushing contribute to abrasion more than brush bristles themselves." The

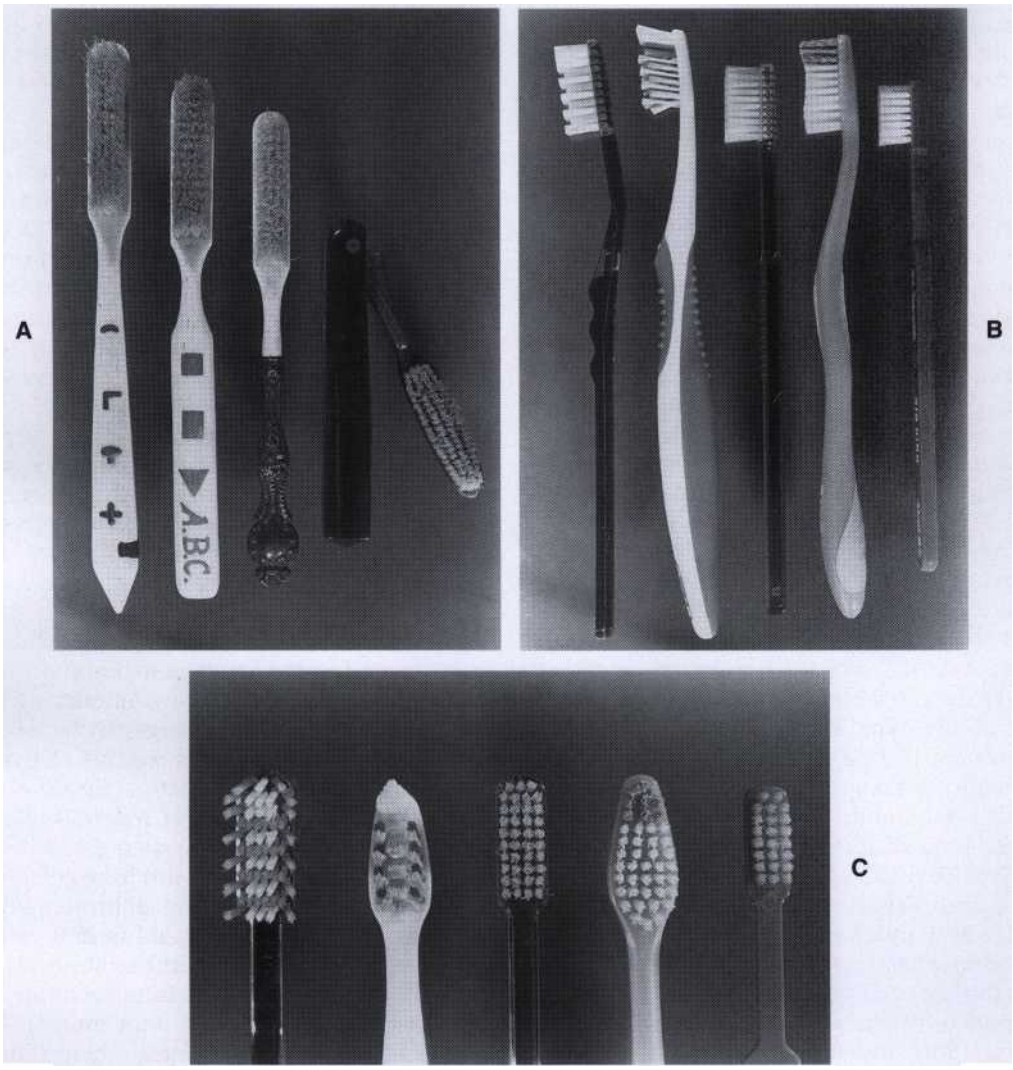

Fig. 49-1 Manual toothbrushes. A, Toothbrushes from the 19th and 20th centuries, two with ivory handles from about 1890 *(left),* one with a sterling silver handle *(center),* and an early travel brush with a plastic handle from about 1930 *(right).* The ivory-handled brushes belonged to dental students who used the handles to practice cutting preparations and using filling materials. The designs are "filled" with either gold foil or amalgam. B, A variety of toothbrushes are available; note the variation in brush head and handle design. C, Close-up view of brush heads showing various bristle configurations. (Antique brushes from the UCSF School of Dentistry Historical Collection, courtesy Dean Charles N. Bertolami, San Francisco, Calif.)

type of brush is largely a matter of individual preference. However, there is common agreement that use of a hard toothbrush, vigorous horizontal brushing, and possibly use of very abrasive dentifrice may lead to cervical abrasions of teeth and recession of gingva"

Recently, some novel designs intended to make brushing easier and hard-to-reach areas more accessible have been described. One has curved bristles on both sides of the brush head and shorter bristles running down the center. It is designed to brush buccal, lingual, and occlusal/incisal surfaces of the teeth at one time. One study demonstrating its plaque removal ability showed statistically significant differences between the curved bristles and a conventional brush, but absolute differences were slight.30 Another design featured a U-shaped head with bristles that would also reach buccal, lingual, and occlusal/incisal surfaces at one time. This study also showed slight differences in plaque removal favoring the new design over a conventional brush and a powered toothbrush. It did not evaluate changes in gingival condition."' The notion of brushing all reachable surfaces of the teeth at one time is attractive, and these inventive brush designs may be useful for some patients to achieve better plaque control. There is no reason to discourage use of any particular device, especially if the patient likes it and uses it more or better than a conventional brush. There may well be a truly better design in the hands of any individual patient that results in better plaque removal and improved gingival health.

Two kinds of bristle material are used in toothbrushes: natural bristles from hogs and artificial filaments made predominantly of nylon. Both types remove plaque, and

nylon bristles vastly predominates in the market.[21] However, in terms of homogeneity of the material, uniformity of bristle size, elasticity, resistance to fracture, and repulsion of water and debris, nylon filaments are clearly superior. Because of their tubular form, natural bristles are significantly more susceptible to fraying, breaking, contamination with diluted microbial debris, softening, and loss of elasticity. Patients accustomed to the softness of an older natural bristle brush can traumatize the gingiva when using a new brush with comparable vigor. It is helpful to point this out when a patient changes from natural to nylon bristles.

Toothbrush bristles are grouped in tufts that are usually arranged in three or four rows. Multitufted toothbrushes contain more bristles and may clean more efficiently than skimpier brushes. Rounded bristle ends cause fewer scratches on the gingiva than flat cut bristles with sharp ends.[37,134] The question of the most desirable bristle hardness is not settled. Bristle hardness is proportional to the square of the diameter and inversely proportional to the square of bristle length.[70] Diameters of commonly used bristles range from 0.007 inch (0.2 mm) for soft brushes to 0.012 inch (0.3 mm) for medium brushes and 0.014 inch (0.4 mm) for hard brushes.[76] Soft bristle brushes of the type described by Bass'" have gained wide acceptance. Bass recommended a straight handle and nylon bristles 0.007 inch (0.2 mm) in diameter and 0.406 inch (10.3 mm) long, with rounded ends, arranged in three rows of tufts, six evenly spaced tufts per row, with 80 to 86 bristles per tuft. For children, the brush is smaller, with thinner (0.005 inch or 0.1 mm) and shorter (0.344 inch or 8.7 mm) bristles."$

Opinions regarding the merits of hard and soft bristles are based on studies carried out under differing conditions; these studies are often inconclusive and contradict one another.[77] Soft bristles are more flexible, clean beneath the gingival margin when used with a sulcus brushing technique,[17] and reach further onto the proximal tooth surfaces.[57] Use of hard-bristled toothbrushes is associated with more gingival recession, and frequent brushers who use hard bristles have more recession than those who use soft bristles.[86] However, the manner in which a brush is used and the abrasiveness of the dentifrice affect the action and abrasion to a greater degree than the bristle hardness itself.[1,109] Bristle hardness does not significantly affect wear on enamel surfaces.[128]

Overzealous brushing can lead to gingival recession; bacteremia, especially in patients with pronounced gingivitis, wedge-shaped defects in the cervical area of root surfaces[56,127]; and painful ulceration of the gingiva.[120] This type of brushing should be identified and discouraged.

To maintain cleaning effectiveness, toothbrushes must be replaced periodically. Wear patterns differ widely among individuals, but with conscientious, regular use, most brushes show signs of wear within a few months. If all the bristles are flattened after 1 week, brushing is probably quite vigorous; if the bristles are still straight after 6 months, either the brushing is done very gently or the brush has not been used every day. The amount of force used to brush does not appear to be critical in plaque removal.[144] Nor does the amount of visible bristle wear appear to affect plaque removal function for up to 9 weeks.[36] Unfortunately, people tend to use toothbrushes as long as possible, often long after the bristles are quite worn. Toothbrushes with wear reminders (e.g., a blue dye on some of the bristles) are currently available. The dye fades with use and can be helpful in reminding patients to replace their toothbrushes periodically.

The preference of handle characteristics is a matter of individual taste. The handle should fit comfortably in the palm of the hand; it may be straight or angled, thick or thin (see Fig. 49-1). Brushes with modest angulation between the head and the handle are available, and some clinical evidence supports the idea that these brush handles improve access for plaque removal under supervised brushing conditions. In fact, a recent study described a toothbrush with a double angulation of the neck of the handle and demonstrated significantly more plaque reduction, especially on the buccal and lingual surfaces. The clinical significance of these findings has not been determined, but it is reasonable to surmise that modifications improving access may help some patients to brush more effectively.

For most patients, short-headed brushes with straight-cut, round-ended, soft to medium nylon bristles arranged in three or four rows of tufts are recommended. However, if a patient perceives any benefit from a particular brush design characteristic, use of that brush should be encouraged.

POWERED TOOTHBRUSHES

Electrically powered toothbrushes were invented in 1939 and intended to make plaque control easier for patients to master. The first powered toothbrushes were designed to mimic hand toothbrushing techniques using back-and-forth motions. Some were subsequently designed with circular or elliptic motions, and some with combinations of motions. Today, many types of powered toothbrushes designed for home use are available, some with reciprocating bristle tufts (Fig. 49-2) and brushes that use low-frequency acoustic energy to enhance cleaning ability. Powered toothbrushes that have shaped tips designed for interproximal cleaning are also available (Fig. 49-3).

All powered toothbrushes rely on mechanical contact between the bristles and the tooth to remove plaque. The addition of low-frequency acoustic energy generates dynamic fluid movement and provides cleaning slightly away from the bristle tips. The vibrations have also been shown to interfere with bacterial adherence to oral surfaces. Neither the sonic vibrations nor the mechanical motion of powered toothbrushes has been shown to affect bacterial cell viability.[106]

One review suggested that acoustic microstreaming, hydrodynamic shear forces that may disrupt plaque, are the likely mechanism of action for these powered brushes. The authors noted that most comparison studies between powered toothbrushes, manual toothbrushes, or other powered devices demonstrate, at best, slightly improved plaque removal for the device of interest in short-term clinical trials. Although this permits advertising claims of superiority, improved oral health for all patients or all periodontal patients has not been

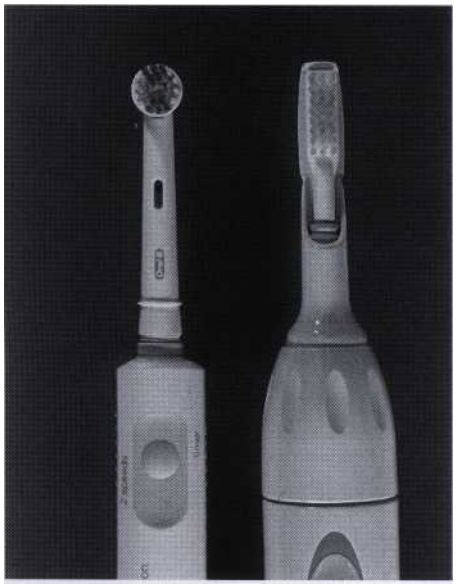

Fig. 49-2 Powered toothbrush designs offer options in head shape and size.

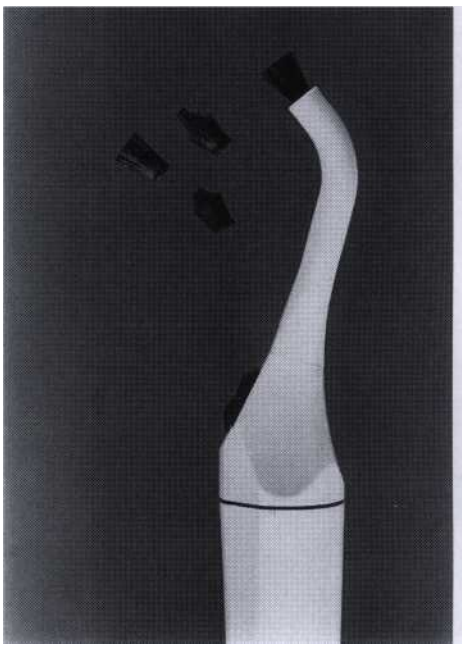

Fig. 49-3 Powered toothbrush with shaped tips can be used for interproximal cleaning and other difficult areas around the teeth.

demonstrated. Patient acceptance of powered toothbrushes is good. A recent study reported that 88.9% of patients introduced to a powered toothbrush would continue to use it.[148] Patients quit using powered toothbrushes after about 5 or 6 months, presumably when the novelty has worn off." However, modern powered toothbrushes with additional features such as sonic technology to reach further onto proximal surfaces and timers to remind patients to brush longer are considered by some to be superior to manual brushes.[145]

Regardless of the type of device, the best plaque removal results are obtained when the patient is instructed in its proper use. This assures that the moving bristles have to be placed correctly around the mouth.[11,145] In fact, instructional videos have been shown to be an effective way of educating patients on the proper use of powered toothbrushes.[123]

Patients who can develop the ability to use a toothbrush properly usually do equally well with a manual or a powered toothbrush. Less diligent brushers do better with powered toothbrushes, which generate stroke motions automatically and require less operator effort.[60] Powered toothbrushes have been shown to improve oral health for: (1) children and adolescents, (2) children with physical or mental disabilities, (3) hospitalized patients, including older adults who need to have their teeth cleaned by caregivers, and (4) patients with fixed orthodontic appliances. They have not been shown to routinely provide benefits for patients with rheumatoid arthritis, children who are well-motivated brushers, and patients with chronic periodontitis.[73]

Powered toothbrushes are not generally superior to manual ones. Although some researchers have reported that powered toothbrushes remove more plaque than manual toothbrushes, reduce calculus accumulation, and improve gingival health,[101,108] other authors have reported that the same brushes failed to perform better than comparisons.[14,15,54,60,112,145] Identified improvements tend to be slight and localized in terms of improved gingival health,' but more plaque is typically removed from proximal surfaces using the newer devices.[143] One interesting study demonstrated reductions in gingival fluid flow for patients with moderate periodontal disease when the sonic toothbrush was used over an 8-week period. The authors suggested the sonic toothbrush might have some effect on inflammation beyond that achieved by manual toothbrushing.'" Generally, powered toothbrushes are at least as good for plaque removal as manual brushes. If a powered toothbrush can be helpful to a particular patient, it should be recommended and encouraged.

No specific toothbrush can be singled out as clearly superior for the routine removal of dental plaque from the teeth when measured by improvement in gingival health. Requirements for a good toothbrush differ greatly among individuals, and any toothbrush, including powered toothbrushes, should be recommended after considering factors such as patient interest, morphology of the dentition, periodontal health, and manual dexterity. Because of the wide acceptance of oral hygiene principles first reported by Bass,[11,18] the one brush probably most commonly recommended by dentists appears to be the four-row, multitufted, soft, nylon, handheld toothbrush. This style of brush is certainly adequate but does not fit the needs or provide the best choice for every patient in every practice.

Powered toothbrushes can be valuable replacements for manual brushes if used regularly and properly. They are particularly useful for cleaning proximal surfaces and for people with limited dexterity, children who like them, and caregivers of ill patients. Some patients simply

prefer powered toothbrushes and are more compliant with oral hygiene procedures when using them.

DENTIFRICES

Dentifrices aid in cleaning and polishing tooth surfaces. They are used mostly in the form of pastes, although tooth powders and gels are also available. Dentifrices are made up of abrasives such as silicon oxides, aluminum oxides, and granular polyvinyl chlorides; water; humectants; soap or detergent; flavoring and sweetening agents; therapeutic agents such as fluorides and pyrophosphates; and coloring agents and preservatives.

Dentifrices should be sufficiently abrasive for satisfactory cleansing and polishing but should provide a margin of safety to protect the aggressive toothbrusher from wearing away root structure and soft restorative materials.[130] Abrasives, commonly in the form of insoluble inorganic salts, make up 20% to 40% of a dentifrice. The proper use of a dentifrice can enhance the abrasive action of a toothbrush as much as 40 times.[109] Tooth powders contain about 95% abrasives and are five times more abrasive than pastes. The abrasive quality of dentifrices affects enamel, but abrasion is more of a concern for patients with exposed roots because dentin is abraded 25 times faster and cementum 35 times faster than enamel. This can lead to root surface abrasion and root sensitivity.[139] Existing literature suggests that hard tissue damage from oral hygiene procedures is mainly due to abrasive dentifrices, whereas gingival lesions can be produced by the toothbrush alone[120,121] (Fig. 49-4).

Abrasions are more prevalent on maxillary than on mandibular teeth and are found more frequently on the left than on the right half of the dental arch. This suggests that access and right- or left-handedness may also contribute to the abrasion. Dentifrices that provide the effectiveness required for plaque control with a minimum of abrasion are preferable.

There is considerable interest in improving dentifrices by using them as vehicles for chemotherapeutic agents to inhibit plaque, calculus, caries, or root hypersensitivity. The pronounced caries-preventive effect of fluorides incorporated in dentifrices has been proved beyond question.[131] To achieve this effect, free fluoride ions must be available in the paste, not bound to the ingredients in the abrasive system. The American Dental Association (ADA) Council on Scientific Affairs[3] (formerly the Council on Dental Therapeutics) has voluntarily evaluated fluoride dentifrices. Several toothpastes have been found to have fluoride available in the correct amount (1000 to 1100 ppm), along with clinical studies documenting their caries reduction effects. Toothpaste products that have been tested by the ADA and have been determined to have fluoride ion available in the appropriate amount carry the ADA seal of approval for caries control and can be relied on to provide caries protection.

Substances such as chlorhexidine,[45] penicillin, dibasic ammonium phosphate, vaccines, vitamins, chlorophyll, and formaldehyde have proved to be of little therapeutic value in toothpastes. Tartar control toothpastes with the active ingredient pyrophosphate are currently available. This ingredient interferes with crystal formation in calculus and does not affect the fluoride ion in the paste or increase tooth sensitivity. This type of dentifrice has reduced the formation of new supragingival calculus by 30% or more .[83,107,154] These pastes are beneficial only for supragingival calculus. They do not affect subgingival calculus formation or gingival inflammation. To achieve the greatest effect from anti-calculus toothpaste, the patient's teeth must be cleaned and completely free of supragingival calculus when starting to use the product daily. The inhibitory effect will only work against the deposition of new calculus.

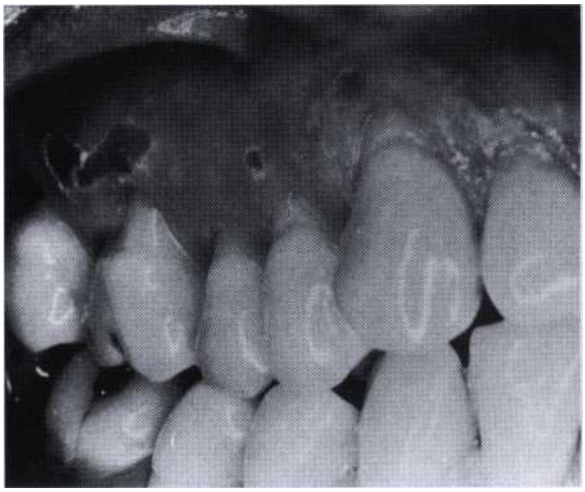

Fig. 49-4 Vigorous tooth brushing with an abrasive dentifrice can result in trauma and wearing away of the tooth surfaces, especially root surfaces, and contribute to gingival recession.

TOOTHBRUSHING METHODS

Many methods for brushing the teeth have been described and promoted as being efficient and effective. These methods can be categorized primarily according to the pattern of motion when brushing[81]:

Roll: The roll method' or modified Stillman" technique
Vibratory: The Stillman,"' Charters ,[29] or Bass" techniques
Circular: The Fones[53] technique
Vertical: The Leonard technique[96]
Horizontal: The scrub technique"o

Controlled studies evaluating the effectiveness of the most common brushing techniques have not demonstrated any clear superiority for any one method. The scrub technique is probably the simplest and most common method of brushing. Patients with periodontal disease are most frequently taught a sulcular brushing technique using a vibratory motion to improve access in the gingival areas. The roll technique seems to be the least effective method, perhaps because it generates only intermittent pressure against the teeth compared with the sustained force applied with the sulcular and scrub techniques.[22]

Three common methods of brushing the teeth are presented here, any of them, if properly performed, can provide excellent plaque control. The goal of brushing is

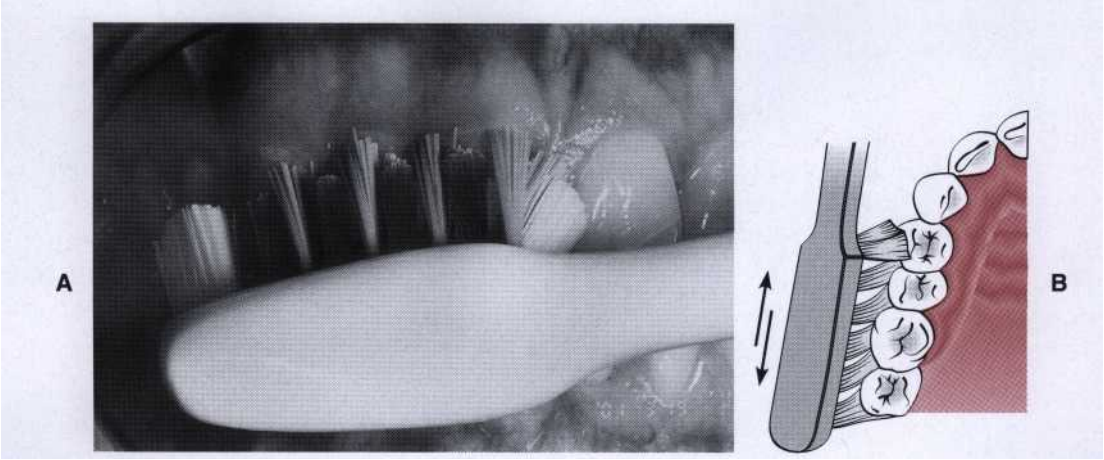

Fig. 49-5 Bass method. A, Place the toothbrush so that the bristles are angled approximately 45 degrees from the tooth surfaces. B, Start at the most distal tooth in the arch and use a vibrating, back-and-forth motion to brush.

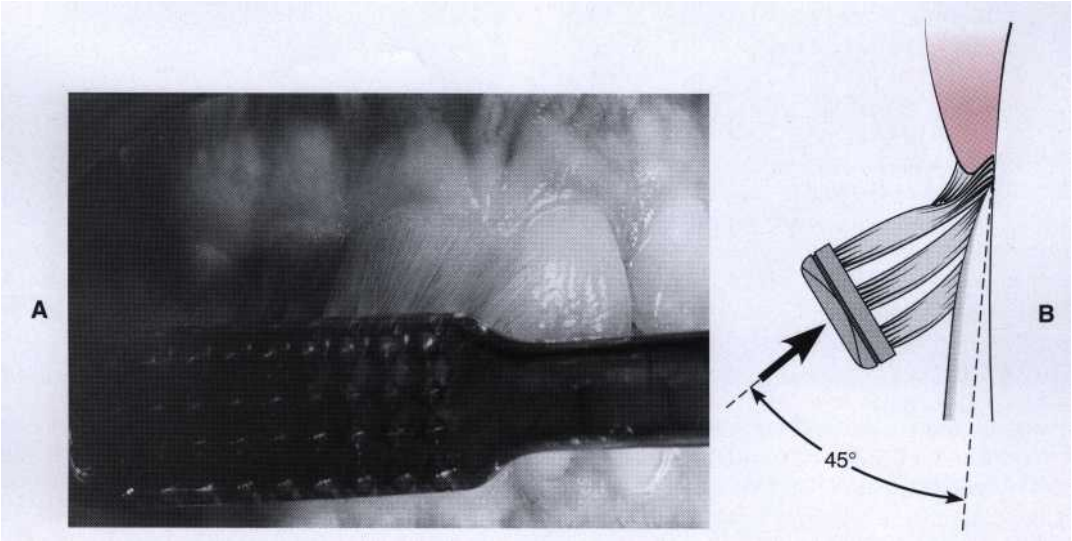

Fig. 49-6 Bass method. A, Proper position of the brush in the mouth aims the bristle tips toward the gingival margin. B, Diagrams shows the ideal placement, which could permit slight subgingival penetration of the bristle tips.

to remove as much plaque from the accessible tooth surfaces as possible. The best brushing method for each patient is determined when forming an individualized and complete plaque control program. It also should be remembered that brushing with a powered toothbrush is an equally good alternative.

The Bass Method

Technique. Place the head of a soft brush parallel with the occlusal plane, with the brush head covering three to four teeth, beginning at the most distal tooth in the arch. Place the bristles at the gingival margin, establishing an angle of 45 degrees to the long axis of the teeth. Exert gentle vibratory pressure, using short back-and-forth motions without dislodging the tips of the bristles. This motion forces the bristle ends into the gingival sulcus area (Fig. 49-5) as well as partially into the interproximal embrasures. The pressure should produce perceptible blanching of the gingiva (Fig. 49-6). Complete approximately 20 strokes in the same position. This repeated motion cleans the tooth surfaces, concentrating on the apical third of the clinical crowns, the gingival sulci, and as **far onto the** proximal surfaces as the bristles can reach. Lift the brush, move it to the adjacent teeth, and repeat the process for the next three or four teeth.

Continue around the arch, brushing about three teeth at a time, then use the same method to brush the lingual surfaces (Figs. 49-7 and 49-8). After completing the maxillary arch, move the brush to the mandibular arch and brush in the same manner until the entire dentition is completed. To help reach the lingual surfaces of the anterior teeth if the brush seems too large, insert the brush vertically (Figs. 49-9 and 49-10). Press the end of the

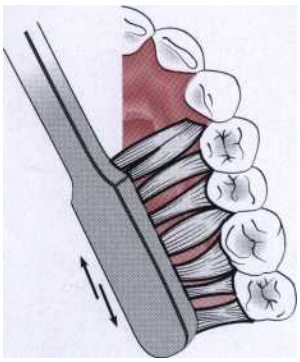

Fig. 49-7 Bass method. The correct palatal position on molars and premolars is with the bristle tips at the gingival margin as shown in the diagram, not on the occlusal surfaces.

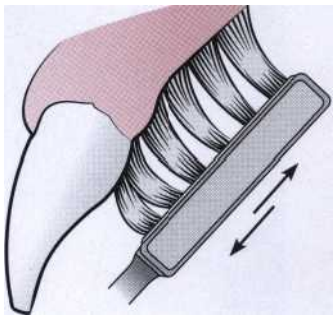

Fig. 49-9 Bass method. Adjusting the palatal position of the toothbrush on incisors, as shown in the diagram, may provide better access for plaque removal.

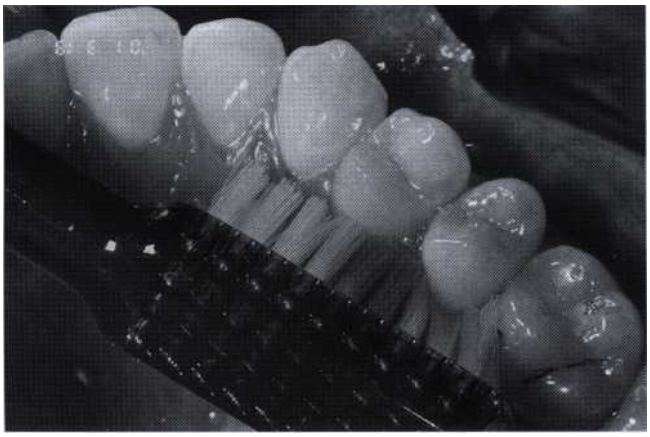

Fig. 49-8 Bass method. Palatal position of the soft toothbrush on the molars and premolars permits bristle tip penetration into the interproximal areas and possibly slightly subgingivally.

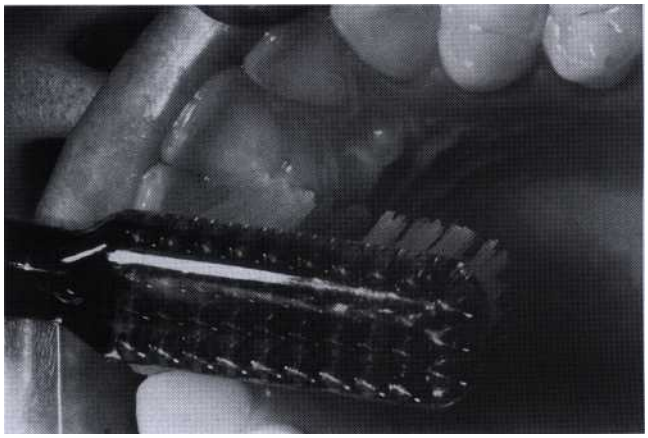

Fig. 49-10 Bass method. Placement of the bristles on the palatal surfaces of the incisor teeth can be difficult and often requires this modified approach.

brush into the gingival sulcus area and proximal surfaces at a 45-degree angle to the long axis of the teeth and brush with multiple short vibratory strokes.

Press the bristles firmly into the pits and fissures of the occlusal surfaces (Fig. 49-11) and brush with about 20 short back-and-forth strokes. Use this technique and brush a few teeth at a time until all posterior teeth in all four quadrants are cleaned.

The Bass technique requires patience and placement of the toothbrush in many different positions to cover the full dentition. Patients need to be instructed to brush in a controlled and systematic sequence to optimize plaque removal.

The Bass method has certain advantages over other techniques, as follows:

1. The short back-and-forth motion is easy to master because it is a simple movement familiar to most patients who brush using a scrub technique.
2. It concentrates the cleaning action on the cervical and interproximal portions of the teeth, where microbial plaque is most likely to have accumulated.

The Bass technique is efficient and can be recommended for any patient with or without periodontal involvement.

The Modified Stillman Method

The modified Stillman method[137] requires that the brush be placed with the bristle ends resting partly on the cervical portion of the teeth and partly on the adjacent gingiva, pointing in an apical direction and at an oblique angle to the long axis of the teeth (Fig. 49-12). Apply pressure against the gingival margin to produce a perceptible blanching. Then move the brush about 20 short back-and-forth strokes while simultaneously moving it coronally along the attached gingiva, the gingival margin, and the tooth surface. A soft or medium multitufted brush should be used with this technique to minimize trauma to the gingiva.

This process must be repeated on all tooth surfaces, proceeding systematically around the mouth. To reach the lingual surfaces of the maxillary and mandibular incisors, the handle of the brush can be held in a vertical position,

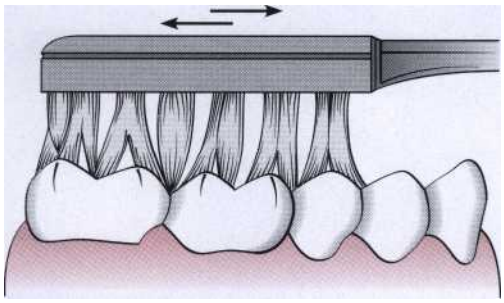

Fig. 49-11 **This brush position on occlusal surfaces of the teeth is used with any technique, including the Bass, Stillman, or Charters method.**

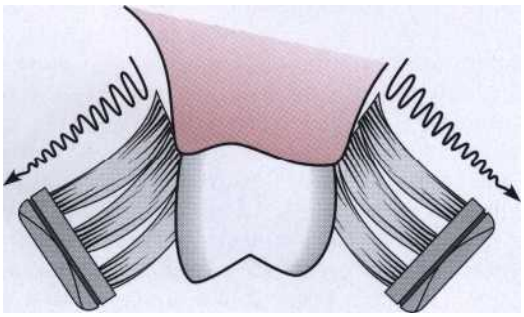

Fig. 49-12 **Modified Stillman method. This method requires placement of the sides of the bristles against the teeth and gingiva while moving the brush with short, back-and-forth strokes in a coronal direction.**

engaging the end of the brush. With this technique, the sides rather than the ends of the bristles do the work. The bristles tend not to penetrate into the gingival sulcus.

The occlusal surfaces of molars and premolars are cleaned with the bristles placed perpendicular to the occlusal plane and penetrating into the grooves and interproximal embrasures (see Fig. 49-11).

The modified Stillman method may be recommended for cleaning in areas with progressing gingival recession and root exposure to minimize abrasive tissue destruction.

The Charters Method

The Charters method requires placement of a soft or medium multitufted brush on the teeth with the bristles pointed toward the crown at a 45-degree angle to the long axis of the teeth (Fig. 49-13). The sides of the bristles should be flexed against the gingiva, and a back-and-forth vibratory motion used to brush. The technique was designed to gently massage the gingiva, so the bristle tips should not drag across the gingiva. The bristle tips should be placed in the pits and fissures, and short back-and-forth strokes should be used to clean the occlusal

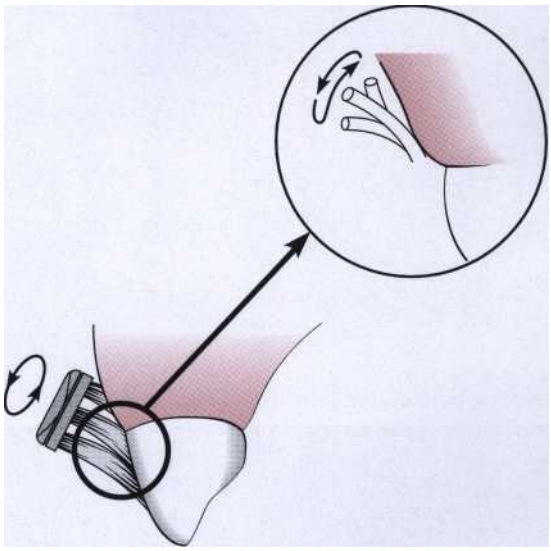

Fig. 49-13 **Charters method. The Charters method requires that the bristles be pressed against the sides of the teeth and gingiva. The brush is moved with short circular or back-and-forth strokes.**

surfaces (see Fig. 49-11). The procedures are repeated systematically until all surfaces are cleaned.

The Charters method provides gentle plaque removal. This technique can be recommended for cleaning in areas of healing wounds after periodontal surgery.

Methods of Cleaning with Powered Toothbrushes

The various mechanical motions built into powered toothbrushes do not require special techniques of application. The patient need only concentrate on placing the brush head next to the teeth at the gingival margin and proceeding systematically around the dentition. Additional placement adjustments can be made to clean difficult areas, such as the distal surfaces of the third molars, furcations, or gingival clefts. The methods described for manual brushing are also suitable for application with powered toothbrushes (Fig. 49-14).

INTERDENTAL CLEANING AIDS

Any toothbrush, regardless of the brushing method used, does not completely remove interdental plaque. This is true both in individuals with healthy periodontal conditions and those with periodontal destruction resulting in open embrasures [58,63,131] Interdental plaque removal is crucial to augment the effects of tooth brushing because, as previously noted, the majority of dental and periodontal disease originates in interproximal areas. Other conditions found in periodontal and gingival diseases also demand an emphasis on interproximal cleaning. The gingival tissues are swollen in the presence of gingival inflammation, rendering the self-cleansing mechanisms of the mouth less effective than in a healthy periodontium. Also, tissue destruction associated with periodontal disease may leave large open spaces between teeth and long-exposed root surfaces with anatomical concavities and furcations. These are difficult areas to

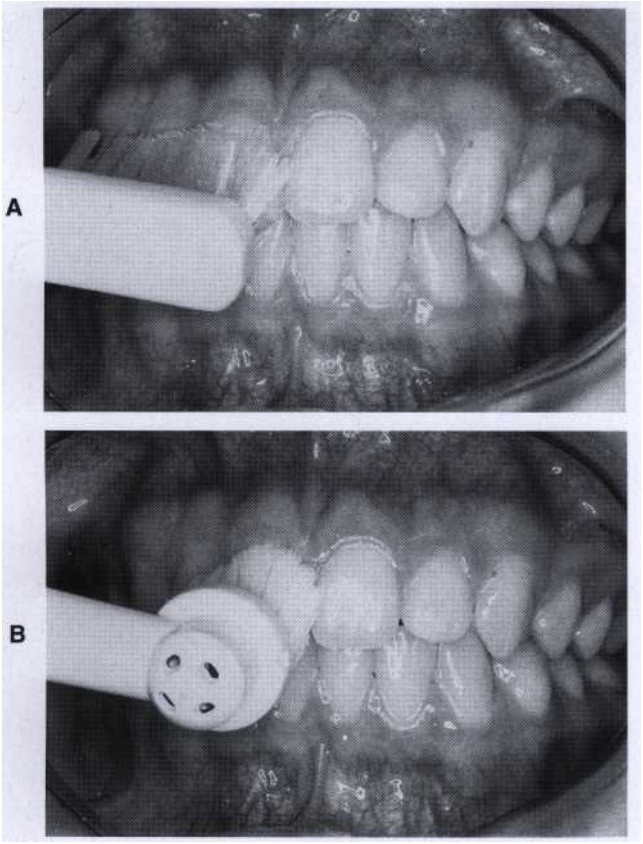

Fig. 49-14 Positioning of the powered toothbrush head and bristle tips so that they reach the gingival margin is critical to achieving the most effective cleaning results. A, Straight head placement. B, Round head placement.

clean and only poorly accessible to the toothbrush.[88] Interdental cleaning should occur every day for the same rationale as brushing daily.'

The purpose of interdental cleaning is to remove plaque, not to dislodge fibrous threads of food wedged between teeth. Although interdental cleaning does dislodge food fragments, correcting proximal tooth contacts and plunger cusps is required to stop chronic food impaction.

The specific aids required for interproximal cleaning depend on various criteria such as the size of the interdental spaces, the presence of furcations, tooth alignment, and the presence of orthodontic appliances or fixed prostheses.

Among the numerous aids available, dental floss and interdental cleaners such as wooden or plastic tips and interdental brushes are commonly recommended.

Dental Floss

Dental floss is the most widely recommended tool for removing plaque from proximal tooth surfaces." Floss is available as a multifilament nylon yarn that is twisted or nontwisted, bonded or nonbonded, waxed or unwaxed, and thick or thin. Monofilament flosses made of a

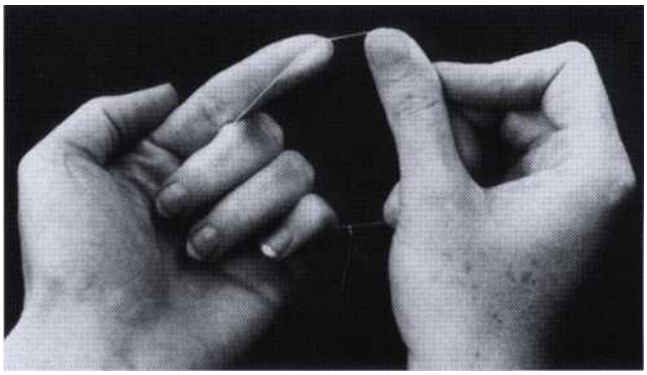

Fig. 49-15 Dental floss may be held securely in the fingers or tied in a loop.

Teflon-type material are preferred by some individuals because they are slick and do not fray. A variety of individual factors determine the choice of dental floss, such as the tightness of tooth contacts, roughness of proximal surfaces, and patient's manual dexterity, not the superiority of any one product. Clinical research so far has not been able to show any significant differences in the ability of the various types of floss to remove dental plaque; they all work equally well.'[1,75,84,85,128] In the past, waxed dental floss was thought to leave a waxy film on proximal surfaces, thus contributing to plaque accumulation and gingivitis. It has been shown, however, that wax is not deposited on tooth surfaces[121] and that improvement in gingival health is unrelated to the type of floss used." Therefore recommendations about type of floss should be based on ease of use and personal preference.

Technique. The floss must contact the proximal surface from line angle to line angle to clean effectively. It must also clean the entire proximal surface, not just be slipped apical to the contact area. The following description is a primer in floss technique:

- Start with a piece of floss long enough to grasp securely; 12 to 18 inches is usually sufficient. It may be wrapped around the fingers, or the ends may be tied together in a loop.
- Stretch the floss tightly between the thumb and forefinger (Fig. *49-15),* or between both forefingers, and pass it gently through each contact area with a firm back-and-forth motion. Do not snap the floss past the contact area, because this may injure the interdental gingiva. In fact, zealous snapping of floss through contact areas creates proximal grooves in the gingiva.
- Once the floss is apical to the contact area between the teeth, wrap the floss around the proximal surface of one tooth, and slip it under the marginal gingiva. Move the floss firmly along the tooth up to the contact area and gently down into the sulcus again, repeating this up-and-down stroke several times (Fig. *49-16).* Then move the floss across the interdental gingiva and repeat the procedure on the proximal surface of the adjacent tooth.

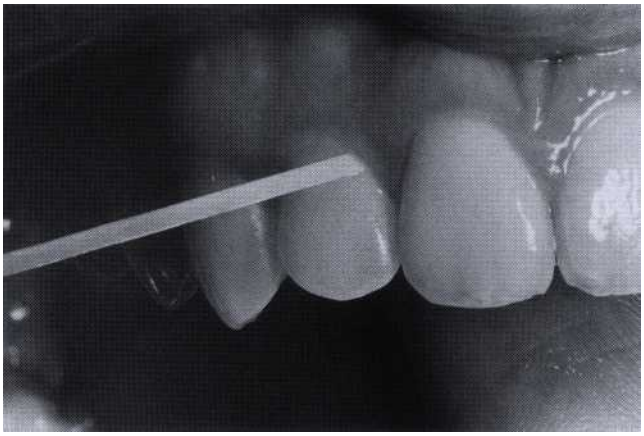

Fig. 49-16 Dental floss technique. The floss is slipped between the contact area of the teeth (in this case teeth #7 and #8), wrapped around proximal surface, and removes plaque by using several up-and-down strokes. The process must be repeated for the distal surface of tooth #8.

- Continue through the whole dentition, including the distal surface of the last tooth in each quadrant. When the working portion of the floss becomes soiled or begins to shred, move to a fresh portion of floss.

Flossing can be made easier by using a floss holder (Fig. 49-17, A). Although use of such devices can be more time consuming than finger flossing, they are helpful for patients lacking manual dexterity and for nursing personnel assisting handicapped and hospitalized patients in cleaning their teeth. A floss holder should possess these features: (1) one or two forks that are rigid enough to keep the floss taut when penetrating into tight contact areas, and (2) an effective and simple mounting mechanism to hold the floss firmly in place. The disadvantage of floss tools is that they must be rethreaded whenever the floss becomes soiled or begins to shred.

Disposable, single-use floss holders with prethreaded floss are available and may be useful for some patients. Short-term clinical evidence suggests that plaque reduction and improvement in gingivitis scores are similar for individuals instructed in the use of disposable floss devices when compared with scores for those instructed in finger flossing (see Fig. 49-17, B).

Powered flossing devices are also available (Fig. 49-18). These devices have a single bristle that moves in a circular motion. The devices have been shown to be safe and effective but no better at plaque removal than finger flossing. 34.64

The establishment of a lifelong habit of flossing the teeth is difficult to achieve for both patients and dentists, regardless of whether one uses a tool or flosses with the fingers. In fact, the daily use of floss is universally low. It was recently reported that only about 8% of 12- to 16-year olds in Great Britain floss daily,'°s a number similar to other countries.$$ An analysis of the British adolescents showed that daily flossing was correlated to frequent hand washing and bathing and having recently visited the dentist.'°s No information is available about the establishment of long-term flossing habits comparing the various tools to finger flossing. However, the tools may be useful to help some individuals begin flossing or make flossing possible if they have limited dexterity. The benefits of interproximal cleaning using dental floss are undisputed. Proper manipulation of floss requires good dexterity and repeated reinforcement.

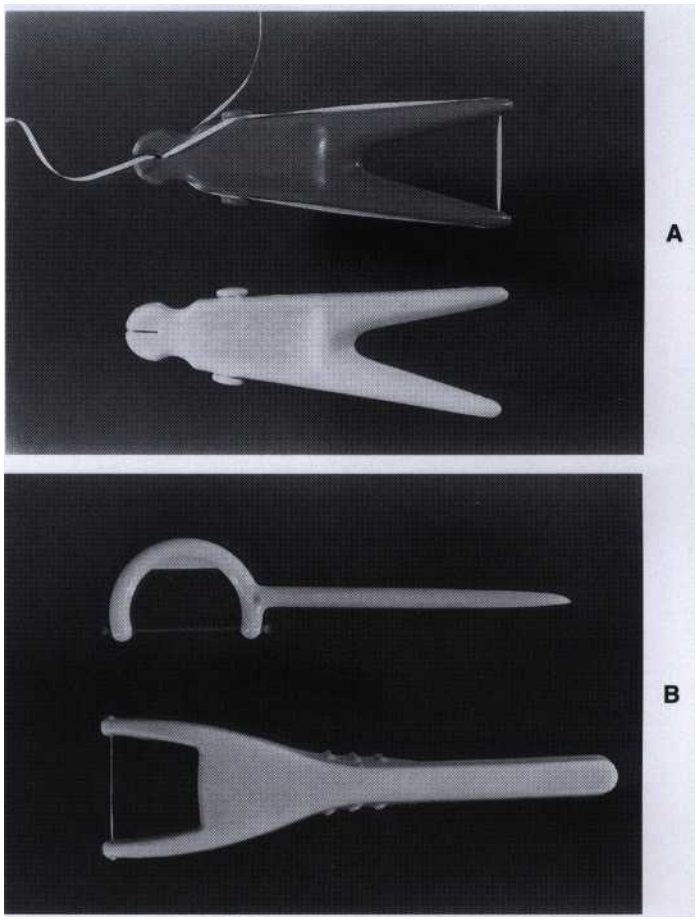

Fig. 49-17 Floss holders can simplify the manipulation of dental floss. A, Reusable floss tools require stringing the floss around a series of knobs and grooves to secure it. B, Disposable floss tools have prestrung floss and are easy to use, but the floss may shred and break, requiring several tools to complete flossing the teeth.

iinterclental Cleaning Devices

Dental floss is probably the most effective dental hygiene aid for cleaning in narrow gingival embrasures that are occupied by intact papillae and bordered by tight contact zones. Concave root surfaces and furcations that are often present in periodontal patients who have experienced significant attachment loss and recession are not as thoroughly cleaned with dental floss alone. A comparison study of dental floss and interdental brushes used by patients with moderate to severe periodontal disease showed that the interproximal brushes removed slightly more interproximal plaque. However, no difference was

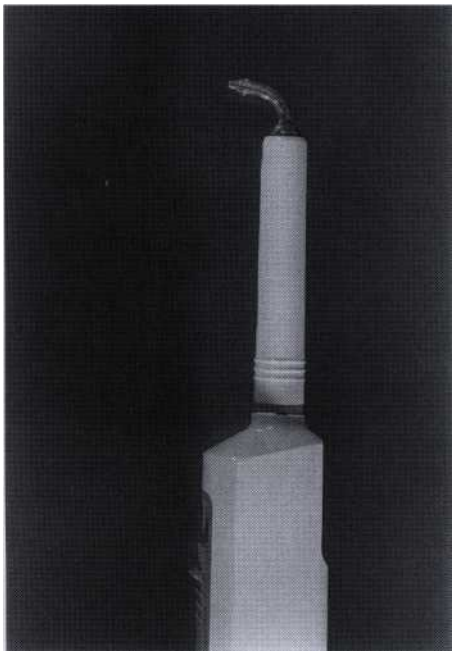

Fig. 49-18 A powered flossing device can be easier to use than hand-held floss. The tip is inserted into the proximal space, and a bristle or wand comes out of the tip and moves in a circular motion when the device is turned on. The bristle mechanically removes the plaque.

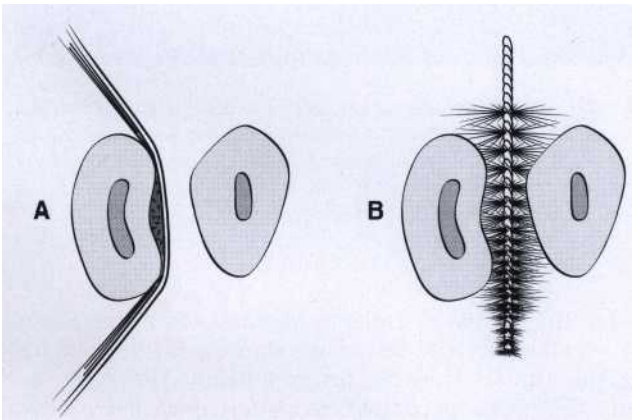

Fig. 49-19 Cleaning of concave or irregular proximal tooth surfaces. Dental floss (A) may be less effective than an interdental brush (B) on long root surfaces with concavities.

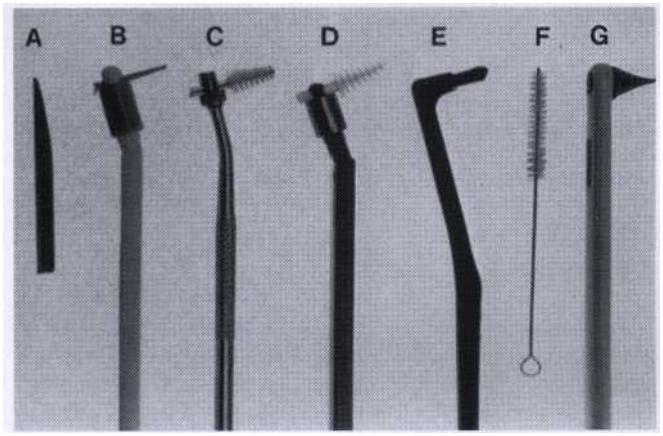

Fig. 49-20 A large variety of interproximal cleaning devices are available: wooden tips (A and B), interproximal brushes (C-F), and rubber tip stimulators (G).

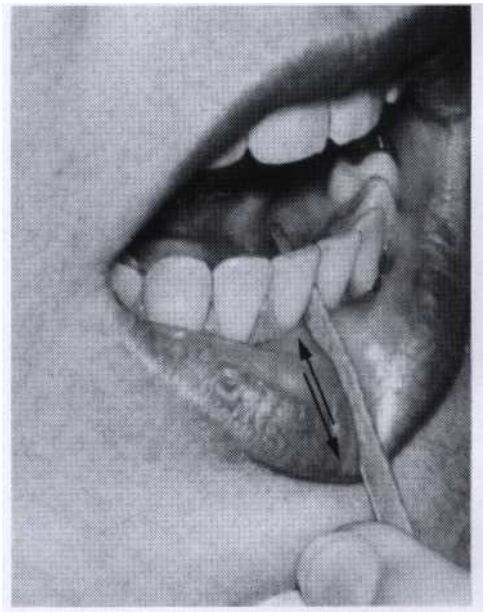

Fig. 49-21 Triangular wooden tip. The tip is inserted between the teeth, with the triangular portion resting on the gingival papilla, and is moved in and out. This device is popular but is very difficult to use on posterior teeth and from the lingual aspect of all teeth.

seen in probe depth reductions or bleeding indices. In addition, the interdental brushes were considered by the subjects to be easier to use than dental floss. Therefore other cleaning aids that are easy to handle and adaptable to irregular and long, exposed root surfaces (Fig. 49-19) can be recommended for proximal cleaning of teeth when interdental spaces permit access. This type of gingival architecture and root exposure is commonly found in periodontal patients.

A wide variety of interdental cleaning devices are available for removing soft debris from tooth surfaces that are not accessible to a full-size toothbrush and dental floss (Fig. 49-20). The most common types are small conical or cylindric brushes, tapered wooden toothpicks that are round or triangular in cross-section, and single-tufted brushes. Many interdental devices can be attached to a handle for convenient manipulation around the teeth and in posterior areas. Clinical research has shown that the devices are effective on lingual and facial tooth surfaces as well as on proximal surfaces.[88,131,146]

Interdental Brushes. Interdental brushes are cone-shaped or cylindric brushes made of bristles mounted on a handle (see Fig. 49-20, C and D), single-tufted brushes

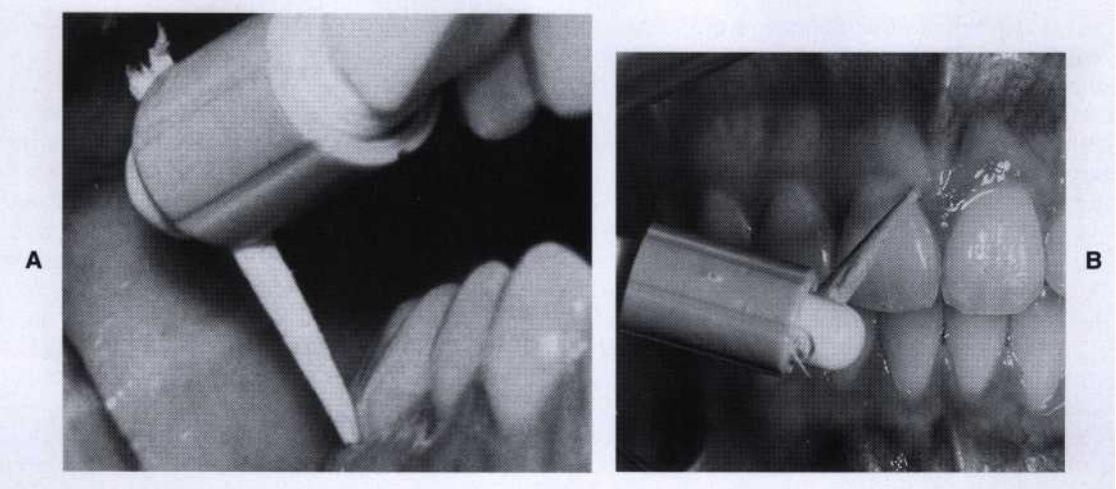

Fig. 49-22 Wooden toothpick. A, The tip is a common wooden toothpick held in a handle and broken off. It is used to clean subgingivally and reach into periodontal pockets. B, The tip can also be used to clean along the gingival margins of the teeth and reach under the gingiva.

(see Fig. 49-20, E), or small cylindric brushes (see Fig. 49-20, F). Interdental brushes are particularly suitable for cleaning large, irregular, or concave tooth surfaces adjacent to wide interdental spaces.

Technique. Interdental brushes of any style are inserted through interproximal spaces and moved back and forth between the teeth with short strokes. For most efficient cleaning, it is probably best to select the diameter of brush that is slightly larger than the gingival embrasures to be cleaned. This size permits bristles to exert pressure on both proximal tooth surfaces, working their way into concavities on the roots. Single-tufted brushes are highly effective on the lingual surface of mandibular molars and premolars, where the tongue often impedes a regular toothbrush, and may provide access to furcation areas and isolated areas of deep recession.

Wooden or Rubber Tips. Wooden tips are used either with or without a handle (Fig. 49-20, A and B). Access is easier from the buccal surfaces for those tips without handles, primarily in the anterior and bicuspid areas. Rubber tips come mounted on handles or the ends of toothbrushes and can easily be adapted to all proximal surfaces in the mouth. Various plastic tips are also available and can be used in a manner similar to wooden tips. Both rubber and plastic tips can be rinsed and reused and easily carried in a pocket or purse, features that are attractive to some patients.

Technique. Soft, triangular wooden picks or plastic alternatives are placed in the interdental space in such a way that the base of the triangle rests on the gingiva and the sides are in contact with the proximal tooth surfaces (Fig. 49-21). The pick is then repeatedly moved in and out of the embrasure, removing soft deposits from the teeth and mechanically stimulating the papillary gingiva. The disadvantage of the triangular toothpick is that it is very hard to access any surfaces other than the facial surfaces in the more anterior region of the mouth.

Rubber tips should be placed into the embrasure space and used in a circular motion. They can be applied to interproximal spaces and other defects throughout the mouth and are easily adaptable to lingual surfaces.

Conventional toothpicks can also be used for interproximal cleaning. They have the advantage of being a common device and readily available in most homes. Toothpicks can be attached to commercially available handles for better access to posterior and lingual areas or used as bought (Fig. 49-20, B). Once mounted on the handle, the toothpick is broken off so that it is only 6 or 7 mm long. The tip of the toothpick is used to trace along the gingival margin and into the proximal areas from both the facial and lingual surfaces throughout the mouth. Plaque can also be removed by using the sides in a manner similar to a wooden pick (Fig. 49-22, A) or the tip of the toothpick (Fig. 49-22, B). This device is particularly efficient for cleaning along the gingival margin and into periodontal pockets and furcations.

Conclusions. A large and changing variety of interdental cleaning aids are available for patients. Experience and patient preference will help you determine which are best for any particular situation. It is important to remember that brushing alone is not sufficient for plaque removal and that some interproximal device needs to be used routinely by the patient in the daily plaque control regimen. In general, the largest brush or device that fits into a space will clean most efficiently, and obviously, the devices the patient likes will be most used.

Embrasure spaces vary greatly in size and shape. A representation of three types of embrasures and the kind of interdental cleaner often recommended for each is shown in Fig. 49-23. As a general rule, the larger the space, the larger the device that should be used. However, some devices are more difficult to assemble and use than others, so a favorite tool of one individual may be impossible for another to use. It is useful to have a variety of aids available so that you and the patient can decide what fits best and is easiest to use. Often the patient

requires three components to the plaque control routine; a brushing method, dental floss to clean subgingivally and tight embrasure spaces, and an interdental aid for larger interdental spaces and furcations. Typically, the routine of complete plaque removal with the brush and required interproximal aids takes the periodontal patient up to 30 minutes every day.

GINGIVAL MASSAGE

Massaging the gingiva with a toothbrush or an interdental cleaning devices produces epithelial thickening, increased keratinization, and increased mitotic activity in the epithelium and connective tissue.[26,28,61,136] The increased keratinization occurs on the oral gingiva and not on the areas more vulnerable to microbial attack, the sulcular epithelium and the interdental areas where the gingival col is present. It has never been demonstrated that epithelial thickening, increased keratinization, and blood circulation provide protection against microorganisms and other local irritants and thus are beneficial or necessary for gingival health.[62] The improved gingival health associated with interdental stimulation is far more likely the result of plaque removal rather than gingival massage. In addition, studies of chemotherapeutic mouthrinses containing chlorhexidine have shown that gingival health can be maintained for periods of time in the absence of any mechanical oral hygiene procedure.[102] These data underscore the importance of emphasizing altering or removing plaque rather than stimulating or thickening the keratinized surface in the plaque control program.

Toothbrushing methods designed to massage the gingiva and devices such as the rubber tip stimulator (see Fig. 49-21, G) result in plaque removal in addition to massage. The plaque removal effect is likely far more important to periodontal health.

ORAL IRRIGATION DEVICES

Supragingival Irrigation

Oral irrigators for daily home use by patients work by directing a high-pressure, steady or pulsating stream of water through a nozzle to the tooth surfaces (see also Chapter 44). Most commonly, a device with a built-in pump generates the pressure (Fig. 49-24, A), but other devices attach to the water faucet. Oral irrigators clean nonadherent bacteria and debris from the oral cavity more effectively than toothbrushes and mouthrinses. They are particularly helpful for removing debris from inaccessible areas around orthodontic appliances and fixed prostheses. When used as adjuncts to toothbrushing, these devices can have a beneficial effect on periodontal health by retarding the accumulation of plaque and calculus and by reducing inflammation and pocket depth.

Oral irrigation has been shown to disrupt and detoxify subgingival plaque and can be useful in delivering antimicrobial agents into periodontal pockets.[114] Irrigation can be supragingival or subgingival. Daily supragingival irrigation with a dilute antiseptic, chlorhexidine, for 6 months resulted in significant reductions in bleeding and gingivitis compared with water irrigation and chlorhexidine rinse controls. Irrigation with water alone also reduced gingivitis significantly but not as much as the dilute chlorhexidine.[52]

Technique. The common home-use irrigator tip is a plastic nozzle with a 90-degree bend at the tip (Fig. 49-24, B), attached to a pump providing pulsating beads of water at speeds regulated by a dial. Patients should be instructed to aim the pulsating jet across the proximal papilla, hold it there for 10 to 15 seconds, then trace along the gingival margin to the next proximal space and repeat the procedure. By the time the patient has

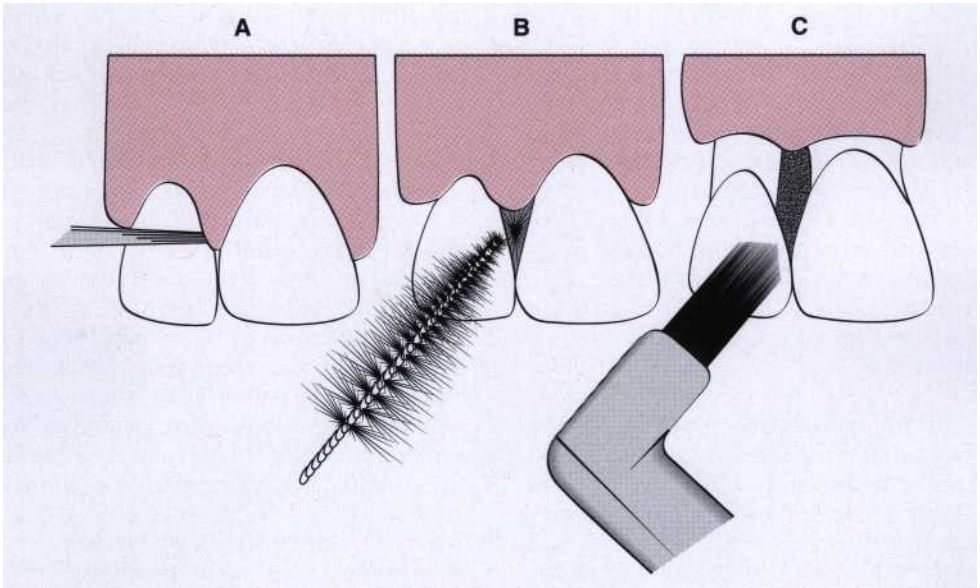

Fig. 49-23 Interproximal embrasure spaces vary greatly in patients with periodontal disease. In general, embrasures with no gingival recession are adequately cleaned using dental floss (A); larger spaces with exposed root surfaces require the use of an interproximal brush (B); and single-tufted brushes clean efficiently in interproximal spaces with no papillae (C).

irrigated all the proximal spaces in the full dentition, the irrigator reservoir will be empty. The irrigator should be used from both the buccal surface and lingual surface. This cleaning must be done while leaning across the bathroom sink because water will drip down the patient's arm. Patients with gingival inflammation usually start at lower pressure and then can increase the pressure comfortably to about medium as tissue health improves. Some individuals like to use the device on the highest pressure setting, with no reported harm. Patient comfort should be the guide for pressure setting.

Subgingival Irrigation

Subgingival irrigation performed both in the dental office or by the patient at home, particularly employing antimicrobial agents, has been shown to provide some site-specific therapy. It is performed by aiming or placing the irrigation tip into the periodontal pocket, attempting to insert the tip at least 3 mm. This is achieved by using a soft rubber tip at home or a canula in the dental office (Fig. 49-24, C and *D)*.[4°] Irrigation performed in the dental office, also called *lavage* or *flushing of the periodontal pocket,* as a one-time treatment after scaling and root planing has not been shown to improve clinical healing. It was reported that the flushing of untreated periodontal pockets with stannous fluoride resulted in slowed regrowth of subgingival bacteria.'" However, other studies have not confirmed this effect. Data from clinical studies of flushing immediately after scaling and root planing do not show improved gingival healing and do not support its use as providing consistent therapeutic results .

Subgingival irrigation performed with an oral irrigator using chlorhexidine diluted to one-third strength, performed regularly at home after scaling, root planing, and in-office irrigation therapy, has produced significant gingival improvement compared with controls.[82] These documented improvements in gingival health, along with other positive clinical results . suggest that patients can and should use subgingival irrigation at least once daily in difficult sites such as furcations and residual pockets. Currently available subgingival irrigation tips have been shown to disrupt plaque about half the depth of pockets, up to 7 mm, much further apically than a toothbrush or floss can reach .[42]

Currently, two types of irrigator tips are useful for subgingival irrigation (see Fig. 49-24, C and D). One is

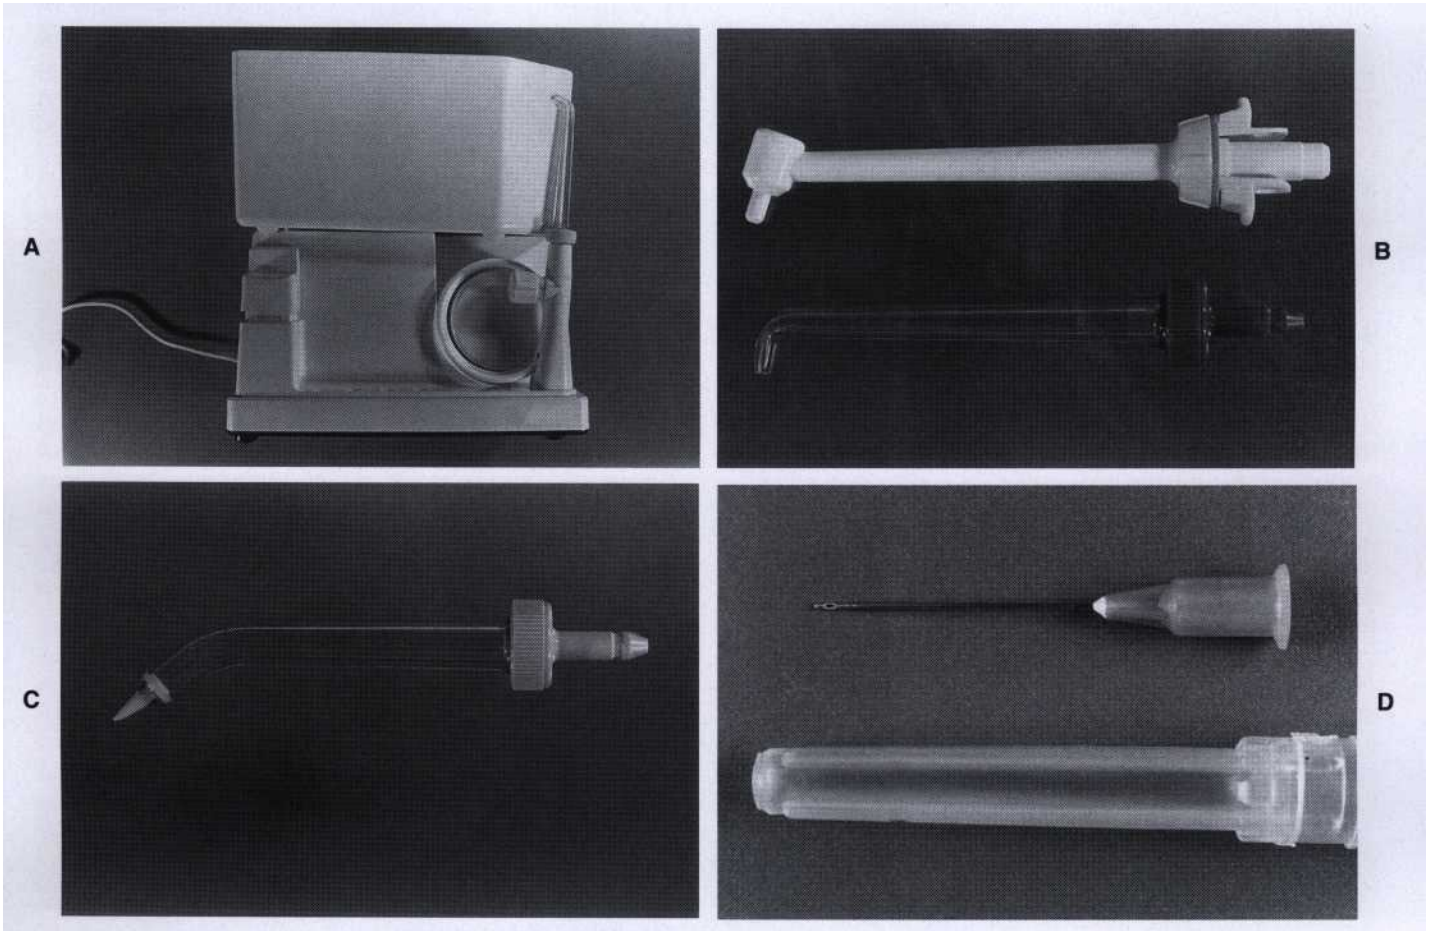

Fig. 49-24 Oral irrigation. A, The most common devices have a built-in pump and reservoir. B, Conventional plastic tips are used for daily supragingival irrigation at home by the patient. C, A soft rubber tip is used for daily subgingival irrigation by the patient at home. D, A canula tip is used for subgingival irrigation by the dentist or dental hygienist in the office.

the cannula type tip recommended for office use, and the other is a soft rubber tip for patient use at home. Both reduce the pressure and flow of the pulsating jet of water. Effective penetration of irrigant of up to 70% in laboratory simulation has been shown when using the cannula tip for deeper pockets.[79] Similar results have been reported for the soft rubber tip." The soft rubber tip, designed to irrigate at low pressure and reduced flow, is recommended for patient use at home.[32]

One cautionary note must be considered. Transient bacteremia has been reported after water irrigation in patients with periodontitiss and patients on periodontal maintenance.[147] However, bacteremia has also been found after toothbrushing[118] and is known to occur in some significant number of patients after scaling alone.[117] According to the Council on Dental Therapeutics of the ADA, bacteremia also can occur in the absence of dental procedures.[35] Therefore dentists should make every attempt to reduce gingival inflammation in susceptible patients by the use of toothbrushes, floss, and antiseptic mouthrinses. Subgingival irrigation at home is not the oral hygiene procedure of choice for patients requiring antibiotic prophylaxis before dental treatment, particularly if extensive inflammation is present.[40] Supragingival irrigation used in combination with toothbrushing and other interdental cleaning aids is acceptable and can result in improved clinical health.

CARIES CONTROL FOR THE PERIODONTAL PATIENT

Dental caries, particularly root caries, can be a problem for periodontal patients because of attachment loss associated with the disease process and periodontal therapeutic procedures. Root caries develops through a process similar to coronal caries, involving the alternating cycle of demineralization and remineralization of the surfaces.[149] The process requires the fermentation of carbohydrates in the plaque by oral bacteria, resulting in loss of mineral from the root surface. *Lactobacilli* and Streptococci species are involved in the root caries process, similar to coronal caries. The major difference is the amount of organic material in the root surfaces is greater than in enamel, so once the demineralization has occurred, the organic matrix-mostly collagen-is exposed. Organic material is then further broken down by bacterial enzymes, resulting in destruction of the root surface.[47]

Fluoride works primarily by topical effects to prevent and reverse the caries process, whether in enamel, cementum, or dentin. Low concentrations of topical fluoride inhibit demineralization, enhance remineralization, and inhibit the enzyme activity in bacteria by acidifying the cells.[48,49]

Topical application of fluorides has been demonstrated to prevent and reverse root surface carious lesions in vitro.[149] Adult patients benefit from the prevention and reversal of root caries provided by low-concentration topical fluoride delivered by toothpastes or other topical applications.[48] It also has been demonstrated that the use of fluoride dentifrice containing 5000 ppm fluoride was more effective in reversing active root caries lesions than the fluoride level of 1100 ppm found in conventional toothpastes.[19]

Periodontal patients require appropriate use of topical fluorides in the daily plaque control regimen to protect and remineralize both exposed root surfaces and coronal surfaces of teeth.

CHEMICAL PLAQUE CONTROL

Mechanical plaque removal remains the primary method used to prevent dental diseases and maintain oral health. However, an improved understanding of the infectious nature of dental diseases has dramatically revitalized interest in chemical methods of plaque control.

The ADA Council on Scientific Affairs has adopted a program for acceptance of plaque control agents. The agents must be evaluated in placebo-controlled clinical trials of 6 months or longer that demonstrate significantly improved gingival health compared with controls. To date, the ADA has accepted two agents for treatment of gingivitis: prescription solutions of chlorhexidine digluconate mouthrinse and nonprescription essential oil mouthrinse.

Chlorhexidine

The agent that has shown the most positive results to date is chlorhexidine, a diguanidohexane with pronounced antiseptic properties. The initial finding that two daily rinses with 10 ml of a 0.2% aqueous solution of chlorhexidine digluconate almost completely inhibited the development of dental plaque, calculus, and gingivitis in the human model for experimental gingivitis[63] has been confirmed by several other clinical investigations. Clinical studies of several months' duration have reported plaque reductions of 45% to 61% and, more importantly, gingivitis reductions of 27% to 67%.[68,92] The 0.12% chlorhexidine digluconate preparation is an equally effective agent currently available in the U.S. for reducing plaque and gingivitis.

Local, reversible side effects to chlorhexidine use may occur, primarily brown staining of the teeth, tongue, and silicate and resin restorations[92] and transient impairment of taste perception.[104] Chlorhexidine has very low systemic toxic activity in humans, has not produced any appreciable resistance of oral microorganisms, and has not been associated with any teratogenic alterations. The preparation contains 12% alcohol, which is of concern to clinicians and patients who know that regular use of alcohol increases the risk of oropharyngeal cancer. However, an extensive review of the available epidemiologic evidence associating alcohol-containing mouthrinse preparations with cancer concluded that existing data do not support this association.[44] Regardless, many patients continue to express this concern or simply do not wish to consume alcohol in any form.

Essential Oil Mouthrinse

Essential oil mouthrinses contain thymol, eucalyptol, menthol, and mythyl salicylate.[7] They have been evaluated in three long-term clinical studies and demonstrate

plaque reductions of 20% to 35% and gingivitis reductions of 25% to 35%.[39,65,89] This type of mouthrinse has a long history of daily use and safety dating back to the 19th century, and many patients have used the products for decades. These products also contain alcohol (up to 24% depending on the preparation), so some patients and clinicians are reluctant to use them.

Other Products

One preparation containing triclosan has shown some effectiveness in reducing plaque and gingivitis. It is available in toothpaste form, and the active ingredient is more effective in combination with zinc citrate or a copolymer of methoxyethylene.[69]

Several other mouthrinse products on the market have shown some evidence of plaque reduction, although long-term improvement in gingival health has not been substantiated. These include stannous fluoride,[98,152] cetylpyridinium chloride (quaternary ammonia compounds),[12,13] and sanguinarine.[110,119] Evidence suggests that these and other available mouthrinse products do not possess the antimicrobial potential of either chlorhexidine products or essential oil preparations. Also available are mouthrinse preparations with no alcohol content, which may be preferable for some patients. However, any of these mouthrinse products can be useful for patients who perceive benefits from the preparations.

One type of agent has been marketed as a prebrushing mouthrinse to improve the effectiveness of toothbrushing. The active ingredient is sodium benzoate. Research to support its effectiveness is contradictory, but the preponderance of evidence suggests that using a prebrushing rinse is no more effective than brushing alone.[20,21]

Chemical plaque control has been shown to be effective for both plaque reduction and improved wound healing after periodontal surgery.[129] Both chlorhexidine[9] and essential oil[77] mouthrinses have significant positive effects when prescribed for use after periodontal surgery for periods of 1 to 4 weeks.

Recommendations

Mechanical plaque control is necessary and not replaceable by chemical plaque control. Fluoride toothpastes are an essential part of any long-term plaque control program. Appropriate topical preparations of fluoride such as mouthrinses and higher concentration gels should be used as needed for caries control. The addition of antimicrobial mouthrinses will likely reduce gingivitis in periodontal patients. Chlorhexidine rinses are very effective agents and can be used to augment plaque control during Phase I therapy, for patients with recurrent problems, for ineffective plaque control for any reason, for some uncommon oral mucous membrane diseases, and for use after periodontal or oral surgery. Essential oil mouthrinses are also effective but to a lesser degree.[69] They may be advantageous because they have fewer side effects and are available without a prescription. Oral irrigators used with dilute solutions of effective antimicrobial agents can improve daily plaque control by patients.[43] The use of other agents such as cosmetic mouthrinses and prebrushing rinses should not be discouraged if patients perceive benefits from them, but they should not be used to replace proven mechanical and chemical means of plaque removal. Active recommendation of the use of all adjunctive agents should be based on evidence of efficacy and confirmed by clinical research on patients.

DISCLOSING AGENTS

Disclosing agents are solutions or wafers capable of staining bacterial deposits on the surfaces of teeth, tongue, and gingiva. They are excellent oral hygiene aids because they can provide the patient with an educational and motivational tool to improve the efficiency of plaque control procedures (Fig. 49-25).

Solutions and wafers are available commercially. Solutions are applied to the teeth as concentrates on cotton swabs or diluted as rinses. They usually produce heavy staining of bacterial plaque, gingiva, tongue, lips, and fingers, as well as the sink. Wafers are crushed between the teeth and swished around the mouth for a few seconds and then spit out. Either should be used in the office for plaque control instruction and dispensed as needed for home use to aid periodontal patients in evaluating the effectiveness of their oral hygiene routines.

FREQUENCY OF PLAQUE REMOVAL

In the controlled and supervised environment of clinical research, where well-trained individuals remove all visible plaque, gingival health can be maintained by one thorough cleaning exercise with brush, floss, and toothpicks every 24 to 48 hours.[81,88,91] Most patients, however, fall far short of this goal. The average cleaning lasts less than 2 minutes every day and removes only 40% of plaque. Several studies report improved plaque removal and therefore improved periodontal health associated with increasing the frequency of brushing up to twice per day.[81,113] Cleaning three or more times per day does not appear to further improve periodontal conditions. Cleaning once a day with all necessary tools is sufficient if it is performed meticulously. If plaque control is not adequate, a second brushing will help.

Recommendation

Emphasis must be placed on the efficiency of complete plaque removal at least once per day, rather than the frequency of brushing alone. However, poor performance of plaque removal can be improved by brushing twice per day.

PLAQUE CONTROL INSTRUCTION

In periodontal therapy, plaque control has two important purposes: to minimize gingival inflammation and to prevent the recurrence or progression of periodontal disease. Daily mechanical removal of plaque by the patient, including the use of appropriate antimicrobial agents, appears to be the only practical means for improving oral hygiene on a long-term basis. The process requires motivation on the part of the patient, education, and

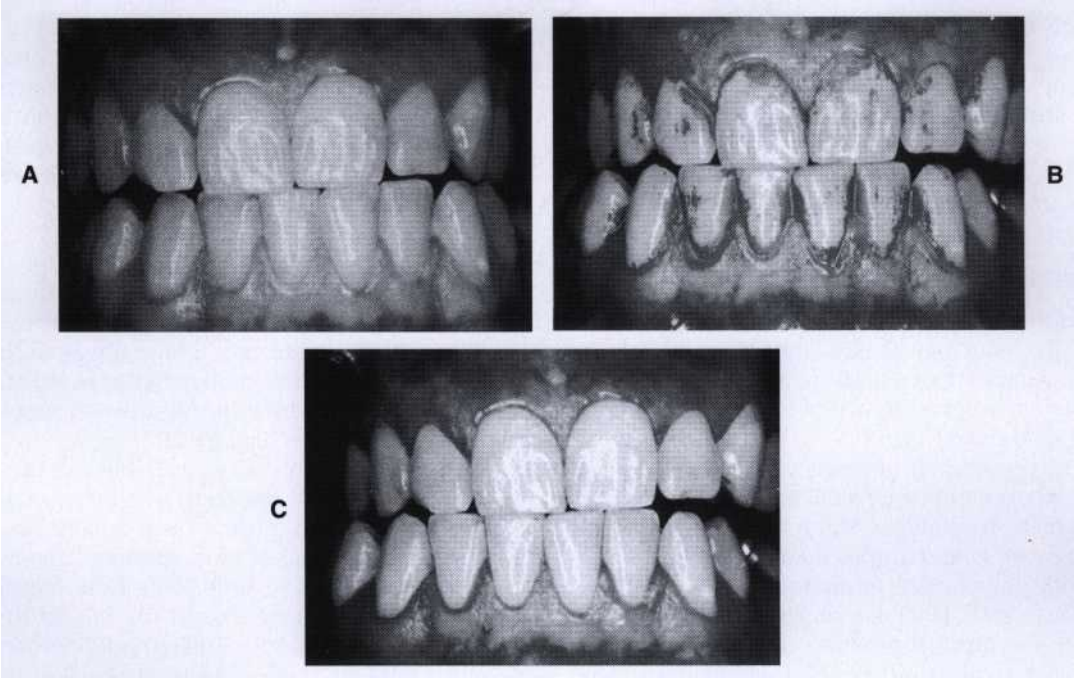

Fig. 49-25 Effect of a disclosing agent. A, Unstained. B, Plaque shows as dark-red particulate matter when stained with a disclosing dye. C, The absence of plaque is dramatically demonstrated by restaining the teeth after mechanical plaque control procedures.

instruction, followed by encouragement and reinforcement. An example of a plaque control record that permits repeated measures and comparison over time is presented in Fig. 49-26.

Motivation for Effective Plaque Control

Undoubtedly, mechanical oral hygiene practices, whether or not they are supplemented with chemical plaque control, are key in the restoration of health and prevention of disease in dentistry. This is true for the two major oral health diseases, dental caries and periodontal disease. Although this chapter has focused on plaque control for patients with periodontal disease, appropriate use of fluoride products to promote remineralization of tooth surfaces and deter demineralization are also essential elements in all individual plaque control programs. These must be used along with appropriate mechanical implements and disinfecting solutions.

Once the patient and clinician have determined the appropriate regimen, changing and augmenting patient behavior remains a significant challenge. Motivating patients to perform effective plaque control is one of the most critical and difficult elements of long-term success in periodontal therapy. It requires both the patient's commitment to adopting new habits of daily plaque control and regular return visits for maintenance and reinforcement.

Patient noncompliance with both prescribed oral hygiene regimens and regular return visits is a common occurrence in dental practice. To give a sense of the magnitude of the problem with plaque control devices, it has been shown that patients stop using interproximal cleaning aids in a very short period of time. Heasman and co-workers followed 100 patients who had been treated for moderate to severe periodontal disease.72 All had been taught to use one or more interdental cleaning aids, but only 20% used the aids after 6 months. Of those who had started using three devices, one third had stopped all interdental cleaning at 6 months; the others used one or two of the aids. The situation is no better when looking at patient willingness to return for office visits. One study of private patients in a dental clinic showed very disappointing compliance with recall maintenance, the long-term reinforcement and prevention of recurrence aspects of periodontal care. Of 1280 patients, most of whom had periodontal surgery in multiple sites after intensive scaling, root planing, and plaque control instruction, 25% never returned for a follow-up visit. Only 40% returned regularly.'" Wilson reported that 67% of periodontal patients were noncompliant with return visits in a 20-year retrospective of a private periodontal practice.

Yet motivating patients to adopt new habits and return for office visits is not an impossible task. To be successful, the patient must be:

1. Receptive: Required to understand the concepts of the pathogenesis, treatment, and prevention of periodontal disease.
2. Willing to change the habits of a lifetime: Necessary to adopt a successful, self-administered daily plaque control regimen.
3. Able to make behavioral changes: Required to adjust the hierarchy of a person's beliefs, practices, and values to accommodate the required new oral hygiene habits and return for regular periodontal maintenance visits.

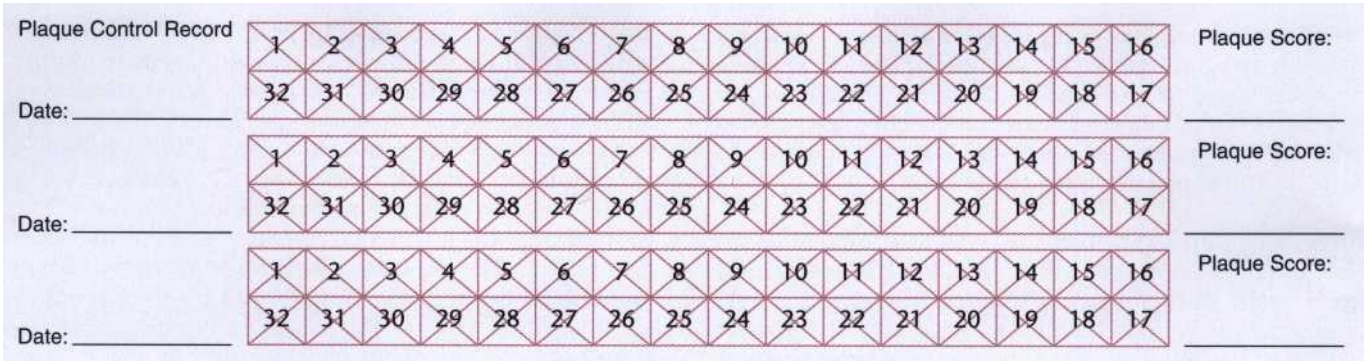

Fig. 49-26 **The plaque control record can be an effective motivator for patients. This form permits easy comparison of scores over time. (Courtesy Dean Charles N. Bertolami, UCSF School of Dentistry, San Francisco, Calif.)**

The patient must understand what periodontal disease is, what its effects are, that he or she is susceptible to it, and what his or her responsibility is in achieving and maintaining oral health. Manual skills must be developed and used to establish an effective plaque control regimen. In addition, the benefits of a clean mouth must be understood. The patient must both learn and adopt the required plaque control measures and return for periodic recall treatment to achieve long-term health benefits.'" If not, long-term success of treatment is far less likely and can lead to frustration for both the dentist and the patient. Changes in the habits of individuals' entire lives are difficult to achieve but essential. This process begins with educating the patient, developing an acceptable plaque control strategy, and reinforcing positive changes in behavior.

Education

Many patients believe that visits to the dental office for periodontal care will eliminate the disease process. It is incumbent on the dentist to educate and inform the patient to reinforce patient responsibility for long-term success of therapy and cure. Patient-administered plaque control currently is the most important preventive and therapeutic procedure in periodontal therapy. Our health-conscious society is an advantage with regard to patient education. Most patients know what gingivitis is because they have heard about it on television or read about it in magazines. They are willing to spend time and money to try new products such as toothbrushes and mouthrinses. Each patient education experience must be individualized according to need and level of understanding.

Patients must be informed that periodic assessment and debridement of the teeth in the dental office are required to prevent recurrence of periodontal diseases and identify problems that may arise. These procedures work best if combined with individualized oral hygiene procedures practiced daily at home. Therefore time spent in the dental office teaching the patient how to perform plaque control procedures is as central to ongoing care as scaling the teeth. The purpose of the recall visit is not to remove plaque because plaque forms every day. Patients sometimes have the concept that "cleanings" by the dentist or dental hygienist once every few months are sufficient for plaque removal and disease control. It must be explained that dental visits two or three times a year are only part of the maintenance needed; effective daily home plaque control is the rest. This information gives each patient responsibility for health care and control over the disease process. Only the combination of regular office visits with conscientious home care significantly reduces gingivitis and loss of supporting periodontal tissues over the long term. [99-141]

The periodontal patient should be shown that periodontal disease has manifested itself in his or her own mouth. Stained dental plaque, the bleeding of inflamed gingiva, and demonstrations of the periodontal probe inserted into pockets are impressive and convincing demonstrations of the presence of pathogens and symptoms of disease. It also is of educational value to a patient to have his or her oral cleanliness and periodontal condition recorded periodically." The patient and the dentist can use this as feedback information about the level of performance and positive reinforcement for improvement. The Plaque Control Record and the Bleeding Points Index are simple indices and are commonly used for patient reinforcement.

Plaque Control Record (the O'Leary Index).'" Disclosing solution is applied to all supragingival tooth surfaces. After the patient has rinsed to remove excess dye, each tooth surface (except occlusal surfaces) is examined for the presence or absence of stained deposits at the dentogingival junction, four surfaces for each tooth. Plaque, if present, is indicated on the appropriate box in a diagram. After all teeth have been scored, the index is calculated by dividing the number of surfaces with plaque by the total number of surfaces scored and then multiplied by 100 to get a percentage of surfaces with plaque present. A reasonable goal for patients is 10% or fewer surfaces with plaque, unless plaque is always present in the same areas. If so, special instructions should be directed toward improving performance in those areas. It is extremely difficult to achieve a perfect score of 0, so patients should be rewarded for approaching it.

Some commonly used plaque indices do not require staining the teeth, such as the Plaque Index of Silness

and Loe.[133] These may seem more convenient to use and possibly more acceptable to patients, but they have some disadvantages for patient education. Identification of plaque is not as quick and easy for the clinician's record making, and because plaque is not stained, it is not highlighted for the patient to see and remove.

Bleeding Points Index.[95] The Bleeding Points Index provides an evaluation of bleeding gingiva around each tooth in the patient's mouth. Retract the cheek, and place the periodontal probe 1 mm into the sulcus or pocket at the distal aspect of the most posterior tooth in the quadrant. Carry the probe lightly across the length of the sulcus to the mesial interproximal area on the facial aspect. Continue along all the teeth in the quadrant from the facial aspect. Wait 30 seconds, and record the presence of bleeding on the distal, facial, and mesial surfaces on the chart. Repeat on the lingual-palatal aspect, recording bleeding only for the direct lingual surface, not for the mesial or distal surfaces. This results in four separate scores for each tooth and does not score the mesial and distal surfaces twice. Repeat the steps for each quadrant.

The percentage of the number of bleeding surfaces is then calculated to provide the patient's score. Divide the number of surfaces that bled by the total number of tooth surfaces (4 per tooth) and convert the number to a percentage by multiplying by 100.

This index is designed to demonstrate bleeding gingiva rather than the presence of plaque. Again, a goal of 10% or fewer bleeding points is good, but 0 is ideal. If a few bleeding points repeatedly occur in the same areas, plaque control for those areas should be reinforced or modified.

Significance of Plaque Scores and Bleeding Scores. Plaque scores are helpful as indicators of patient compliance and success with daily plaque control procedures. They once were used as an educational tool to demonstrate improvement in patient technique and give positive reinforcement. However, plaque levels themselves do not necessarily reflect gingival health or risk of disease progression, even though plaque is highly correlated with the presence of gingivitis.[103] In terms of predicting success in controlling inflammation and reducing the chance of disease progression, bleeding is by far the better indicator. Bleeding on probing is not the most specific and sensitive of measures of health; however, it has a strong negative correlation to disease progression. If bleeding is absent at any given site in the mouth, reflecting good plaque control and disease management, the chance that periodontal disease will progress is unlikely.

Instruction and Demonstration

Patients can reduce the incidence of plaque and gingivitis with repeated instruction and encouragement far more effectively than with self-acquired oral hygiene habits.[66,141] However, instruction in how to clean teeth must be more than a cursory chairside demonstration of the use of a toothbrush. It is a painstaking procedure that requires patient participation, careful supervision with correction of mistakes, and reinforcement during return visits until the patient demonstrates that he or she has developed the necessary proficiency.[8,97]

One useful strategy for introducing plaque control to the periodontal patient includes several elements. At the first instruction visit, the patient should be given a new toothbrush, an interdental cleaner, and a disclosing agent. The patient's plaque should be disclosed. Small amounts of dental plaque are difficult for the patient to see if not disclosed (see Fig. 49-25, A); heavier accumulations of plaque and debris may be visible as gray, yellow, or white material on the teeth, along the gingival margin, and in faciolingual embrasures. Then a disclosing solution or wafer is used to stain the invisible plaque. After a brief water rinse to remove excess dye and stained saliva, which would obscure the view of the teeth, the stained plaque and **pellicle can be clearly demonstrated to the** patient **(see** Fig. 49-25, B). Polished dental restorations do not take up the stain, but the oral mucosa and the lips may retain it for up to several hours. Covering the lips lightly with petroleum jelly before using the dye is helpful.

Toothbrushing should be demonstrated in the patient's mouth while he or she observes with a hand mirror. The patient then takes over and repeats the procedures on his or her own teeth with the instructor giving assistance, correction, and positive reinforcement.

Repeat the demonstration and instruction process with dental floss and interdental cleaning aids according to the patient's needs. The teeth can be restained to evaluate the efficiency of plaque removal, but even after vigorous cleaning, some stain usually remains on proximal surfaces (see Fig. 49-25, C). Teaching videos and pamphlets can be used to augment personalized instruction, but they are not a substitute; reminder pamphlets may be useful for the patient to take home.

The patient should be given the hygiene aids necessary to get started. He or she must be encouraged to clean the teeth at least once a day, with thorough attention to all areas. Home care procedures on a full dentition take 5 to 10 minutes; in complex periodontal maintenance cases, such procedures may require up to 30 minutes. The patient should set aside a convenient time and place in his or her daily schedule to perform the procedures reliably every day.

Subsequent instruction visits should be used to reinforce or modify previous instructions, periodically recording the state of gingival health and amount of plaque.

In general, some strategies will help improve patient compliance. These include the following:

- Providing clinician encouragement
- Demonstrating how devices should work
- Providing samples
- Showing improvements
- Generally using positive reinforcement[142]

In addition, some strategies are sure not to work. These include the following:

- Showing insensitivity to patient needs and situation
- Instructing at the end of the appointment, when the

plaque has either been removed by the clinician or the patient is exhausted or sore

Failing to provide reinforcement at subsequent appointments

Handing the patient too many tools

Relying only on a pamphlet to provide education

Reinforcement and encouragement should be given often to help patients modify long-standing habits, adopt new ones, and understand that their plaque control is also important to the clinician.

Sensitivity to patient needs, patience on the clinician's part, and positive reinforcement are the secrets of success in plaque control instruction.

SUMMARY

1. All patients require the regular use of a toothbrush, either manual or electric, at least once per day. The brushing method should include access to the gingival margin of all accessible surfaces and extension as far onto the proximal surfaces as possible.
2. Dental floss should be used in all interdental spaces that are filled with gingiva. The technique requires wrapping the floss around the proximal surfaces and inserting the floss as far subgingivally as possible. Flossing may be accomplished either with a tool or by using the fingers.
3. Interdental aids such as interproximal brushes, wooden tips, rubber tips, or toothpicks should be used in all areas where the toothbrush and floss techniques cannot adequately remove the plaque. This includes large embrasure spaces and furcation areas.
4. All periodontal patients should use some form of low-concentration topical fluoride on a daily basis, a fluoride containing dentifrice at the very least. Topical rinses and gels may be required if the patient demonstrates a risk of caries or history of root caries.
5. Daily home-delivered subgingival irrigation may be a good choice for reduction of inflammation and maintenance for patients with residual deep pockets and those who struggle with mechanical interproximal cleaning devices. The effectiveness of irrigation is enhanced by the addition of chlorhexidine or essential oil mouthrinse to the irrigation water.
6. Chemical antimicrobial agents such as chlorhexidine or essential oil mouthwashes can be prescribed to disinfect the patient's mouth and control the infection. They may be continued indefinitely, as no specific duration of time for use of these products has been recommended. In fact, many patients have used essential oil mouthrinses for years. The staining of teeth and taste alteration side effects may limit patient use of these products.
7. Reinforcement of daily plaque control practices and routine visits to the dental office for maintenance care are essential to successful plaque control and long term success of therapy.

Chemotherapeutic Agents in the Treatment of Periodontal Diseases

David L. Jolkovsky and Sebastian G. Ciancio

CHAPTER OUTLINE

SYSTEMIC ADMINISTRATION OF ANTIBIOTICS
- **Tetracyclines**
- **Metronidazole**
- **Penicillins**
- **Cephalosporins**
- **Clindamycin**
- **Ciprofloxacin**
- **Macrolides**

SERIAL AND COMBINATION ANTIBIOTIC THERAPY
- **Rationale**
- **Clinical Use**

HOST MODULATION
- **Doxycycline Hyclate**
- **Nonsteroidal Antiinflammatory Drugs**

LOCAL DELIVERY OF ANTIBIOTICS
- **Tetracycline-Containing Fibers (Actisite)**
- **Subgingival Delivery of Doxycycline (Atridox)**
- **Subgingival Delivery System for Minocycline (Dentamycin and PerioCline)**
- **Subgingival Delivery of Metronidazole**

LOCAL DELIVERY OF AN ANTISEPTIC AGENT

The various periodontal diseases result from susceptible hosts having their periodontal tissues colonized by specific oral pathogens in numbers sufficient to overwhelm their tissue defenses. Clinical success in the treatment of these diseases thus requires reduction of the bacterial load or enhancement of the host tissues' ability to defend or repair itself. Traditionally, the foundations of clinical success include education of patients in daily oral hygiene; surgical and nonsurgical mechanical root debridement to remove subgingival bacteria and their accretions from root surfaces; and supportive periodontal therapy generally at 3- to 6-month intervals. In certain types of periodontal disease including chronic advanced periodontitis, refractory periodontitis, aggressive periodontitis, and periodontitis as a manifestations of systemic diseases, adjunctive chemotherapeutic agents may be necessary to control the disease process.' This chapter reviews the indications and use of chemotherapeutic agents in the treatment of periodontal disease.

Chemotherapeutic agent is a general term for a chemical substance that provides a clinical therapeutic benefit. This term does not specify in what way the agent aids in attaining a clinical benefit. Clinical benefits can be derived through antimicrobial actions or an increase in the host's resistance. An antimicrobial agent is a chemotherapeutic agent that works by reducing the number of bacteria present. Antibiotics are a naturally occurring, semisynthetic or synthetic type of antimicrobial agent that destroys or inhibits the growth of selective microorganisms, generally at low concentrations. Antiseptics are chemical antimicrobial agents that are applied topically or subgingivally to mucous membranes, wounds, or intact dermal surfaces to destroy microorganisms and inhibit their reproduction or metabolism.18 In dentistry, antiseptics are widely used as the active ingredient in antiplaque and antigingivitis mouthrinses and dentifrices. Disinfectants, a subcategory of antiseptics, are antimicrobial agents that are generally applied to inanimate surfaces to destroy microorganisms.18

Chemotherapeutic agents can be administered locally, orally, or parenterally. In either case, their purpose is to reduce the number of bacteria present in the diseased periodontal pocket. Systemic antibiotics may be a necessary adjunct in controlling bacterial infection because bacteria

can invade periodontal tissues, making mechanical therapy alone sometimes ineffective.[11,15,60] *Local administration* of antimicrobial agents, generally directly in the pocket, has the potential to provide greater concentrations directly to the infected area and reduce possible systemic side effects.

A single chemotherapeutic agent can have a dual mechanism of action. For instance, tetracycline is a chemotherapeutic agent that can reduce collagen and bone destruction through its ability to inhibit the enzyme collagenase. As an antibiotic agent, it also can reduce periodontal pathogens in periodontal tissues.[17,18] Additionally, tetracyclines have been shown to be effective when administered systemically and applied locally.

SYSTEMIC ADMINISTRATION OF ANTIBIOTICS

The treatment of periodontal diseases is based on the infectious nature of these diseases (Table 50-1). Ideally, the causative microorganism(s) should be identified and the most effective agent selected using antibiotic sensitivity tests. Although this appears simple, the difficulty lies primarily in identifying specific etiologic microorganism(s) rather than microorganisms simply associated with various periodontal disorders.[16,17]

The possible clinical benefits of administering antibiotics to help control periodontal disease must be weighed against possible adverse reactions. Some adverse reactions include allergic/anaphylactic reactions, superinfections of opportunistic bacteria, development of resistant bacteria, interactions with other medications, upset stomach nausea, and vomiting.[38] Common and indiscriminate use of antibiotics worldwide has contributed to increasing numbers of resistant bacterial strains over the last 15 to 20 years, and this trend is likely to continue given the widespread use of antibiotics." The overuse, misuse, and widespread prophylactic application of antimicrobial drugs are some of the factors that have led to the emergence of resistant microorganisms. Increasing levels of resistance of subgingival microflora to antibiotics has been correlated with the increased use of antibiotics in individual countries.[73]

An ideal antibiotic for use in prevention and treatment of periodontal diseases should be specific for periodontal pathogens, allogenic and nontoxic, substantive,

TABLE 50-1

Antibiotics Used to Treat Periodontal Diseases: Their Major Features and Indications

Category/Family	Agent(s) Used to Treat Periodontal Diseases	Major Features	Indications
Penicillin	Amoxicillin	Extended spectrum of antimicrobial activity, excellent oral adsorption; used systemically.	LAP, GAP, MRP, RP.
	Augmentin	Effective against penicillinase producing microorganisms; used systemically.	
Tetracycline	Minocycline	Effective against broad spectrum of microorganisms; used systemically and applied locally (subgingivally).	
	Doxycycline	Effective against broad spectrum of microorganisms; used systemically and applied locally (subgingivally); chemotherapeutically used in subantimicrobial dose for host modulation (Periostat).	
	Tetracycline	Effective against broad spectrum of microorganisms; applied locally (subgingivally) in fiber (Actisite).	
Quinolone	Ciprofloxacin	Effective against gram-negative rods, promotes health-associated microflora.	
Macrolide	Azithromycin	Concentrates at sites of inflammation; used systemically.	
Lincomycin derivative	Clindamycin	Used in penicillin-allergic patients; effective against anaerobic bacteria; used systemically.	
Nitroimidazole	Metronidazole	Effective against anaerobic bacteria; used systemically and applied locally (subgingivally) as a gel.	LAP, GAP, MRP, RP, AP, NUG.

CP, Chronic periodontitis; *LAP,* localized aggressive periodontitis; *GAP,* generalized aggressive periodontitis; *MRP,* medically related periodontitis; *NUG,* necrotizing ulcerative periodontitis; *RP,* refractory periodontitis.

not in general use for treatment of other diseases, and inexpensive.26 Currently, an ideal antibiotic for the treatment of periodontal diseases does not exist.38 Although oral bacteria are susceptible to many antibiotics, no single antibiotic at concentrations achieved in body fluids inhibits all putative periodontal pathogens.81 Indeed, a combination of antibiotics may be necessary to eliminate all putative pathogens from some periodontal pockets" (Table 50-2).

Guidelines for use of antibiotics in periodontal therapy include the following:

1. The clinical diagnosis and situation dictate the need for possible antibiotic therapy as an adjunct in controlling active periodontal disease (Fig. 50-1). The patient's diagnosis can change over time. For instance, a patient that presents with generalized slight chronic periodontitis can return to a diagnosis of periodontal health after initial therapy. However, if this patient has been treated appropriately and continues to have active disease, the diagnosis can change to refractory periodontitis.
2. Continuing disease activity, as measured by continuing attachment loss, purulent exudate, and/or continuing periodontal pockets of >_5 mm43,44 that bleed on probing, is an indication for microbial analysis and further periodontal therapy.
3. **When used to treat periodontal disease, antibiotics are selected based on the microbial composition of the** plaque, the patient's medical status and the current medications.38
4. Microbiologic sampling is performed according to the instructions of the reference microbiologic laboratory. Commonly, the samples are taken at the beginning of an appointment before instrumentation of the pocket. Supragingival plaque is removed and an endodontic paper point is inserted subgingivally into the deepest pocket(s) present to absorb bacteria in the loosely associated plaque. This endodontic point is placed in reduced transfer fluid and sent overnight to the laboratory. The laboratory will then send the referring dentist a report that includes the pathogens present and any appropriate antibiotic regimen.
5. Plaque sampling can be performed at the initial examination, root planing, reevaluation, or supportive periodontal therapy appointment. As noted previously, clinical indications for microbial testing include aggressive forms of periodontal disease, diseases refractory to standard mechanical therapy, and periodontitis associated with systemic conditions (see Fig. 50-1).
6. Antibiotics have been shown to have value in reducing the need for periodontal surgery in patients with chronic periodontitis.47
7. Antibiotic therapy should not be used as a monotherapy (Figs. 50-1 and 50-2). That is, it must be part of the comprehensive periodontal treatment plan. This therapy should have debridement of root surfaces, optimal oral hygiene, and frequent supportive periodontal therapy at the center of therapy. Other chemotherapeutic adjuncts include locally placed subgingival antimicrobial agents, subgingival ultrasonic irrigation with iodophors during root debridement, chlorhexidine rinse after debridement for 2 weeks, and home intraoral irrigation with or without chemotherapeutic agents.38 Chlorhexidine gluconate is effective as an antiplaque rinse, but its antimicrobial activity is greatly reduced in the presence of organic matter in the subgingival periodontal pocket. However, povidone-iodine (Betadine) is an effective antibacterial agent when used directly into the periodontal pocket, even at low concentrations. 38,59 Povidone-iodine must be used with caution in patients sensitive to iodine, although the sensitization rate is low. 52 It also should be used with caution in patients who are pregnant or lactating. 14
8. Slots and co-workers have described a series of steps using antimicrobial agents for enhancing regenerative healing. They recommend starting antibiotics 1 to 2 days before surgery and continuing for a total of at least 8 days .38,54,62

TABLE 50-2

Common Antibiotic Regimens Used in Treating Periodontal Diseases 38

	Regimen	Duration
Single Agent		
Metronidazole	250-500 mg 3 times daily	8 days
Ciprofloxacin	500 mg 2 times daily	8 days
Clindamycin	300 mg 2 times daily	8 days
Combination Therapy		
Metronidazole/ amoxicillin	250 mg of each 3 times daily	8 days
Metronidazole/ ciprofloxacin	500 mg of each 2 times daily	8 days

These regimens are prescribed with a review of the patient's medical history, periodontal diagnosis, and antimicrobial testing. Consult *Mosby's GenRx61* or manufacturer's guidelines for contraindications and precautions.

Tetracyclines

Tetracyclines have been widely used in the treatment of periodontal diseases. They have been frequently used in treating refractory periodontitis, including localized aggressive periodontitis (see Table 50-1). Tetracyclines have the ability to concentrate in the periodontal tissues and inhibit the growth of Actinobacillus actinomycetemcomitans. In addition, they exert an anticollagenase effect that can inhibit tissue destruction and may aid bone regeneration (see Host Modulation).

Pharmacology. The tetracyclines are a group of antibiotics produced naturally from certain species of Streptomyces or derived semisynthetically. These antibiotics are bacteriostatic and are effective against rapidly multiplying bacteria. They generally are more effective against gram-positive bacteria than gram-negative bacteria.83

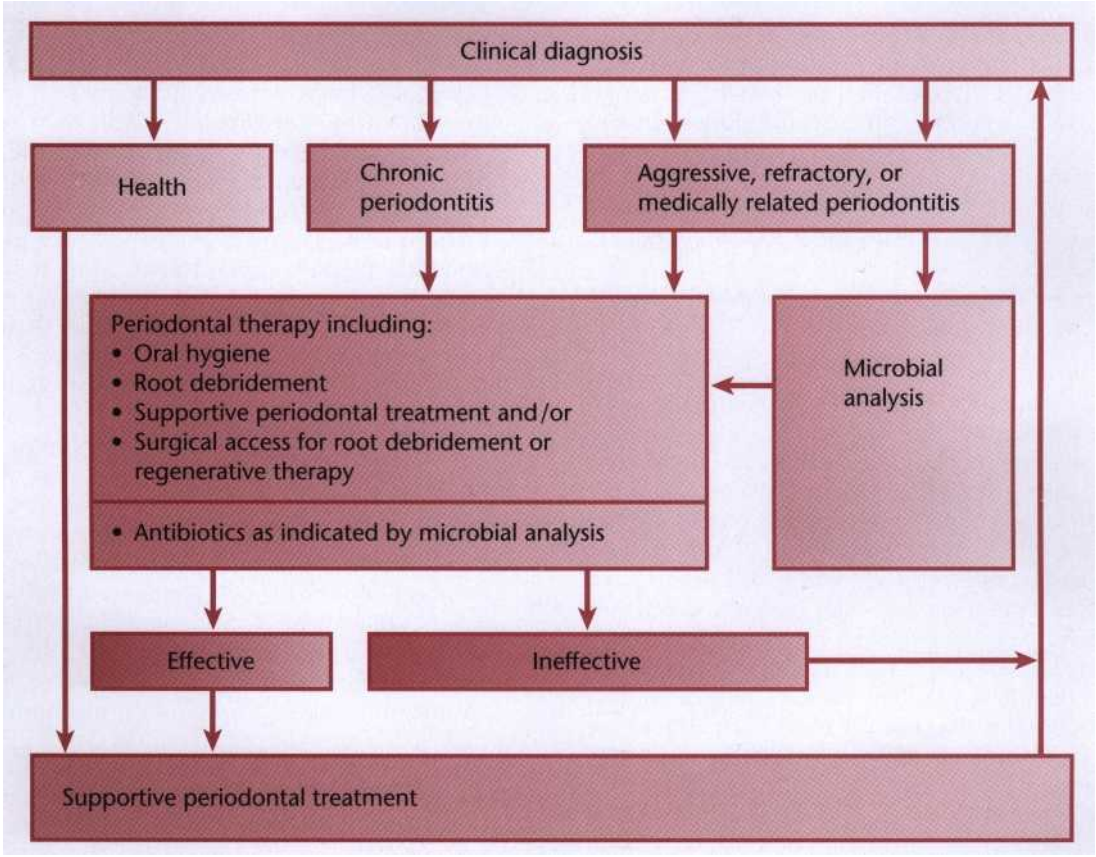

Fig. 50-1 Guidelines for use of antimicrobial therapy.

Tetracyclines are effective in treating periodontal diseases in part because their concentration in the gingival crevice is 2 to 10 times that in serum .[2,5,31] This allows a high drug concentration to be delivered into periodontal pockets. In addition, several studies have demonstrated that tetracyclines at a low gingival crevicular fluid concentration (2 to 4 leg/ml) are very effective against many periodontal pathogens.[6,7,81]

Clinical Use. Tetracyclines have been investigated as adjuncts in the treatment of localized aggressive periodontitis (LAP). *A. actinomycetemcomitans is* a frequent causative microorganism in LAP and is tissue invasive. Therefore mechanical removal of calculus and plaque from root surfaces may not eliminate this bacterium from the periodontal tissues. Systemic tetracycline can eliminate tissue bacteria and has been shown to arrest bone loss and suppress *A. actinomycetemcomitans* levels in conjunction with scaling and root planing."M This combined form of therapy allows mechanical removal of root surface deposits and elimination of pathogenic bacteria from within the tissues. Increased posttreatment bone levels have been noted using this method .[25,61]

Long-term use of low doses of tetracyclines has been advocated in the past. One long-term study of patients taking low doses of tetracycline (250 mg per day for 2 to 7 years) showed persistence of deep pockets that did not bleed on probing. These sites contained high proportions of tetracycline-resistant, gram-negative rods (i.e., *Fusobacterium nucleatum).* After the antibiotic was discontinued, the flora was characteristic of sites with disease .[42] Therefore it is not advisable to engage in long-term regimens of tetracyclines because of the possible development of resistant bacterial strains. Although commonly used in the past as antimicrobial agents, especially for localized aggressive periodontitis and other types of aggressive periodontitis, tetracyclines now tend to be replaced by more effective combination antibiotics .[38,73]

Specific Agents. Tetracycline, minocycline, and doxycycline-all semisynthetic members of the tetracycline group-have been used in periodontal therapy.

TETRACYCLINE. Tetracycline requires administration of 250 mg qid. It is inexpensive, but compliance may be reduced by having to take four capsules per day.

MINOCYCLINE. Minocycline is effective against a broad spectrum of microorganisms. In patients with adult periodontitis, it suppresses spirochetes and motile rods as effectively as scaling and root planing, with suppression remaining evident for up to 3 months after therapy. Minocycline can be given twice a day, thus facilitating compliance when compared with tetracycline. Although it is associated with less photo- and renal toxicity than tetracycline, it may cause reversible vertigo. Minocycline administered in a dosage of 200 mg per day for 1 week results in a reduction in total bacterial counts,

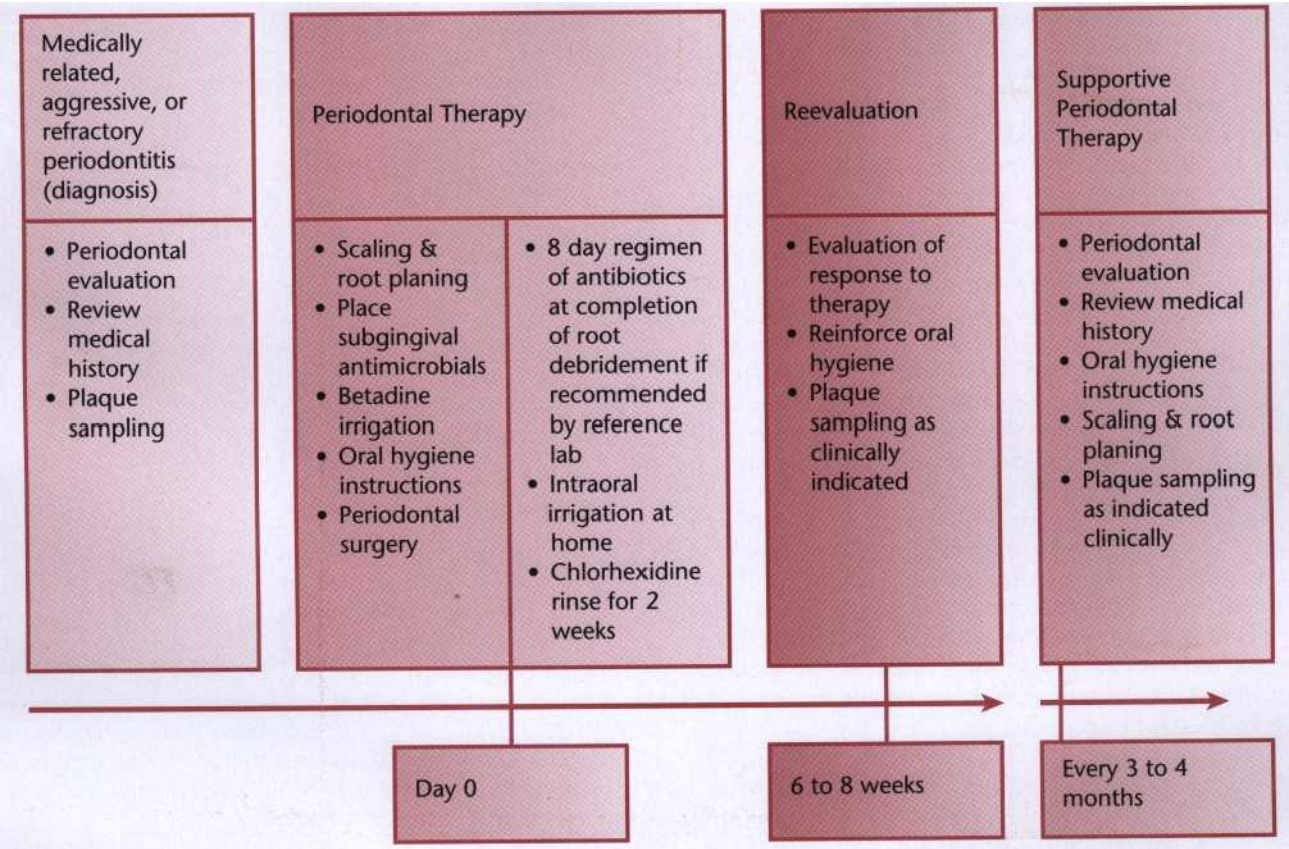

Fig. 50-2 Sequencing of antimicrobial agents. (Adapted from Jorgensen MG, Slots J: Practical antimicrobial periodontal therapy. Compend Contin Educ Dent 2000; 21:111.)

complete elimination of spirochetes for periods of up to 2 months, and improvement in all clinical parameters.[20]

DOXYCYCLINE. Doxycycline has the same spectrum of activity as minocycline and may be equally as effective." Because it can be given only once daily, patients may be more compliant. Compliance is also favored because its absorption from the gastrointestinal tract is not altered by calcium, metal ions, or antacids, as is absorption of other tetracyclines. The recommended dosage when used as an antimicrobial agent is 100 mg twice daily the first day, then 100 mg once daily. To reduce gastrointestinal upset, 50 mg can be taken twice daily. When used in a subantimicrobial dose to inhibit collagenase, it is recommended in a 20-mg dose twice daily" (see Host Modulation).

Metronidazole

Pharmacology. Metronidazole is a nitroimidazole compound developed in France to treat protozoal infections. It is bactericidal to anaerobic organisms and is believed to disrupt bacterial DNA synthesis in conditions in which a low reduction potential is present. Metronidazole is not the drug of choice for treating A. *actinomycetemcomitans* infections, but it may be effective at therapeutic levels owing to its hydroxy metabolite. However, it is effective against A. *actinomycetemcomitans* when used in combination with other antibiotics.[56,57] Metronidazole is also effective against anaerobes such as *Porphyromonas gingivalis* and *Prevotella intermedia.*[34]

Clinical Usage. Metronidazole has been used clinically to treat gingivitis, acute necrotizing ulcerative gingivitis, chronic periodontitis, and aggressive periodontitis. It has been used as monotherapy and also in combination with both root planing and surgery or with other antibiotics. Metronidazole has been used successfully for treating necrotizing ulcerative gingivitis."

Studies in humans[46,47] have demonstrated the efficacy of metronidazole in the treatment of gingivitis and periodontitis. A single dose of metronidazole (250 mg orally) appears in both serum and gingival fluid in sufficient quantities to inhibit a wide range of suspected periodontal pathogens. Administered systemically (750 to 1000 mg/day for 2 weeks), this drug reduces the growth of anaerobic flora, including spirochetes, and decreases the clinical and histopathologic signs of periodontitis.[46] The most commonly prescribed regimen is 250 mg tid for 7 days.[45] Loesche and co-workers found that 250 mg of metronidazole given three times daily for 1 week was of benefit to patients with a diagnosed anaerobic periodontal infection. In this study, an infection was considered anaerobic when spirochetes composed 20% or more of the total microbial count. Metronidazole used as a supplement to rigorous scaling and root planing resulted in a significantly reduced need for surgery when compared

with root planing alone. The bacteriologic data of this study showed that only the spirochete count was significantly reduced.47 Currently, the critical level of spirochetes needed to diagnose an anaerobic infection, the appropriate time to give metronidazole, and the ideal dosage or duration of therapy are unknown.34

As monotherapy (no concurrent root planing), metronidazole is inferior and at best only equivalent to root planing. Therefore if metronidazole is used, it should not be administered as monotherapy.

Metronidazole offers some benefit in the treatment of refractory periodontitis, particularly when used in combination with amoxicillin. The existence of refractory periodontitis as a diagnostic category indicates that some patients do not respond to conventional therapy, including root planing, surgery, or both. Soder and co-workers showed that metronidazole was more effective than placebo in the management of sites unresponsive to root planing.65 Nevertheless, many patients still had sites that bled on probing despite metronidazole therapy.

Studies have suggested that when combined with amoxicillin or amoxicillin-clavulanate potassium (Augmentin), metronidazole may be of value in the management of patients with localized aggressive or refractory periodontitis (see later discussion).

Side Effects. Metronidazole has an antabuse effect when alcohol is ingested. The response is generally proportional to the amount ingested and can result in severe cramps, nausea, and vomiting. Products containing alcohol should be avoided during therapy and for at least 1 day after therapy is discontinued. Metronidazole also inhibits warfarin metabolism. Patients undergoing anticoagulant therapy should avoid metronidazole because it prolongs prothrombin time."34 It also should be avoided in patients who are taking lithium.

Penicillins

Pharmacology. Penicillins are the drugs of choice for the treatment of many serious infections in humans and are the most widely used antibiotics. Penicillins are natural and semisynthetic derivatives of broth cultures of the *Penicillium* mold. They inhibit bacterial cell wall production and therefore are bactericidal.

Clinical Usage. Penicillins other than amoxicillin and amoxicillin-clavulanate potassium (Augmentin) have not been evaluated, and their use in periodontal therapy does not appear to be justified.82

Side Effects. Penicillins may induce allergic reactions and bacterial resistance; up to 10% of patients may be allergic to penicillin.

Amoxicillin. Amoxicillin is a semisynthetic penicillin with an extended antimicrobial spectrum that includes gram-positive and gram-negative bacteria. It demonstrates excellent absorption after oral administration. Amoxicillin is susceptible to penicillinase, a penicillin ring structure and thereby renders penicillins ineffective.82

Amoxicillin may be useful in the management of patients with aggressive periodontitis, both in the localized and generalized forms. Recommended dosage is 500 mg tid for 8 days.38,39

Amoxicillin-Clavulanate (Augmentin). The combination of amoxicillin with clavulanate potassium makes Augmentin resistant to penicillinase enzymes produced by some bacteria. Augmentin may be useful in the management of patients with refractory or localized aggressive periodontitis.57 Bueno and co-workers reported that Augmentin arrested alveolar bone loss in patients with periodontal disease that was refractory to treatment with other antibiotics including tetracycline, metronidazole, and clindamycin.10

Cephalosporins

Pharmacology. The family of /3-lactams known as *cephalosporins is* similar in action and structure to penicillins. They are frequently used in medicine and are resistant to a number of ß-lactamases normally active against penicillin.

Clinical Usage. Cephalosporins are generally not used to treat dental-related infections. The penicillins are superior to cephalosporins in their range of action against periodontopathic bacteria.

Side Effects. Patients allergic to penicillins must be considered allergic to all ß-lactam products. Rashes, urticaria, fever, and gastrointestinal upset have been associated with cephalosporins.78

Clindamycin

Pharmacology. Clindamycin is effective against anaerobic bacteria." It is effective in situations in which the patient is allergic to penicillin.

Clinical Usage. Clindamycin has shown efficacy in patients with periodontitis refractory to tetracycline therapy. Walker and co-workers" have shown aid in stabilizing refractory patients. Dosage used in their studies was 150 mg qid for 10 days. Jorgensen and Slots have recommended a regimen of 300 mg twice daily for 8 days.39

Side Effects. Clindamycin has been associated with pseudomembranous colitis more often than other antibiotics, thereby limiting its use. When needed, however, it can be used with caution. Diarrhea or cramping that develops during the use of clindamycin may be indicative of cholitis, and clindamycin should be discontinued. If symptoms persist, the patient should be referred to an internist.

Ciprofloxacin

Pharmacology. Ciprofloxacin is a quinolone active against gram-negative rods, including all facultative and some anaerobic putative periodontal pathogens.

Clinical Usage. Because it demonstrates minimal effect on Streptococcus species, which are associated with

periodontal health,[56] ciprofloxacin therapy may facilitate the establishment of a microflora associated with periodontal health. At present, ciprofloxacin is the only antibiotic in periodontal therapy to which all strains of *A. actinomycetemcomitans* are susceptible. It also has been used in combination with metronidazole.[56]

Side Effects. Nausea, headache, and abdominal discomfort have been associated with ciprofloxacin. Quinolones inhibit the metabolism of theophylline, and caffeine and concurrent administration can produce toxicity. Quinolones have also been reported to enhance the effect of warfarin and other anticoagulants.[$]

Macrolicles

Pharmacology. Macrolide antibiotics contain a many-membered lactone ring to which one or more deoxy sugars are attached. They inhibit protein synthesis by binding to the 50 S ribosomal subunits of sensitive microorganisms. They can be bacteriostatic or bactericidal, depending on the concentration of the drug and the nature of the microorganism.

Clinical Usage. Erythromycin does not concentrate in gingival crevicular fluid, and it is not effective against most putative periodontal pathogens. For these reasons, it is not recommended as an adjunct to periodontal therapy. Spiramycin is active against gram-positive organisms; it is excreted in high concentrations in saliva. It is used as an adjunct to periodontal treatment in Canada and Europe but is not available in the U.S. Several studies have shown benefits, as measured by the Gingival Index, the Plaque Index, pocket depth, and crevicular fluid flows[50,68] when spiramycin was prescribed in advanced periodontal disease. In addition, it is a safe, nontoxic drug with few and infrequent side effects and is not in general use for medical problems.[28] Azithromycin (Zithromax) is a member of the azalide class of macrolides. It is effective against anaerobes and gram-negative bacilli. After an oral dosage of 500 mg once daily for three consecutive days, significant levels of azithromycin can be detected in most tissues for 7 to 10 days.[' The concentration of azithromycin in tissue specimens from periodontal lesions is significantly higher than that of normal gingiva.[49] It has been proposed that azithromycin penetrates fibroblasts and phagocytes in concentrations 100 to 200 times greater than that of the extracellular compartment. The azithromycin is actively transported to sites of inflammation by phagocytes and then released directly into the sites of inflammation as the phagocytes rupture during phagocytosis.[27-36] Therapeutic use requires a single dose of 250 mg per day for 5 days after an initial loading dose of 500.['8]

SERIAL AND COMBINATION ANTIBIOTIC THERAPY

Rationale

Because periodontal infections may contain a wide diversity of bacteria, no single antibiotic is effective against all putative pathogens. Indeed, differences exist in the microbial flora associated with the various periodontal disease syndromes.[80] These "mixed" infections can include a variety of aerobic, microaerophilic, and anaerobic bacteria, both gram negative and gram positive. In these instances, it may be necessary to use more than one antibiotic, either serially or in combination.[57] However, before combinations of antibiotics are used, the periodontal pathogen(s) being treated must be identified and antibiotic susceptibility testing performed.

Clinical Use

Antibiotics that are *bacteriostatic (e.g.,* tetracycline) generally require rapidly dividing microorganisms to be effective. They do not function well if a *bactericidal* antibiotic (e.g., amoxicillin) is given concurrently. *When both types of drugs are required, they are best given serially, not in combination.*

Rams and Slots reviewed combination therapy using systemic metronidazole along with amoxicillin, Augmentin, or ciprofloxacin.[57] The metronidazole-amoxicillin and metronidazole-Augmentin combinations provided excellent elimination of many organisms in adult and localized aggressive periodontitis that had been treated unsuccessfully with tetracyclines and mechanical debridement. These drugs have an additive effect regarding suppression of *A. actinomycetemcomitans.* Tinoco and coworkers" found metronidazole and amoxicillin to be clinically effective in treating localized aggressive periodontitis, although 50% of patients harbored A. *actinomycetemcomitans* one year later. Metronidazole-ciprofloxacin combination is effective against A. *actinomycetemcomitans.* Metronidazole targets obligate anaerobes, and ciprofloxacin targets facultative anaerobes. This is a powerful combination against mixed infections. Studies of this drug combination in the treatment of refractory periodontitis have documented marked clinical improvement. This combination may provide a *therapeutic benefit* by reducing or eliminating pathogenic organisms and a *prophylactic benefit* by giving rise to a predominantly streptococcal microflora.[56]

Systemic antibiotic therapy combined with mechanical therapy appears valuable in the treatment of recalcitrant periodontal infections and localized aggressive periodontitis infections involving *A. actinomycetemcomitans.* Antibiotic treatment should be reserved for specific subsets of periodontal patients who do not respond to conventional therapy. Selection of specific agents should be guided by the results of cultures and sensitivity tests for subgingival plaque microorganisms.

HOST MODULATION

Doxycycline Hyclate

The U.S. Food and Drug Administration recently granted marketing approval for doxycycline hyclate (Periostat) for the adjunctive treatment of periodontitis. Periostat, available as a 20-mg capsule of doxycycline hyclate, is prescribed for use by patients twice daily. The mechanism of action is by suppression of the activity of collagenase, particularly that produced by polymorphonuclear leukocytes. A schematic diagram of the role of matrix metalloproteinases in the progression of periodontal

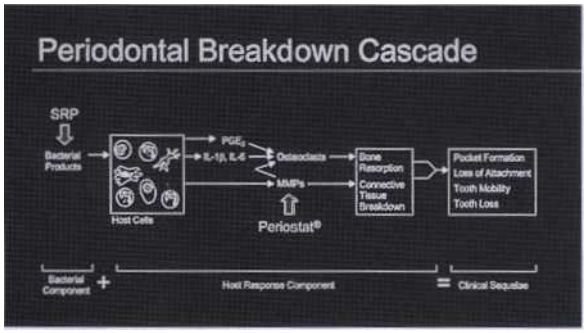

Fig. 50-3 Matrix metalloproteinases in the progression of periodontal disease.

disease is seen in Fig. 50-3. Although this drug is in the antibiotic family, it does not produce antibacterial effects because the dose of 20 mg twice daily is too low to affect bacteria. As a result, resistance to this medication has not been seen.

Four double-blind, clinical, multicenter studies of more than 650 patients have demonstrated that doxycycline hyclate improves the effectiveness of professional periodontal care and slows the progression of the disease process. The results of the first three studies showed that doxycycline hyclate resulted in approximately a 50% improvement in clinical attachment levels in pockets with probing depths (PD) of 4 to 6 mm and a 34% improvement in pockets with probing depths >_ 7 mm. It was also noted that attachment loss was prevented in sites with normal probing depths (0 to 3 mm), whereas the placebo groups lost 0.13 mm at 12 months (p = 0.05). [12,19]

A recent study by Caton and co-workers has shown statistically significant reductions in probing depths and increases in clinical attachment levels with adjunctive Periostat in conjunction with root planing at 3-, 6-, and 9-month evaluations compared with placebo groups undergoing root planing alone." Although statistically significant, the net changes were considered limited alterations in patients with moderate to severe chronic periodontitis. [4]

Results of safety studies showed the use of 20-mg Periostat BID either with or without mechanical therapy (SRP) did not exert an antimicrobial effect on the periodontal microflora and did not result in a detrimental shift in the normal flora. The colonization or overgrowth of **the periodontal pocket by bacteria resistant** to doxycycline, tetracycline, minocycline, amoxicillin, erythromycin, or clindamycin has not been observed. In addition, no evidence of any tendency toward the acquisition of multiantibiotic resistance was found. [21,76]

Nonsteroidal Anti inflammatory Drugs

It is only relatively recently that the role of the host's inflammatory system in periodontal disease has begun to be understood. Following activation of inflammatory cells in the periodontium by bacteria, phospholipids in the plasma membranes of cells are acted on by phospholipase. This leads to the liberation of free arachidonic acid,[58] which then can be metabolized into prostaglandins, thromboxanes, and prostacycline by the enzyme cyclooxygenase. The lipoxygenase pathway can produce leukotrienes and hydroxyeicosatetraenoic acids from arachidonic acid. Strong evidence suggests that cyclooxygenase pathway products (e.g., prostaglandins) may be important mediators of some pathologic events occurring in periodontal diseases$ Therefore modulation of the host's inflammatory response to bacteria may alter the incidence and severity of periodontal disease. Nonsteroidal antiinflammatory drugs (NSAIDs) may be of therapeutic value in treating periodontal disease because of their ability to interfere with arachidonic acid metabolism and thereby inhibit the inflammatory process. This expectation has been validated in studies in both animals and humans. [23,55,75,86,88] Some NSAIDs have been shown to affect the response of polymorphonuclear neutrophils (PMNs) to inflammation not related to prostaglandin inhibition."," Beneficial effects of NSAIDs have also been found after topical application [11,74,85] Drugs such as flurbiprofen, ibuprofen, mefenamic acid, and naproxen have been studied.

Flurbiprofen appears to be an NSAID worthy of further investigation. It inhibits PMN migration, reduces vascular permeability, and inhibits platelet aggregation by inhibiting cyclooxygenase. [35] In a 3-year study, Williams and co-workers reported that flurbiprofen significantly inhibited radiographic alveolar bone loss when compared with placebo. Unfortunately, by 24 months, the difference in the rate of bone loss had disappeared. [14] This group also reported a return to baseline in the rate of bone loss after treatment with flurbiprofen was discontinued. [87]

LOCAL DELIVERY OF ANTIBIOTICS

The limitations of mouthrinsing and irrigation have prompted research for the development of alternative delivery systems. Recently, advances in delivery technology have **resulted in the controlled release** of drugs (Table 50-3). The requirements for treating periodontal disease include a means for **targeting an antimicrobial to infection sites and sustaining its localized concentration at effective** levels for a sufficient time while concurrently evoking minimal or no side effects.

Tetracycline-Containing Fibers (Actisite)

The first local delivery product available in the U.S., one which has been extensively studied, is an ethylene/vinyl acetate copolymer fiber, diameter 0.5 mm, containing tetracycline, 12.7 mg/9 inches (Actisite tetracycline fiber; manufactured by Alza Corporation, Palo Alto, CA; distributed by Procter & Gamble Co., Cincinnati, OH) (Fig. 50-4). When packed into a periodontal pocket, it is well tolerated by oral tissues, and for 10 days it sustains tetracycline concentrations exceeding 1300 ltg/ml, well beyond the 32 to 64 wg/ml required to inhibit the growth of pathogens isolated from periodontal pockets .[70,79] In contrast, crevicular fluid concentrations of only 4 to 8 Ag/ml are reported after systemic tetracycline administration, 250 mg four times daily for 10 days (total oral dose, 10 g). [32]

Studies demonstrate that tetracycline fibers applied with or without scaling and root planing reduce probing

TABLE 50-3

Currently Available or Investigational, Locally Delivered Antimicrobials for Periodontal Therapy

Product	Antimicrobial Agent	FDA Clearance	Dosage Form	Manufacturer
Actisite	Tetracycline	Yes	Nonresorbable fiber	Alza Corp., Palo Alto, CA
Arestin	Minocycline	No	Biodegradable powder in syringe	Orapharma Corp., Warminster, PA
Atridox	Doxycycline	Yes	Biodegradable mixture in syringe	Atrix Labs, Ft. Collins, CO
Dentamycin, Perio Cline	Minocycline	No	Biodegradable mixture in syringe	Sunstar Corp., Tokyo, Japan
Elyzol	Metronidazole	No	Biodegradable mixture in syringe	Dumex Corp., Copenhagen, Denmark
PerioChip	Chlorhexidine	Yes	Biodegradable device	Dexcel Pharma, Inc., Jerusalem, Israel

depth, bleeding on probing, and periodontal pathogens and provide gains in clinical attachment level. Such effects are significantly better than those attained with scaling and root planing alone or with placebo fibers. In a 2-month study, compared with scaling and root planing, the fibers used alone have provided more than a 60% greater improvement in probing depth and clinical attachment level than scaling alone .[29]

No change in antibiotic resistance to tetracycline has been found following tetracycline fiber therapy among the tested putative periodontal pathogens.[30] Disadvantages of the fiber include the length of time required for placement (10 minutes or more per tooth), the considerable learning curve required to gain proficiency at placement, and the need for a second patient appointment 10 days after placement for removal of the fiber. Also, placement of fibers around 12 or more teeth has resulted in oral candidiasis in a few cases.

Another study suggested that rinsing with 0.12% chlorhexidine (Peridex; Zila Pharmaceuticals, Inc., Phoenix, AZ) after fiber placement had a synergistic effect, enhancing the reduction of bacterial pathogens.[53]

Evaluation of the effect of tetracycline fibers on root surfaces, using fluorescent light and scanning electron microscopy,[51] showed superficial penetration of tetracycline, with minor penetration into dental tubules, and a few areas of demineralized root surface. Scanning electron microscopic observations made in this study also revealed reductions in the subgingival microbial flora on **the root surfaces of teeth treated with the fibers versus the control specimens.**

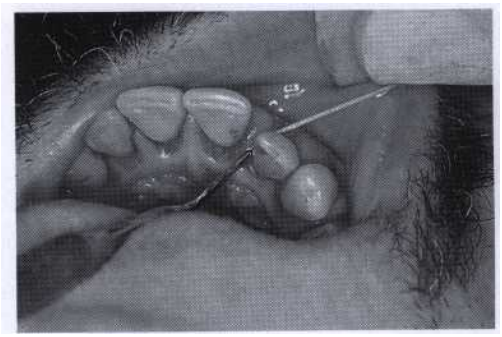

Fig. 50-4 Placement of Actisite fiber.

Fig. 50-5 Placement of Atridox gel.

Subgingival Delivery of Doxycycline (Atridox)

Atridox® (manufactured by Atrix Laboratories, Fort Collins, CO; licensed for marketing by Block Drug, Inc., Jersey City, NJ) is a gel system that incorporates the antibiotic doxycycline (10%) in a syringeable gel system (Fig. 50-5). Atridox is cleared by the FDA for sale in the U.S.

In a 9-month multicenter study of 180 patients, treatment with Atridox alone was more effective than the **other treatments at all time periods, with the exception of the** 3-month clinical attachment level value. For the Atridox group, the reduction in clinical attachment level at 9 months showed a gain of 0.4 mm compared with vehicle control, the reduction in probing depth was 0.6 mm greater than vehicle control, and the reduction of bleeding on probing was 0.2 units greater than vehicle control. The differences were clinically small but statistically significant. Although resistance was not evaluated in this study, the local application of doxycycline has

Fig. 50-6 Minocycline syringable gel.

previously been reported to show transient increases in resistance in oral microbes and no overgrowth of foreign pathogens.[4s]

Data also has been reported from two multicenter clinical trials, each studying 411 patients with moderate to severe periodontitis.[24] At baseline, patients were randomized to one of four treatment groups: Atridox, vehicle control, oral hygiene only, and scaling and root planing. Sites with probing depth >5 mm that bled on probing were treated at baseline and then again with the same treatment at 4 months. Clinical assessments were made for 9 months, measuring clinical attachment level, probing depth, and bleeding on probing. All treatment groups in both studies showed clinical improvements from baseline over the 9-month period. The results for all parameters measured were significantly better in the Atridox group compared with vehicle control and oral hygiene only. Compared with scaling and root planing, the effects of Atridox as a monotherapy on clinical attachment level gain and probing depth reduction were equivalent.

Subgingival Delivery System for Minocycline (Dentamycin and PerioCline)

A subgingival delivery system of 2% (w/w) minocycline hydrochloride (Dentamycin, Cyanamid International, Lederle Division, Wayne, NJ; PerioCline, SunStar, Osaka, Japan) is available in many countries for use as an adjunct to subgingival debridement. This system is a syringeable gel suspension delivery formulation (Fig. 50-6).

In a four-center, double-blind, randomized trial, patients with periodontal pockets at least 5 mm deep were selected, and either 2% minocycline gel or vehicle were applied once every 2 weeks for four applications following initial scaling and root planing. '2 A total of 343 teeth (976 sites) were included in the minocycline group, with 299 teeth (810 sites) in the control group.

Reductions in P. *gingivalis* and P. *intennedia* at weeks 2, 4, 6, and 12 and at weeks 6 and 12 for A. *actinomycetemcomitans* were statistically significant. These results demonstrated the advantages of supplementing standard subgingival debridement with minocycline gel application.

The three primary clinical efficacy variables in this study were probing depth, clinical attachment level, and bleeding index. There was a trend toward clinical improvement in both the treatment groups for all three measures, and the reduction in probing depth was significantly greater with minocycline gel.

When sites with probing depth of at least 7 mm and significant bleeding at baseline were considered, the improvements were greater than with 5-mm pockets. The improvements with minocycline were statistically significantly better than the vehicle-control group.

Applications of 2% minocycline were also evaluated in a 3-month study in 30 patients.[33] Active or placebo gel was placed subgingivally at planed sites in each subject according to a double-blind protocol, immediately after scaling and root planing and 2 and 4 weeks later. Differences between groups in mean probing depth did not reach statistical significance at any visit, but mean clinical attachment levels were different in favor of the minocycline group ($p < 0.05$) at both reassessments. A difference was found in the number of sites that bled after deep probing at 12 weeks, favoring the minocycline group ($p < 0.05$). This product (2% minocycline) is not available in the U.S.

Subgingival Delivery of Metronidazole

A topical medication (Elyzol; Dumex, Copenhagen, Denmark) containing an oil-based metronidazole 25% dental gel (glyceryl mono-oleate and sesame oil) has been tested in a number of studies.' It is applied in viscous consistency to the pocket, where it is liquidized by the body heat and then hardens again forming crystals in contact with water. As a precursor, the preparation contains metronidazole-benzoate, which is converted into the active substance by esterases in the crevicular fluid. Two 25% gel applications at a 1-week interval have been used in clinical studies."

Studies of the metronidazole gel have shown it to be equivalent to scaling and root planing but have not shown adjunctive benefits in conjunction with scaling and root planing. For example, a recent 6-month study of 30 patients showed the following[67]: The treatment consisted of two applications of the dental gel in two randomly selected quadrants at 1-week intervals as well as simultaneous subgingival scaling of the remaining quadrants. Oral hygiene instructions were given on day 21. Statistical analyses showed that both treatments were effective in reducing probing depth and bleeding on probing over the 6-month period. At the end of the follow-up period, the mean reduction in probing depth was 1.3 mm after gel treatment and 1.5 mm after subgingival scaling. Bleeding on probing was reduced by 35% and 42%, respectively. No significant differences between the two treatments were detected. Dark-field microscopy showed a shift towards a seemingly more healthy microflora for both treatment modalities; this effect persisted throughout the 6-month period.

A large, multicenter study of 206 subjects investigated two applications of this gel in two randomly selected quadrants versus two quadrants of scaling.' Probing depths were reduced by 1.2 mm in the gel and 1.5 mm in the scaling group. At 6 months, the differences between treatments were statistically but not clinically significant. Also, bleeding on probing was reduced by 88% for both treatment groups.

LOCAL DELIVERY OF AN ANTISEPTIC AGENT

A resorbable delivery system (Periochip) has been tested for the subgingival placement of chlorhexidine gluconate with positive clinical results. It is a small chip (4.0 x 5.0 x 0.35 mm) composed of a biodegradable hydrolyzed gelatin matrix, cross-linked with glutaraldehyde and also containing glycerin and water, into which 2.5 mg chlorhexidine gluconate has been incorporated per chip. This delivery system releases chlorhexidine and maintains drug concentrations in the gingival crevicular fluid greater than 100 hg/ml for at least 7 days,66 concentrations well above the tolerance of most oral bacteria.' Because the chip biodegrades in 7 to 10 days, a second appointment for removal is not needed.

Two multicenter, randomized, double-blind, parallel group, controlled clinical trials of this chip were conducted in the U.S. with a total of 447 patients in 10 centers .3' In these studies, patients received a supragingival prophylaxis for up to 1 hour, followed by scaling and root planing for 1 hour. Chips were placed in target sites with probing depth of 5 to 8 mm at baseline that bled on probing and again at 3 and 6 months if probing depth remained >_5 mm. Sites in control-group subjects received either a placebo chip (inactive) with scaling and root planing or scaling and root planing alone. Sites in test-group subjects received either a chlorhexidine chip (active) with scaling and root planing or scaling and root planing alone (to maintain the study blind). Examinations were performed at baseline and again at 3, 6, and 9 months. At 9 months, significant decreases in probing depth from baseline favoring the active chip compared with controls were observed: chlorhexidine chip with scaling and root planing, -0.95 ± 0.05 mm; placebo chip with scaling and root planing, -0.69 ± 0.05 mm ($p = 0.001$); scaling and root planing alone, -0.65 ± 0.05 mm ($p = 0.00001$). Although statistically significant, the net clinical changes were limited. The proportion of pocket sites with a probing depth reduction of 2 mm or more was increased in the chlorhexidine chip group (30%) compared with scaling and root planing alone (16%), a difference which was statistically significant on a per patient basis ($p < 0.0001$).

No signs of staining were noted in any of the above three studies as a result of the "chlorhexidine chip" treatment, as measured by a stain index. Adverse effects were minimal, with a few patients who complained of slight pain and swelling in the first 24 hours after chip placement.

Periodontal Management of HIV-Infected Patients

Terry D. Rees

CHAPTER OUTLINE

PERIODONTAL TREATMENT PROTOCOL
- **Health Status**
- **Infection Control Measures**
- **Goals of Therapy**
- **Supportive Periodontal Therapy**
- **Psychologic Factors**

ORAL CANDIDIASIS
ORAL HAIRY LEUKOPLAKIA
KAPOSI'S SARCOMA
BACILLARY (EPITHELIOID) ANGIOMATOSIS
NONSPECIFIC ORAL ULCERATIONS AND RECURRENT APHTHAE
PERIODONTAL DISEASE IN HIV-POSITIVE INDIVIDUALS
- **Linear Gingival Erythema**
- **Necrotizing Ulcerative Gingivitis**
- **Necrotizing Ulcerative Stomatitis**
- **Necrotizing Ulcerative Periodontitis**

Acquired immunodeficiency syndrome (AIDS) is a universal epidemic that significantly affects dental practice, regardless of geographic location. The oral cavity is a frequent site for clinical manifestations of the disease. The ability to recognize and manage the oral manifestations of this disease is an important part of dental practice. The dentist should be prepared to assist human immunodeficiency virus (HIV)-infected patients in maintenance of oral health throughout the course of their disease.

The detection and diagnosis of oral lesions in HIV-positive patients was described in Chapter 29. The clinical management of these conditions, with particular emphasis on periodontal conditions, is presented in this chapter.

PERIODONTAL TREATMENT PROTOCOL

To safely and effectively provide periodontal therapy to HIV-infected individuals, several treatment considerations are important.

Health Status

The patient's health status should be determined from the health history, physical evaluation, and consultation with his or her physician. Treatment decisions will vary depending on the patient's state of health. For example, delayed wound healing and increased risk of postoperative infection are possible complicating factors in AIDS patients, but neither concern should significantly alter treatment planning in an otherwise healthy, asymptomatic, HIV-infected patient with a normal or near-normal CD4 count and a low viral bioload.[21,29,36] It is important to obtain information regarding the patient's immune status. What is the CD4+ T4 lymphocyte level? What is the current viral load? How do current CD4+ T4 cell and viral load counts differ from previous evaluations? How often are such tests performed? How long ago was the HIV infection identified? Is it possible to identify the approximate date of original exposure? Is there a history of drug abuse, sexually transmitted diseases, multiple infections, or other factors that might alter immune response? For example, does the patient have a history of chronic

hepatitis B, hepatitis C, neutropenia, thrombocytopenia, nutritional deficiency, or adrenocorticoid insufficiency? What medications is the patient taking? Does the patient describe or present with possible adverse side effects from medications being taken?

Infection Control Measures

Clinical management of HIV-infected periodontal patients requires strict adherence to established methods of infection control, based on guidance from the American Dental Association (ADA) and the Centers for Disease Control and Prevention (CDC).[5] Compliance, especially with universal precautions, will eliminate or minimize risks to patients and the dental staff.[28-33] Immunocompromised patients are potentially at risk for acquiring as well as transmitting infections in the dental office or other health care facility.[4,27,31,53]

Goals of Therapy

A thorough oral examination will determine the patient's dental treatment needs. The primary goals of dental therapy should be the restoration and maintenance of oral health, comfort, and function. At the very least, periodontal treatment goals should be directed toward control of HIV-associated mucosal diseases such as chronic candidiasis and recurrent oral ulcerations. Acute periodontal and dental infections should be managed, and the patient should receive detailed instructions in performance of effective oral hygiene procedures.[47] Conservative, nonsurgical periodontal therapy should be a treatment option for virtually all HIV-positive patients, and performance of elective surgical periodontal procedures to include implant placement has been reported.[15,30] Necrotizing ulcerative periodontitis (NUP) or necrotizing ulcerative stomatitis (NUS) can be severely destructive to periodontal structures, but a history of these conditions does not automatically dictate extraction of involved teeth unless the patient is unable to maintain effective oral hygiene in affected areas. Decisions regarding elective periodontal procedures should be made with the informed consent of the patient and after medical consultation, when possible.

Supportive Periodontal Therapy

It is imperative that the patient maintain meticulous personal oral hygiene. In addition, periodontal maintenance recall visits should be conducted at short intervals (2 to 3 months) and any progressive periodontal disease treated vigorously. As mentioned earlier, however, systemic antibiotic therapy should be administered with caution. Blood and other medical laboratory tests may be required to monitor the patient's overall health status, and close consultation and coordination with the patient's physician are necessary.

Psychologic Factors

HIV infection of neuronal cells may affect brain function and lead to outright dementia. This may profoundly influence the responsiveness of affected patients to dental treatment. However, psychologic factors are numerous in virtually all HIV-infected patients, even in the absence of neuronal lesions. Patients may be greatly concerned with maintenance of medical confidentiality, and such confidentiality must be upheld. Coping with a life-threatening disease may elicit depression, anxiety, and anger in such patients, and this anger may be directed toward the dentist and the staff.[1] It is important to display concern and understanding for the patient's situation. Treatment should be provided in a calm, relaxed atmosphere, and stress to the patient must be minimized.[1]

The dentist should be prepared to advise and counsel patients on their oral health status. Dentists often encounter HIV-infected patients who are unaware of their disease status. Early diagnosis and treatment of HIV infection can have a profound effect on the patient's life expectancy and quality of life, and the dentist should be prepared to assist the patient in obtaining testing.[41] Any patient with oral lesions suggestive of HIV infection should be informed of the findings and, if appropriate, questioned regarding any previous exposure to HIV. If HIV testing is requested, it must be accompanied by patient counseling. For this reason, such tests might best be obtained through medical referral. However, if the dentist elects to request testing for HIV antibody, the patient must be informed. In most circumstances, written informed consent is desirable prior to testing.

ORAL CANDIDIASIS

Early oral lesions of HIV-related candidiasis are usually responsive to topical antifungal therapy (Fig. 51-1). More advanced lesions, including hyperplastic candidiasis, may require systemic antifungal drugs; systemic therapy is mandatory for esophageal candidiasis (Fig. 51-2).[42,51]

With any therapy, lesions tend to recur after the drug is discontinued, and resistant strains of candidal organisms have been described, especially with the use of systemic agents.[8,42,48,51] Box 51-1 identifies therapeutic agents commonly prescribed for treatment of candidal infections. Most oral topical antifungal agents contain large quantities of sucrose, which may be cariogenic after long-term use. For this reason, some authorities recommend oral use of vaginal tablets because they do not contain sucrose. However, such tablets are relatively low in active units (100,000) versus usual oral dosages of 200,000 to 600,000 units. Sucrose-free nystatin is also available in a powder form, which may be mixed extemporaneously with water at each use (5 tsp powder to 1/2 glass water). Recently, sucrose-free oral suspensions of itraconazole and amphotericin B oral rinse have become available. To date, no comparative studies have been performed regarding the effectiveness of these products. Amphotericin B oral suspension is more effective against *Candida albicans* than other species. Patients should be instructed to rinse with the oral suspension for several minutes, then swallow.[34] Fluconazole oral suspension has been reported to be more effective as an antifungal than liquid nystatin.[35] Chlorhexidine and cetylpyridinium chloride oral rinses may also be of some prophylactic value against oral candidal infection.[10,14]

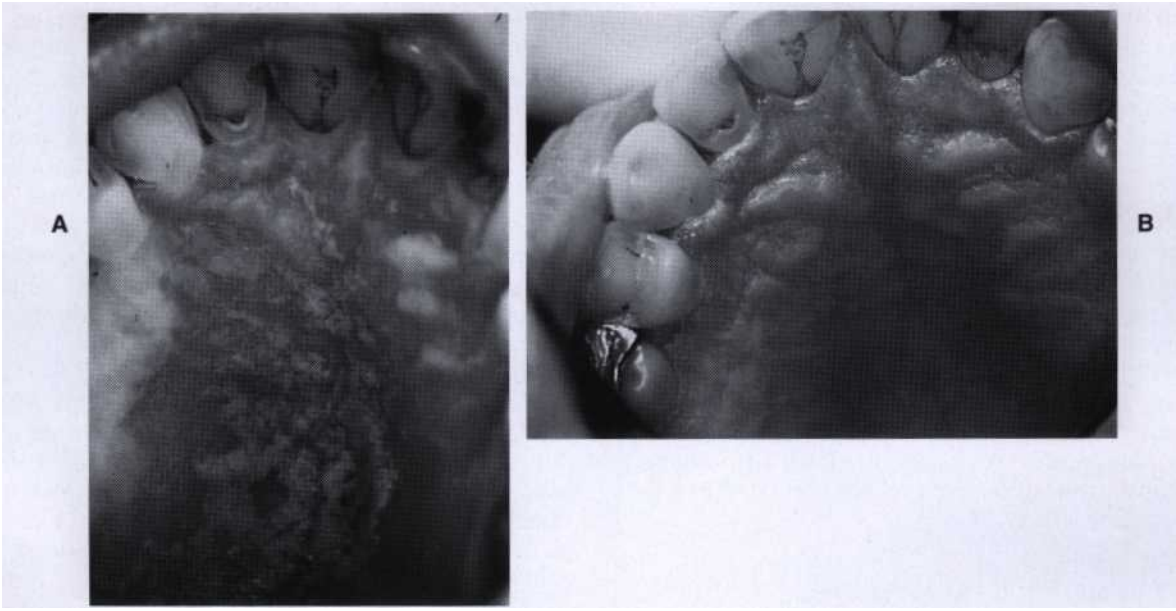

Fig. 51-1 Erythematous and pseudomembranous candidiasis. A, Before treatment. B, Resolution after 1 week of topical clotrimazole therapy.

Fig. 51-2 Marked hyperplastic candidiasis in corner of mouth. A, Before treatment. B, After 2 weeks of systemic fluconazole therapy.

Long-term prophylactic effectiveness of once-weekly systemic fluconazole also has been described. [10-42]

Systemic antifungal agents such as ketoconazole, fluconazole, itraconazole and amphotericin B are effective in treatment of oral candidiasis (see Box 51-1). Ketoconazole may be the agent of choice when systemic therapy is required.[1,11] As mentioned before, however, resistant strains of candidal organisms may develop with prolonged use of any systemic agent, potentially rendering the drugs ineffective against life-threatening candidal infections in the later stages of immune suppression.[1] In addition, significant adverse side effects may occur. As an example, long-term use of ketoconazole may induce liver damage in individuals with preexistent liver disease. The increased risk of chronic hepatitis B or hepatitis C infection in immunosuppressed individuals may put some patients at risk for ketoconazole-induced liver damage. If ketoconazole is prescribed, patients should receive liver function tests at baseline and at least monthly during therapy. The drug is contraindicated if the patient's aspartate transaminase (AST) level is greater than 2.5 times normal.[11] Ketoconazole absorption also may be hampered by the gastropathy experienced by many HIV-infected individuals.[25]

BOX 51-1

Commonly Prescribed Antifungal Therapeutic Agents for Oral Candidiasis

Topical Drugs

1. Clotrimazole (Mycelex), 10-mg tablets: Dissolve in mouth 3–5 tablets daily for 7–14 days.
2. Nystatin (Mycostatin, Nilstat).
   (a) Oral suspension.
   - 100,000 U/ml: Disp 240 ml.
   - Rinse with 1 tsp (5 ml) qid.

   (b) Oral suspension (extemporaneous).
   - Disp 2–4 billion U.
   - Mix $\frac{1}{8}$ tsp (500,000 U) in 4 oz water ($\frac{1}{2}$ cup).
   - Rinse 4 times daily.
   - *Note*: Extemporaneous nystatin is sucrose free.

   (c) Tablets (500,000 U): Dissolve 1 tablet in mouth, 4–5 times daily.
   (d) Pastilles (200,000 U): Dissolve 1–2 pastilles in mouth, 4–5 times daily.
   (e) Vaginal tablets (100,000 U): Dissolve 1 tablet in mouth tid.
   - *Note*: Vaginal troches are sucrose free.

   (f) Ointment (for angular cheilitis), 15-g tube: Apply to affected area 3–4 times daily.
3. Clotrimazole ointment, 15-g tube: Apply to affected area qid.
4. Miconazole 2% ointment, 15-g tube: Apply to affected area qid.
5. Itraconazole oral suspension (Sporanox), 100–200 mg, once daily for 7–28 days.
6. Fluconazole oral suspension (Diflucan), 200 mg of first day followed by 100 mg once daily for at least 2 weeks.
7. Amphotericin B oral suspension (Fungizone), 100 mg, four times daily for 2 weeks.

Systemic Drugs

1. Ketoconazole (Nyzoral), 200-mg tablets: Take 2 tablets immediately, then 1–2 tablets daily with food for 5–14 days.
2. Fluconazole (Diflucan), 100-mg tablets: Take 2 tablets immediately, then 1 tablet daily for 7–14 days.
3. Itraconazole (Sporanox), 100-mg capsules: 200 mg once daily with meals for 4 weeks IDS and neutropenic patients.

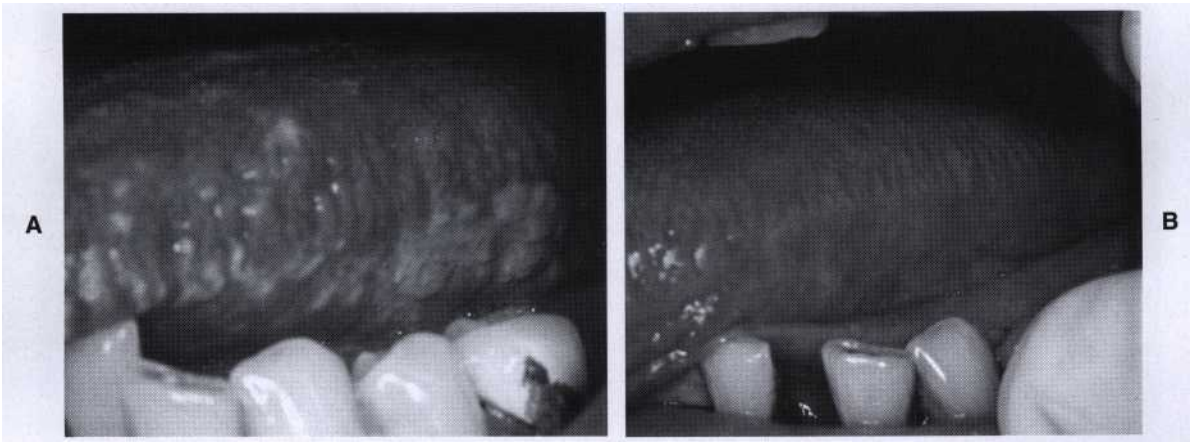

Fig. 51-3 Oral hairy leukoplakia of 2 years' duration. A, Before treatment. B, Unexpected remission after initiation of zidovudine therapy.

ORAL HAIRY LEUKOPLAKIA

At present, there appears to be little advantage in treating oral hairy leukoplakia (OHL) in most patients. Lesions can be successfully removed, however, with laser or conventional surgery. Resolution has been reported after therapy with zidovudine (Fig. 51-3) or topical retinoids, but systemic antiviral agents such as acyclovir may elicit remission more predictably (Fig. 51-4), although lesions reappear when antiviral therapy is discontinued. [2,38,40]

Clinical impressions suggest that the incidence of OHL has been markedly reduced since the advent of multidrug antiviral therapy for HIV infection.

KAPOSI'S SARCOMA

Although Kaposi's sarcoma (KS) has been the most common tumor encountered in HIV-positive individuals, its incidence may be markedly decreasing since the advent of multidrug antiviral therapy. [49] Treatment of oral KS may

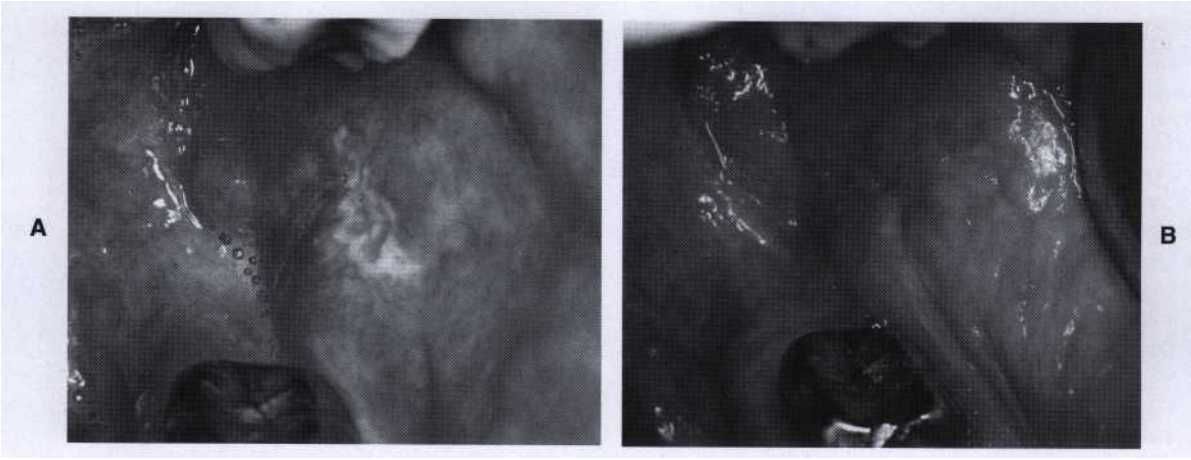

Fig. 51-4 Oral hairy leukoplakia of left buccal mucosa. A, Before treatment. B, Remission after initiation of systemic acyclovir therapy.

C, Partial resolution of facial gingival lesion after two vinblastine injections. D, Partial resolution of palatal lesion. Patient was satisfied with results and declined additional therapy.

include use of antiretroviral agents, laser excision, radiation therapy, or intralesional injection with vinblastine (Fig. 51-5), interferon *a,* or other chemotherapeutic drugs.[11,12,13,40,43,49] Nichols et al[32] described the successful use of intralesional injections of vinblastine at a dosage of 0.1 mg/cm2 using a 0.2 mg/ml solution of vinblastine sulfate in saline. In responsive patients, treatment was repeated at 2-week intervals until resolution or stabilization of the lesions. Side effects included some posttreatment pain and occasional ulceration of the lesions, but in general the therapy was well tolerated. Total resolution was achieved in 70% of 82 intraoral KS lesions with one to six treatments. Lesions tended to recur, however, thus indicating that treatment probably should be reserved for

Fig. 51-6 Major aphthae of soft palate in a 28-year-old HIV-positive man. A, Before treatment. B, Remission of lesion 1 week after prescribing topical corticosteroids.

oral KS lesions that are easily traumatized or interfere with chewing or swallowing. On some occasions, treatment may be indicated when KS lesions create an unsightly appearance on the lips or in the anterior oral cavity.

Destructive periodontitis has also been reported in conjunction with gingival KS. In such instances, scaling and root planing and other periodontal therapy may be indicated in addition to intralesional or systemic chemotherapy.[43,48]

BACILLARY (EPITHELIOID) ANGIOMATOSIS

Treatment of bacillary angiomatosis consists of broad-spectrum antibiotics such as erythromycin or doxycycline in conjunction with conservative periodontal therapy and possibly excision of the lesion.[16,18,30]

NONSPECIFIC ORAL ULCERATIONS AND RECURRENT APHTHAE

Recent evidence indicates that many nonspecific oral ulcerations may be of viral origin with herpes simplex, Epstein-Barr virus, and cytomegalovirus being most common." For this reason, the practitioner should consider viral culturing of such lesions and the use of antiviral agents in treatment where appropriate.

Oral viral infections in immunocompromised individuals are often treated with acyclovir (200 to 800 mg administered five times daily for at least 10 days). Subsequent daily maintenance therapy (200 mg two to five times daily) may be required to prevent recurrence. Resistant viral strains are treated with foscarnet, ganciclovir, or valacyclovir hydrochloride.[48,50]

Topical corticosteroid therapy (fluocinonide gel applied three to six times daily) is safe and efficacious for treatment of recurrent aphthous ulcer or other mucosal lesions in immunocompromised individuals (Fig. 51-6). However, topical corticosteroids may predispose immunocompromised individuals to candidiasis. Consequently, prophylactic antifungal medications should be prescribed.

On occasion, large aphthae in HIV-positive individuals may prove resistant to conventional topical therapy. In this event, systemic corticosteroids (prednisone 40 to 60 mg daily) (Fig. 51-7) or alternative therapy (thalidomide, levamisole, pentoxifylline, or others) must be considered.[6,17,19,24,45]

These agents may have significant side effects, however, and the clinician should remain alert for any evidence suggestive of an adverse drug reaction or adverse interaction with currently prescribed medications.[22] It should be noted that virtually all antiviral agents used in treatment of HIV infection have the potential for adverse side effects or drug interactions. For these reasons, the dental clinician should consider topical therapy as long as it is effective.

PERIODONTAL DISEASE IN HIV-POSITIVE INDIVIDUALS

As described in Chapter 29, gingival and periodontal manifestations may be found in HIV-positive individuals. The former include linear gingival erythema and necrotizing ulcerative gingivitis (NUG), both of which may develop into rapidly progressive necrotizing ulcerative stomatitis (NUS) or necrotizing ulcerative periodontitis (NUP).[9] Management of these conditions should be preceded by a thorough medical evaluation, including determination of the CD4 and viral load status, in consultation with the treating physician.

Linear Gingival Erythema

LGE is often refractory to treatment, but lesions may undergo spontaneous remission. Recent evidence suggests that LGE may result from a chronic infection with C. *albicans* or other candidal strains.[52] The recommended management of this condition is as follows:

Step 1: Instruct the patient in performance of meticulous oral hygiene.
Step 2: Scale and polish affected areas, and perform subgingival irrigation with chlorhexidine.

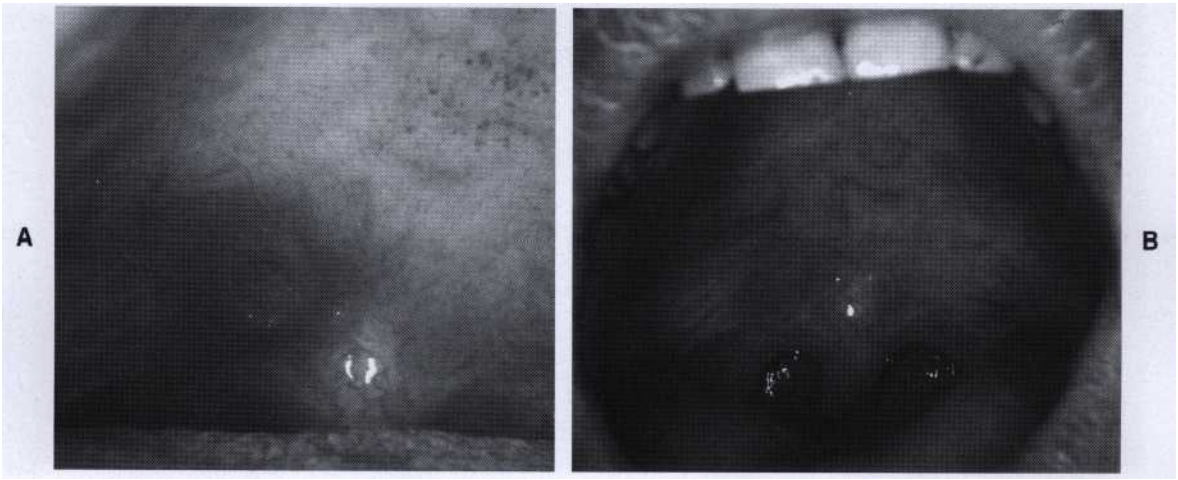

Fig. 51-7 Persistent ulceration of soft palate. A, Lesion was refractory to topical corticosteroids. B, Healing after 1 week of systemic corticosteroid therapy (40 mg prednisone daily).

Step 3: Prescribe chlorhexidine gluconate mouthrinse.
Step 4: Reevaluate the patient in 2 to 3 weeks. If lesions persist, evaluate for possible candidiasis. Consider empiric administration of a systemic antifungal agent such as fluconazole for 7 to 10 days.
Step 5: Re-treat if necessary.
Step 6: Place the patient on 2- to 3-month recall.

Necrotizing Ulcerative Gingivitis

There is no consensus on whether the incidence of NUG increases in HIV-positive patients.[23] The treatment of this condition in these individuals does not differ from that in HIV-negative individuals (see Chapter 45). Basic treatment may consist of cleaning and debridement of affected areas with a cotton pellet soaked in peroxide after application of a topical anesthetic. Escharotic oral rinses such as hydrogen peroxide should only rarely be used, however, for any patient and are especially contraindicated in immunocompromised individuals. The patient should be seen daily or every other day for the first week; debridement of affected areas is repeated at each visit, and plaque control methods are gradually introduced. A meticulous plaque control program should be taught and started as soon as the sensitivity of the area allows it.

The patient should avoid tobacco, alcohol, and condiments. An antimicrobial mouthrinse such as chlorhexidine gluconate 0.12% is prescribed.

Systemic antibiotics such as metronidazole or amoxicillin may be prescribed for patients with moderate to severe tissue destruction, localized lymphadenopathy or systemic symptoms, or both. The use of prophylactic antifungal medication should be considered if antibiotics are prescribed.

The periodontium should be reevaluated 1 month after resolution of acute symptoms to assess the results of treatment and determine the need for further therapy.

Necrotizing Ulcerative Stomatitis

NUS may be severely destructive and acutely painful. It is characterized by necrosis of significant areas of oral soft tissue and underlying bone. It may occur separately or as an extension of NUP9 and is commonly associated with severe depression of CD4+ immune cells and an increased viral load.

Treatment may include prescription of an antibiotic such as metronidazole and use of an antimicrobial mouthrinse such as chlorhexidine gluconate. If osseous necrosis is present, it is often necessary to remove the affected bone to promote wound healing.

Necrotizing Ulcerative Periodontitis

Therapy for NUP includes local debridement, scaling and root planing, in-office irrigation with an effective antimicrobial agent such as chlorhexidine gluconate or povidone iodine (Betadine), and establishment of meticulous oral hygiene, including home use of antimicrobial rinses or irrigation[20,26,39.s4] (Color Fig. 51-1 and Fig. 51-8).

This therapeutic approach is based on reports involving only a small number of patients.[39] In severe NUP, antibiotic therapy may be necessary but should be used with caution in HIV-infected patients to avoid an opportunistic and potentially serious localized candidiasis or even candidal septicemia.' If an antibiotic is necessary, metronidazole (250 mg, with two tablets taken immediately and then one tablet qid for 5 to 7 days) is the drug of choice. Prophylactic prescription of a topical or systemic antifungal agent is prudent if an antibiotic is used.

Conventional periodontitis should be managed based on the considerations outlined in "Periodontal Treatment Protocol."

SUMMARY

An understanding of the principles of occlusion and the relationship to oral health and disease is necessary for all dental clinicians. Unfortunately, no other discipline in dentistry has been so complicated by confusion and controversy. Historically, occlusal relationships have been considered largely from a morphologic rather than a biologic perspective. This approach has led to an overemphasis on occlusal scheme and jaw position without adequate consideration of the functional status of the patient's entire masticatory system.

The current resurgence of interest in occlusion[18,19,27] coincides with the Institute of Medicine's recommendation that the dental profession make use of scientific evidence, outcomes research, and formal consensus processes when devising practice guidelines.[12] As a result, we now have the opportunity and responsibility to move away from practice based on empiric experience toward practice based on scientific evidence. Application of this approach to the field of occlusion has already begun to have, and is expected to continue to have, a significant impact on clinical practice and an improved standard of patient care, including for those patients undergoing periodontal therapy.[14,19,20]

Contemporary definitions of occlusion reflect the importance of structure-function relationships in biologic systems. For example, McNeill[29] defines occlusion as the functional relationship between the components of the masticatory system, including the teeth, supporting tissues, neuromuscular system, temporomandibular joints, and craniofacial skeleton. An important corollary of this definition is that the occlusion is a dynamic relationship and must be defined physiologically as well as morphologically. The clinical application of this definition is that the occlusion cannot be evaluated or treated in isolation. Instead, each component of the masticatory system must be fully understood along with its potential for adaptation and pathophysiology as well as interactions with the other components. This chapter presents a biologic rationale and practical guidelines for evaluating jaw function status and occlusion in the context of the management of periodontal disease.

TERMINOLOGY

The complexity surrounding occlusal concepts has been compounded by an abundance of heterogeneous terminology requiring definition and clarification. The key

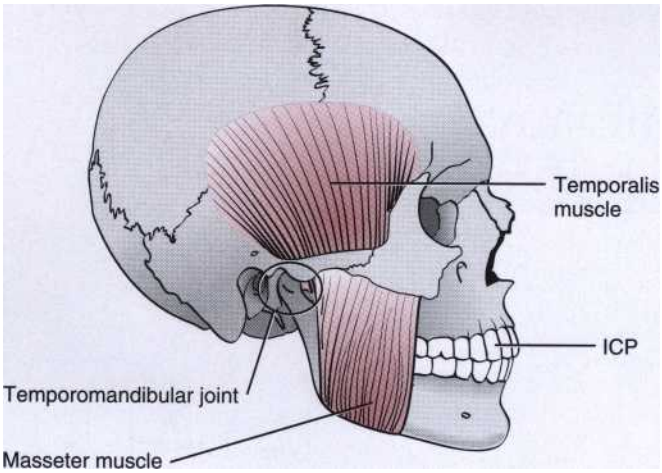

Fig. 52-1 Functional anatomy of the masticatory system shown in sagittal view: the temporomandibular joint *(circled),* **the masseter and temporalis muscles, and the dental occlusion in ICP.**

terms used in this chapter, along with common synonyms, are defined as follows:

Intercuspal position (ICP): The position of the mandible when there is maximal intercuspation between the maxillary and mandibular teeth. *Synonym:* centric occlusion.

Muscular contact position (MCP): The position of the mandible when lifted into contact from resting position.

Excursive movement: Any movement of the mandible away from ICP.

Laterotrusion: Movement of the mandible laterally to the right or left from ICP. *Synonym:* working movement.

Laterotrusive side: The side of either dental arch corresponding to the side of the mandible moving away from the midline. *Synonym:* working side.

Mediotrusive side: The side of either dental arch corresponding to the side of the mandible moving toward the midline. *Synonym:* balancing side, nonworking side.

Protrusion: Movement of the mandible anteriorly from ICP.

Retrusion: Movement of the mandible posteriorly from ICP

Retruded position: The most cranial position of the mandible along the retruded path of closure. *Synonym:* centric relation.

Guidance: Pattern of opposing tooth contact during excursive movements of the mandible. The teeth making such contact cause separation of the other teeth. *Synonym:* disclusion.

Interference: Any contact, in ICP or excursions, that prevents the remaining occlusal surfaces from achieving stable contact. *Synonym:* supracontact.

FUNCTIONAL ANATOMY OF THE MASTICATORY SYSTEM

An understanding of the biologic basis of occlusal function requires that the teeth, temporomandibular joints (TMJs), and muscles of mastication be considered as a functional unit (Fig. 52-1). These structures developed together during embryogenesis and postnatal growth, and perturbations to one component in the system would be expected to influence other components to undergo either adaptive or pathologic changes. Therefore the clinician must recognize that it is inappropriate to consider any component in isolation and instead must include all components of the system and their functional interactions as part of any evaluation.

BIOLOGIC BASIS OF OCCLUSAL FUNCTION

The ideal occlusal relationships depicted in textbook diagrams and on typodont models have served as the primary focus of traditional dental education. In reality, such ideal tooth contact relationships are uncommon in natural dentitions,[2,17,22,35,43] and a variety of occlusal schemes, including chronic excursive interferences,[1,32,33,42] are clinically acceptable.

In addition, it is now recognized that the occlusion is a dynamic relationship reflecting an equilibrium between the various components of the masticatory system.[29] Therefore the functional status of an individual's occlusion is more clinically significant than its morphology.

A widely accepted physiologic classification of occlusion is as follows:

A physiologic occlusion is present when no signs of dysfunction or disease are present and no treatment is indicated.

A nonphysiologic (or traumatic) occlusion is associated with dysfunction or disease due to tissue injury, and treatment may be indicated. In this text, the term *trauma from occlusion is* applied to periodontal tissue injury due to occlusal forces.

A therapeutic occlusion is the result of specific interventions designed to treat dysfunction or disease.

Maintenance of a physiologic occlusion requires favorable structure-function relationships and optimal tissue adaptation throughout the masticatory system. The anatomic features that contribute to a physiologic occlusion and should be the goal in a therapeutic occlusion29 include a stable end-point of mandibular closure, bilateral distribution of occlusal forces across many posterior teeth, and axial loading of these teeth. When occlusal forces are distributed optimally, the occlusion will be stable by objective criteria and is likely to be subjectively comfortable for the patient.

The signs and symptoms of a nonphysiologic occlusion include damaged teeth and restorations, abnormal mobility, fremitus, a widened periodontal ligament, pain, and a subjective sense of bite discomfort. As emphasized in Chapter 24, *the criterion that determines whether an occlusion is traumatic is whether it produces periodontal injury, not how the teeth occlude. Alternatively, many*

so-called malocclusions do not produce discomfort or injury and therefore are not traumatic occlusions by definition.

Adverse tooth loading due to increased force or frequency can result from many factors. One cause is missing or shifting teeth, leading to alterations in arch form and alignment. This situation is frequently seen in patients who have lost teeth due to untreated periodontal disease. In general, occlusal changes that occur gradually are more likely to give the tissue time to adapt, whereas acute occlusal changes, including iatrogenic changes introduced by faulty restorative dentistry, are more likely to produce injury.

Parafunctional habits such as bruxism are another potential cause of occlusal trauma. *Bruxism is* defined as diurnal or nocturnal parafunctional activity including clenching, bracing, gnashing, and grinding of the teeth. Although there is no association between bruxism and gingival inflammation[7] or periodontitis,[15,16] bruxism definitely has the potential to cause tooth wear, fracture, and periodontal and muscle pain and is a major cause of mobility." There is no significant evidence that malocclusions or interferences are causal factors in bruxism,[9] and occlusal adjustment has not proven to be an effective means of treatment.[3,21] Instead, the maxillary stabilization appliance is generally considered the most effective means of managing bruxism.[6]

Chapter 24 provides a detailed description of the response of the periodontium to occlusal forces and discusses the relationship of trauma from occlusion to the etiology and progression of periodontal disease. The literature on this topic includes numerous experimental animal model studies[10,11,23-25,30,31,39,43] in which the challenge is to make clinically relevant extrapolations to human periodontal disease. The current consensus is that trauma from occlusion has the potential to alter disease severity and prognosis. However, the therapeutic priority is to control inflammation, and this must be successful for healing of the periodontal tissues to occur.[14,30,31,36,37,43] Therefore it is recommended that occlusal interventions be deferred until inflammation is controlled and reevaluation determines that any residual mobility is the result of adverse tooth loading rather than decreased support.[13,19,20]

CLINICAL EVALUATION PROCEDURES

The current standard of care requires that a screening evaluation for temporomandibular disorders (TMD) be included in all routine dental examinations.[26] This screening should occur early in the physical evaluation of the patient to ensure that subsequent examination and treatment procedures will not have an adverse impact on preexisting TMDs. In addition, a valid examination of the occlusion requires that the patient's jaw function status be within normal limits.

TMD Screening Examination

The recommended screening examination includes health history questions focused on jaw function status, a brief history, and a cursory examination expected to take approximately 5 minutes. The generally accepted components of this examination[26] are shown in Box 52-1.

BOX 52-1

TMD Screening Evaluation

1. Maximal interincisal opening
2. Opening-closing pathway
3. Auscultation for TMJ sounds
4. Palpation for TMJ tenderness
5. Palpation for muscle tenderness

Interincisal opening. The patient is instructed to "open as wide as possible" while a millimeter ruler is placed on the lower incisors. The interincisal distance is recorded in millimeters (mm).

Opening pathway: The opening/closing pathway is observed, and any deviations from a midline path are diagrammed.

TMJ sounds: Light finger pressure is applied bilaterally over the TMJs while the patient is asked to open and close. Joint sounds are classified as discrete clicks or diffuse grating sounds, termed *crepitus.* The location of the sound in the opening/closing cycle and any associated pain or mechanical disruption should be documented.

TMJ tenderness: Light bilateral palpation over the lateral aspect of the condyles is used to elicit TMJ tenderness if present. It should be recorded as mild, moderate, or severe. The patient should be asked to compare right and left sides for calibration purposes.

Muscle tenderness: The masseter (origin and insertion) and temporalis (anterior and middle) muscles are examined bilaterally using moderate finger pressure. Sites of muscle pain should be localized and described as mild, moderate, and severe on an appropriate anatomic diagram. The most common error is to apply insufficient pressure, so the patient should be advised to expect some discomfort and instructed to differentiate pressure from pain. It is also helpful to ask the patient to compare right and left sides for calibration purposes.

Intraoral Evaluation of Occlusion

In addition to collecting standard data on static occlusal relationships, a functional evaluation of the occlusion (Box 52-2) should be carried out. This includes an assessment of ICP stability, the quality of mandibular movements, and tooth mobility and wear.

Intercuspal position: The patient should be able to close into ICP consistently from MCP without searching for a stable or comfortable bite. The most efficient way to locate zones of ICP contact is to place mylar strips between the teeth and ask the patient to "close and

BOX 52-2

Intraoral Occlusal Evaluation

2. Guidance in excursive movements
3. Tooth mobility
4. Attrition

hold." The presence or absence of contacts should be documented for the molars, premolars, canines, and incisors. More detailed information on the specific sites of ICP contacts can be obtained by using occlusal indicator wax or marking ribbon.

Excursive movements: The quality of tooth contact patterns during mandibular movements out of ICP are observed by asking the patient to move into protrusion and right and left laterotrusion. Mylar strips are useful for verifying tooth contact patterns during excursions.

Tooth mobility: Mobility is recorded as part of the initial occlusal evaluation and to monitor any changes over time. (See Chapter 30 for additional details.)

Attrition: Attrition is defined as wear due to tooth-to-tooth contact. A certain amount of physiologic attrition is normal. However, accelerated attrition should be noted, including the location of significant wear facets.

Role of Articulated Casts

Articulated dental casts are not necessary for a functional evaluation of the occlusion. In specific cases, they may be required for pretreatment documentation of occlusal relationships, localization of wear facets, trial occlusal adjustments, and monitoring of the progression of occlusal changes.

INTERPRETATION AND TREATMENT PLANNING

TMD Screening

The goal of the TMD screening examination is to determine whether jaw function status is sufficiently within the normal range to permit examination procedures and treatment to proceed without provoking or exacerbating symptoms. Therefore the clinical significance of the findings will be considered in this context.

A suggested practical approach is to use the screening examination findings to place the patient in one of the following three categories:

1. The jaw function status is determined to be within normal limits; there are no contraindications to proceeding with further examination and treatment procedures. A patient in this category will have no complaints or significant history of jaw pain or dysfunction, an interincisal opening of at least 40 mm,

BOX 52-3

Requirements for Occlusal Stability

Intercuspal position
- Light or absent anterior contacts
- Well-distributed posterior contacts
- Coupled contacts between opposing teeth
- Cross tooth stabilization
- Forces directed along long axis of each tooth

2. Smooth excursive movements without interferences
3. No trauma from occlusion
4. Favorable subjective response to occlusal form and function

no significant joint or muscle tenderness, and minimal joint sounds.

2. Certain findings should alert the clinician to the potential for aggravating benign problems, especially with wide opening during long appointments. Examples include a history of jaw problems after long appointments, several sites of mild to moderate muscle tenderness, or a previously benign TMJ click. In these cases the patients should be advised of the need to notify the clinician if symptoms develop or progress. Use of a bite block, shortened appointments, and longer intervals between appointments may also be indicated.
3. Significant findings indicate the need for a more comprehensive evaluation or referral prior to any nonemergency treatment. Examples include a restricted interincisal opening, significant pain on jaw use, severe joint or muscle pain, and progressive locking episodes, such as after wide opening. It should be obvious that continuing with nonemergency treatment would be difficult and likely to exacerbate these problems. Furthermore, evaluation of the occlusion will not be valid unless the patient's jaw function status is determined to be within normal limits.

It is important to emphasize that the prevalence of TMD signs and symptoms in adult subjects ranges from 28% to 86% in various studies,[40] but it has been estimated that only 5% to 7% are in need of TMD treatment.[41] In triaging patients as described previously, significant pain or dysfunction and progression of symptoms are the key determinants. Furthermore, clinicians treating older adults should be aware that a high prevalence of crepitus and jaw opening of less than 40 mm has been reported in older individuals compared with young adults.[4] These signs were not associated with pain or disability and do not contraindicate treatment.[4] However, they may have an impact on providing dental care to this age group.

Occlusal Evaluation

The findings from the occlusal examination should be reviewed in the context of the definitions of physiologic

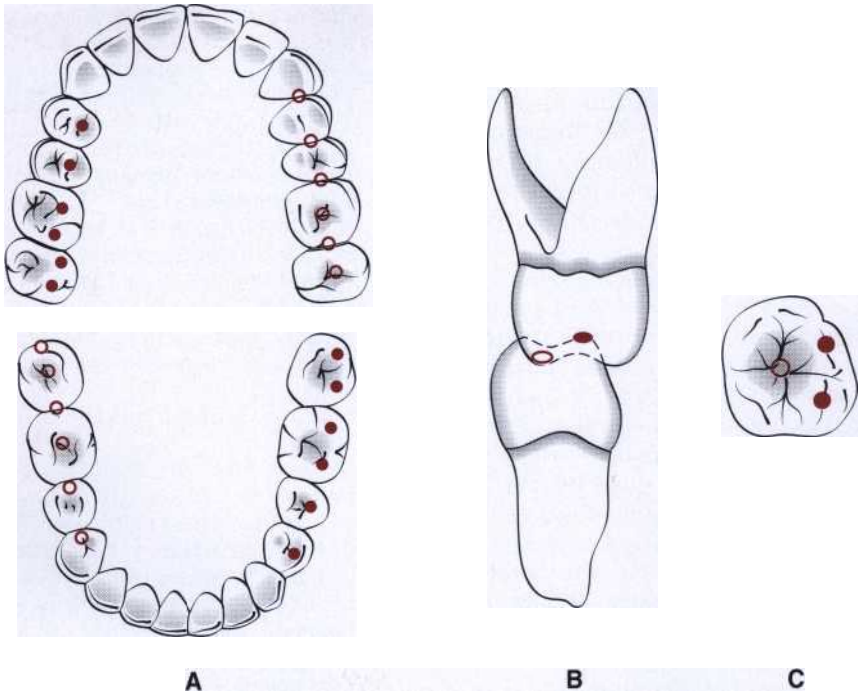

Fig. 52-2 A, Sites of ICP contact on supporting cusps (solid circles) and corresponding vertical stops (open circles). Cross tooth stabilization is shown on proximal (B) and occlusal views (C). Note the direction of occlusal forces along the long axis of the teeth shown in B.

and nonphysiologic occlusions. The most significant concern is whether the occlusion meets the requirements for occlusal stability (Box 52-3). Specific requirements for stability of posterior teeth in ICP are illustrated in Fig. 52-2.

OCCLUSAL THERAPY

The purpose of occlusal therapy is to establish stable functional relationships favorable to the oral health of the patient, including the periodontium. A variety of procedures could contribute to this objective: interocclusal appliance therapy, occlusal adjustment, restorative procedures, orthodontic tooth movement, and orthognathic surgery.

Some overall guidelines apply to occlusal therapy in general. First, there should be a sound biologic rationale for the intervention. Second, occlusal interventions should be considered an adjunct to periodontal therapy. Third, significant irreversible occlusal changes should be considered in the context of the restorative care planned for the patient. Finally, it is imperative that a thorough, informed consent be provided to the patient. With respect to periodontal management, it is critical that the patient understand that the goal of the occlusal intervention is to increase stability and comfort, *not* to treat the periodontal disease.

The contributions of restorative dentistry and orthodontic tooth movement to the management of the periodontal patient are covered elsewhere in this book. Therefore the role of occlusal adjustment and interocclusal appliance therapy is the primary focus of this discussion.

Occlusal Adjustment

Occlusal adjustment, or coronoplasty, is the selective reshaping of occlusal surfaces with the goal of establishing a stable, nontraumatic occlusion. The resulting occlusion should meet the requirements for occlusal stability described previously and would be termed a *therapeutic occlusion.* Many categories of occlusal adjustment exist, ranging from the altering of contours of a single tooth to major full mouth equilibration to the retruded position.

Occlusal adjustment procedures have been used extensively in the past for treating a variety of problems including occlusal trauma, TMD symptoms, bruxism, and headache. However, occlusal adjustment is an invasive, irreversible intervention. Therefore in the current climate of evidence-based practice, the prudent clinician is encouraged to question the scientific evidence in support of such therapy. Specifically, does the evidence support a causal relationship between occlusal factors and the condition being treated? What is the evidence that occlusal adjustment is therapeutically beneficial for the condition being treated?

In the case of TMD, the evidence leads to the conclusion that occlusal adjustment as an irreversible treatment modality should rarely be considered as a primary component of TMD treatment and never as a preventive measure.[26] Similarly, there is no evidence that occlusal adjustment is useful in the management of bruxism.

The role of occlusal adjustment in the management of periodontal disease is more complex because both periodontitis and trauma from occlusion can lead to tooth mobility. In one randomized clinical trial with a two-year follow-up, it was concluded that occlusal adjustment

resulted in a more favorable attachment level but no differences in reduction of mobility or pocket depth. Clearly, additional well-designed outcome studies designed to evaluate the effects of occlusal adjustment on healing after periodontal therapy are needed. These studies should include variables such as timing of the occlusal intervention in the therapeutic sequence, the response of individual teeth rather than dentitions, and long term follow-up.

Until these issues are resolved, it is recommended that occlusal adjustment generally be deferred until inflammation is controlled, time is allowed for tissue healing, and reevaluation determines that any residual mobility is the result of adverse tooth loading rather than decreased support. [13,19,20] Exceptions to this recommendation include the need to address pain or dysfunction clearly determined to be the result of occlusal trauma.

A major consideration prior to occlusal adjustment is the restorative needs of the patient. For example, the benefits of placing provisional restorations with optimal contours and well-adjusted occlusal surfaces should not be overlooked. This approach offers the opportunity to restore occlusal stability by distributing forces as well as to evaluate the response of the periodontium to the anticipated restoration of the patient's dentition.

For cases in which occlusal adjustment has been determined the best approach, the procedure must be preceded by good informed consent,8 and trial adjustment on accurately mounted diagnostic casts is recommended. Clark and McNeill28 have provided detailed practical protocols for occlusal adjustment procedures.

Interocclusal Appliance Therapy

Interocclusal appliances, generally fabricated of hard acrylic resin, have the advantage of providing a reversible means of **redistributing occlusal forces and minimizing excessive force** on individual teeth. A full-coverage, maxillary stabilization appliance is particularly useful in managing bruxism as part of an overall comprehensive treatment plan for the patient. Providing such an appliance to the periodontal patient is likely to contribute to an overall sense of bite comfort in addition to minimizing the destructive consequences of bruxism. Clark' has provided an excellent description of design, delivery, adjustment, and postinsertion instructions for such an appliance.

SUMMARY

Evaluation and management of the periodontal patient must include a thorough examination of the masticatory system, including a TMD screening exam and functional evaluation of the occlusion. Occlusal interventions should be considered an adjunct to periodontal therapy, reversible when possible, and planned in the context of the restorative needs of the patient.

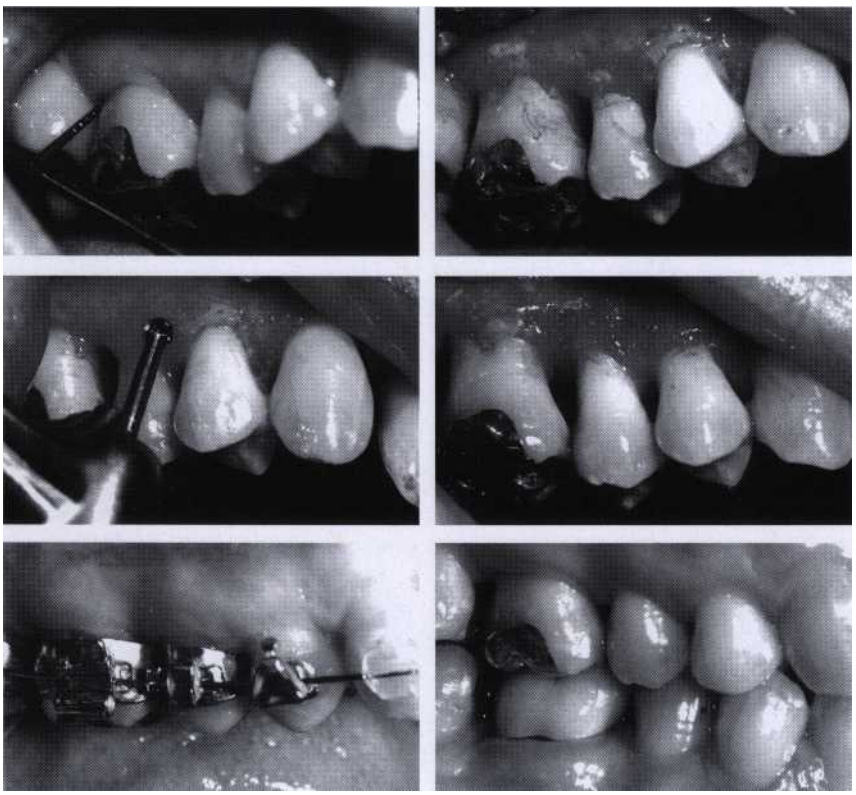
SUMMARY

Orthodontic tooth movement may be a substantial benefit to the adult periorestorative patient. Many adults who seek routine restorative dentistry have problems with tooth malposition that compromise their ability to adequately clean and maintain their dentitions. If these individuals also are susceptible to periodontal disease, tooth malposition could be an exacerbating factor that could cause premature loss of specific teeth. Orthodontic appliances have become smaller, less noticeable, and easier to maintain during orthodontic therapy. Many adults are taking advantage of the opportunity to have their teeth aligned to improve the esthetics of their smiles. If these individuals also have underlying gingival or osseous periodontal defects, these defects often can be improved during orthodontic therapy if the orthodontist is aware of the situation and designs the appropriate tooth movement. In addition, implants have become a major part of the treatment plan for many adults with missing teeth. If adjacent teeth have drifted into edentulous spaces, orthodontics is often helpful to provide the ideal amount of space for implants and subsequent restorations. This chapter shows the ways in which adjunctive orthodontic therapy can enhance the periodontal health and restorability of teeth.

BENEFITS OF ORTHODONTICS FOR A PERIODONTAL PATIENT

Orthodontic therapy can provide several benefits to the adult periodontal patient. The following six factors should be considered:

1. Aligning crowded or malposed maxillary or mandibular anterior teeth permits the adult patient better access to adequately clean all surfaces of their teeth. This could be a tremendous advantage for patients who are susceptible to periodontal bone loss or do not have the dexterity to adequately maintain their oral hygiene.
2. Vertical orthodontic tooth repositioning can improve certain types of osseous defects in periodontal patients. Often, the tooth movement eliminates the need for resective osseous surgery.



3. Orthodontic treatment can improve the esthetic relationship of the maxillary gingival margin levels before restorative dentistry. Aligning the gingival margins orthodontically avoids gingival recontouring, which potentially could require bone removal and exposure of the roots of the teeth.
4. The fourth benefit of orthodontics is for the patient who has suffered a severe fracture of a maxillary anterior tooth, which requires forced eruption to permit adequate restoration of the root. In this situation, erupting the root allows the crown preparation to have sufficient resistance form and retention for the final restoration.
5. Orthodontic treatment allows open gingival embrasures to be corrected to regain lost papilla. If these open gingival embrasures are located in the maxillary anterior region, they can be unaesthetic. In most patients, these areas can be corrected with a combination of orthodontic root movement, tooth reshaping, and/or restoration.
6. Orthodontic treatment could improve adjacent tooth position before implant placement or tooth replacement. This is especially true for the patient who has been missing teeth for several years and has drifting and tipping of the adjacent dentition.

PREORTHODONTIC OSSEOUS SURGERY

The extent of the osseous surgery depends on the type of defect (i.e., crater, hemiseptal defect, three-wall defect, and/or furcation lesion). The prudent clinician knows which defects can be improved with orthodontic treatment and which defects require preorthodontic, periodontal, surgical intervention.

Osseous Craters

An osseous crater is an interproximal, two-wall defect that does not improve with orthodontic treatment. Some shallow craters (i.e., 4- to 5-mm pocket) may be maintainable nonsurgically during orthodontic treatment. However, if surgical correction is necessary, this type of osseous lesion can easily be eliminated by reshaping the defect [12.15] and reducing the pocket depth (Fig. 53-1) (see Chapter 62). This in turn enhances the ability to maintain these interproximal areas during orthodontic treatment. The need for surgery is based on the patient's response to initial root planing, the patient's periodontal resistance, the location of the defect, and the predictability of maintaining defects nonsurgically while the patient is wearing orthodontic appliances.

F

Fig. 53-1 This patient had a 6-mm probing defect distal to the maxillary right first molar (A). When this area was flapped (B), a cratering defect was apparent. Osseous surgery was used to alter the bony architecture on the buccal and lingual to eliminate the defect (C and D). After 6 weeks, the probing pocket defect had been reduced to 3 mm, and orthodontic appliances were placed on the teeth (E). By eliminating the crater before orthodontics, the patient could maintain the area during and after orthodontics (F).

Three-Wall Intrabony Defects

Three-wall defects are amenable to pocket reduction with regenerative periodontal therapy.' Bone grafts using either autogenous bone from the surgical site or allografts along with the use of resorbable membranes have been successful in filling three-wall defects.14 If the result of periodontal therapy is stable (Fig. 53-2) 3 to 6 months after periodontal surgery, orthodontic treatment may be initiated.

ORTHODONTIC TREATMENT OF OSSEOUS DEFECTS

Hemiseptal Defects

Hemiseptal defects are one- or two-wall osseous defects that often are found around mesially tipped teeth (Fig. 53-3) or teeth that have supererupted (Fig. 53-4). Usually, these defects can be eliminated with the appropriate orthodontic treatment. In the case of the tipped tooth, uprighting',' and eruption of the tooth levels the bony defect. If the tooth is supererupted, intrusion and leveling of the adjacent cementoenamel junctions can help level the osseous defect.

It is imperative that periodontal inflammation be controlled before orthodontic treatment. This usually can be achieved with initial debridement and rarely requires any preorthodontic surgery. After the completion of orthodontic treatment, these teeth should be stabilized for at least 6 months and reassessed periodontally. Often, the pocket has been reduced or eliminated and no further periodontal treatment is needed. It would be injudicious to perform preorthodontic osseous corrective surgery in such lesions if orthodontics is part of the overall treatment plan.

In the periodontally healthy patient, orthodontic brackets are positioned on the posterior teeth relative to the marginal ridges and cusps. However, some adult patients may have marginal ridge discrepancies caused by uneven tooth eruption. When marginal ridge discrepancies are encountered, the decision as to where to place the bracket or band is not determined by the anatomy of the tooth. In these situations, it is important to assess these teeth radiographically to determine the interproximal bone level.

If the bone level is oriented in the same direction as the marginal ridge discrepancy, then leveling the marginal ridges will level the bone. However, if the bone level is flat between adjacent teeth (see Fig. 53-4) and the marginal ridges are at significantly different levels, correction of the marginal ridge discrepancy orthodontically produces a hemiseptal defect in the bone. This could cause a periodontal pocket between the two teeth.

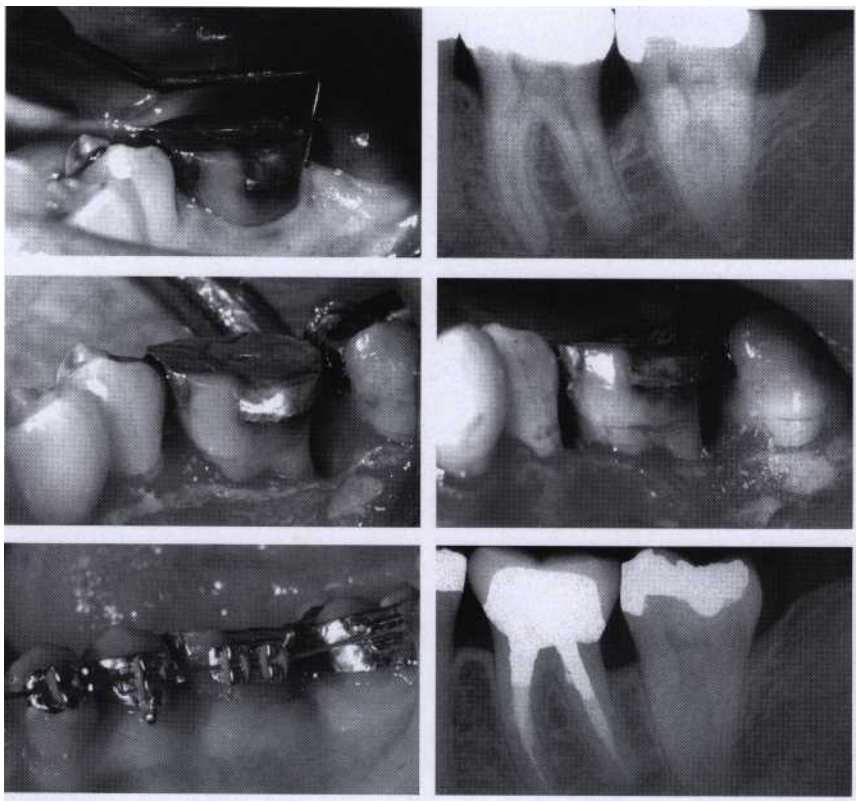


Fig. 53-2 This patient had a significant periodontal pocket (A) distal to the mandibular right first molar. A periapical radiograph (B) confirmed the osseous defect. A flap was elevated (C), revealing a deep, three-wall osseous defect. Freeze-dried bone (D) was placed in the defect 6 months after the bone graft. Orthodontic treatment was initiated (E). The final periapical radiograph shows that the preorthodontic bone graft helped regenerate bone and eliminate the defect distal to the molar (F).

If the bone is flat and a marginal ridge discrepancy is present, the orthodontist should not level the marginal ridges orthodontically. In these situations, it may be necessary to equilibrate the crown of the tooth (see Fig. 53-4). For some patients, the latter technique may require endodontic therapy and restoration of the tooth because of the required amount of reduction of the length of the crown. This approach is acceptable if the treatment results in a more favorable bone contour between the teeth.

In some patients, a discrepancy may exist between both the marginal ridges and the bony levels between two teeth. However, these discrepancies may not be of equal magnitude. In these patients, orthodontic leveling of the bone may still leave a discrepancy in the marginal ridges (Fig. 53-5). In these situations, the crowns of the teeth should not be used as a guide for completing orthodontic therapy. The bone should be leveled orthodontically and any remaining discrepancies between the marginal ridges should be equilibrated. This method produces the best occlusal result and improves the periodontal health.

During orthodontic treatment, when teeth are being extruded to level hemiseptal defects, the patient should be monitored regularly. Initially, the hemiseptal defect has a greater sulcular depth and is more difficult for the patient to clean. As the defect is ameliorated through tooth extrusion, interproximal cleaning becomes easier. The patient should be recalled every 2 to 3 months during the leveling process to control inflammation in the interproximal region.

Advanced Horizontal Bone Loss

After orthodontic treatment has been planned, one of the most important factors that determine the outcome of orthodontic therapy is the location of the bands and brackets on the teeth. In a periodontally healthy individual, the position of the brackets is usually determined by the anatomy of the crowns of the teeth. Anterior brackets should be positioned relative to the incisal edges. Posterior bands or brackets are positioned relative to the marginal ridges. If the incisal edges and marginal ridges are at the correct level, the cementoenamel junction (CEJ) will also be **at the same level.** This relationship creates a flat, bony contour between the teeth. However, if a patient has underlying periodontal problems and significant alveolar bone loss around certain teeth, using the anatomy of the crown to determine bracket placement is not appropriate (Fig. 53-6).

In a patient with advanced horizontal bone loss, the bone level may have receded several millimeters from

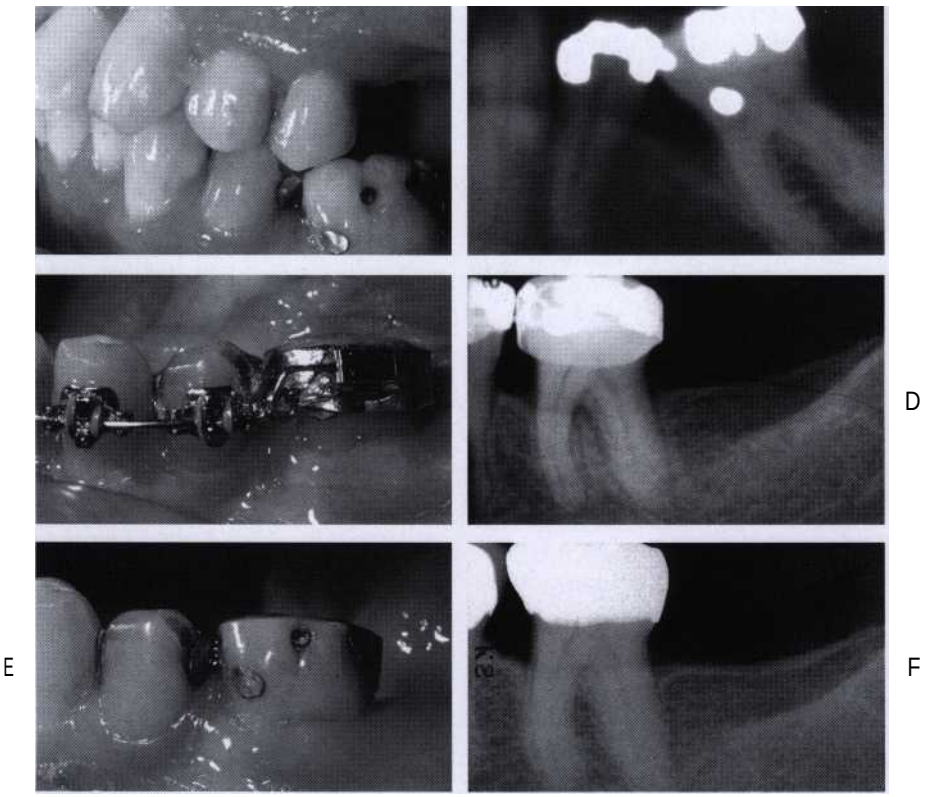

Fig. 53-3 This patient was missing the mandibular left second premolar, and the first molar had tipped mesially (A). A pretreatment periapical radiograph (B) revealed a significant hemiseptal osseous defect on the mesial of the molar. To eliminate the defect, the molar was erupted and the occlusal surface was equilibrated (C). The eruption was stopped when the bone defect was leveled (D). The posttreatment intraoral photograph (E) and periapical radiograph (F) show that the periodontal health had been improved by correcting the hemiseptal defect orthodontically.

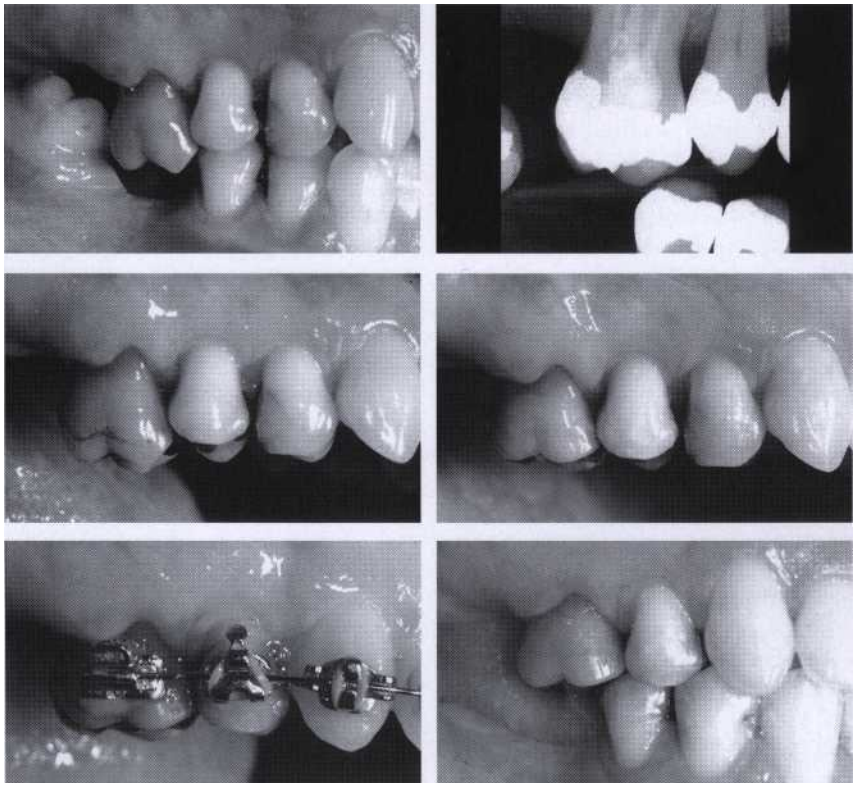

Fig. 53-4 This patient showed overeruption of the maxillary right first molar and a marginal ridge defect between the second premolar and first molar (A). A pretreatment periapical radiograph (B) showed that the interproximal bone was flat. To avoid creating a hemiseptal defect, the occlusal surface of the first molar was equilibrated (C and D) and the malocclusion was corrected orthodontically (E and F).

the CEJ. As this occurs, the crown-to-root ratio becomes less favorable. By aligning the crowns of the teeth, the clinician may perpetuate tooth mobility by maintaining an unfavorable crown-to-root ratio. In addition, by aligning the crowns of the teeth and disregarding the bone level, significant bone discrepancies occur between healthy and periodontally diseased roots. This could require periodontal surgery to ameliorate the discrepancies.

Many of these problems can be corrected by using the bone level as a guide to position the brackets on the teeth (see Fig. 53-6). In these situations, the crowns of the teeth may require considerable equilibration. If the tooth is vital, the equilibration should be performed gradually to allow the pulp to form secondary dentin and insulate the tooth during the equilibration process. The goal of equilibration and creative bracket placement is to provide a more favorable bony architecture as well as a more favorable crown-to-root ratio. In some of these patients, the periodontal defects that were apparent initially may not require periodontal surgery after orthodontic treatment.

Furcation Defects

Furcation defects can be classified as incipient (Class I), moderate (Class 11), or advanced (Class III). These lesions require special attention in the patient undergoing orthodontic treatment. Often, the molars require bands with tubes and other attachments that impede the patient's access to the buccal furcation for home care and instrumentation at the time of recall.

Furcation lesions require special consideration because they are the most difficult lesions to maintain and can worsen during orthodontic therapy. These patients need to be maintained on a 2- to 3-month recall schedule. Detailed instrumentation of these furcations helps minimize further periodontal breakdown.

If a patient with a Class III furcation defect will be undergoing orthodontic treatment, a possible method for treating the furcation is to eliminate it by hemisecting the crown and root of the tooth (Fig. 53-7). However, this procedure requires endodontic, periodontal, and restorative treatment. If the patient will be undergoing orthodontic treatment, it is advisable to perform the orthodontic treatment first. This is especially true if the roots of the teeth will not be moved apart. In these patients, the molar to be hemisected remains intact during orthodontics (see Fig. 53-7). This patient would require 2- or 3-month recall visits to ensure that the furcation defect does not lose bone during orthodontic treatment. Keeping the tooth intact during the orthodontics simplifies the concentration of tooth movement for the orthodontist. After orthodontics, endodontic therapy is

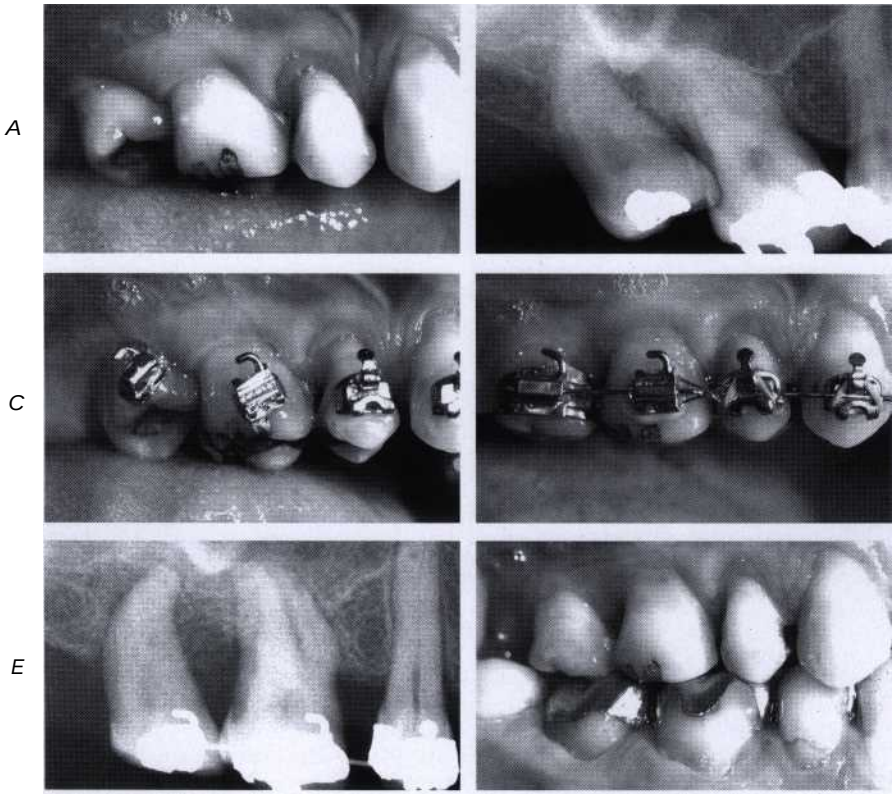

Fig. 53-5 Before orthodontic treatment, this patient had significant mesial tipping of the maxillary right first and second molars, causing marginal ridge discrepancies (A). The tipping produced root proximity between the molars (B). To eliminate the root proximity, the brackets were placed perpendicular to the long axis of the teeth (G). This method of bracket placement facilitated root alignment and elimination of the root proximity as well as leveling of the marginal ridge discrepancies (D, E, and F).

required (followed by periodontal surgery) to divide the tooth.

In some patients requiring hemisection of a mandibular molar with a Class III furcation, pushing the roots apart during orthodontic treatment may be advantageous (Fig. 53-8). If the hemisected molar will be used as an abutment for a bridge after orthodontics, moving the roots apart orthodontically permits a favorable restoration and splinting across the adjacent edentulous spaces.

In the latter situation, hemisection, endodontic therapy, and periodontal surgery must be completed before the start of orthodontic treatment. After these procedures have been completed, bands or brackets can be placed on the root fragments and coil springs used to separate the roots. The amount of separation is determined by the size of the adjacent edentulous spaces and the occlusion in the opposing arch. About 7 or 8 mm may be created between the roots of the hemisected molar. This process eliminates the original furcation problem and allows the patient to clean the area with greater efficiency.

In some molars with Class III furcation defects, the tooth may have short roots, advanced bone loss, fused roots, or other problems that prevent hemisection and crowning of the remaining roots. In these patients (Fig. 53-9), extracting the root with a furcation defect and placing an implant may be more advisable." If this type of plan has been adopted, the timing of the extraction and placement of the implant can occur at any time relative to the orthodontic treatment. In some situations, the implant could be used as an anchor to facilitate prerestorative orthodontic treatment (see Fig. 53-9).

The implant must remain embedded in bone for 4 to 6 months after placement before it can be loaded as an orthodontic anchor. It must be placed precisely so that it not only provides an anchor for tooth movement but also may be used an eventual abutment for a crown or fixed bridge. If the implant will not be used as an anchor for orthodontic movement, it may be placed after the orthodontic treatment has been completed. Considerations regarding timing are determined by the restorative treatment plan.

Root Proximity

When roots of posterior teeth are in close proximity, the ability to maintain periodontal health and accessibility for restoration of adjacent teeth may be compromised.' However, if the patient were undergoing orthodontic therapy, the roots can be moved apart and bone will be formed between the adjacent roots (see Fig. 53-5). This opens the embrasure beneath the tooth contact, provides additional bone support, and enhances the patient's access to the interproximal region for hygiene.

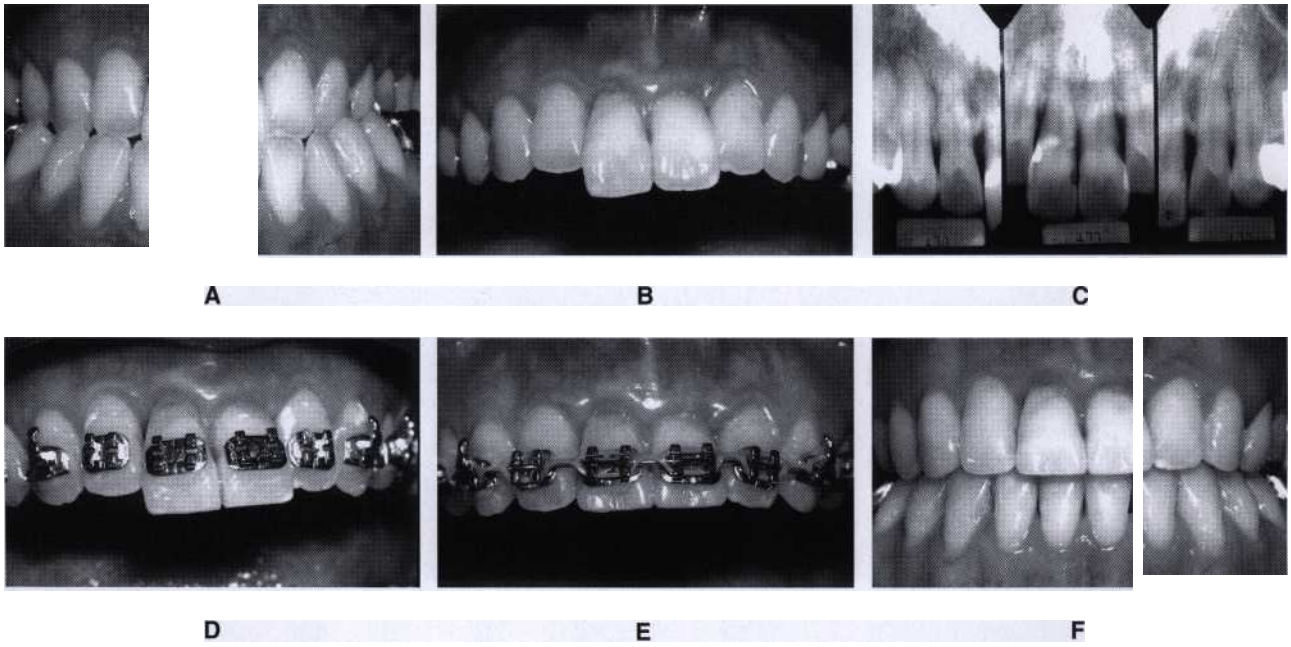

Fig. 53-6 Before orthodontic treatment, this patient had a significant Class III malocclusion (A). The maxillary central incisors had overerupted (B) relative to the occlusal plane. A pretreatment periapical radiograph (C) showed that significant horizontal bone loss had occurred. To avoid creating a vertical periodontal defect by intruding the central incisors, the brackets were placed to maintain the bone height (D). The incisal edges of the centrals were equilibrated (E), and the orthodontic treatment was completed without intruding the incisors (F).

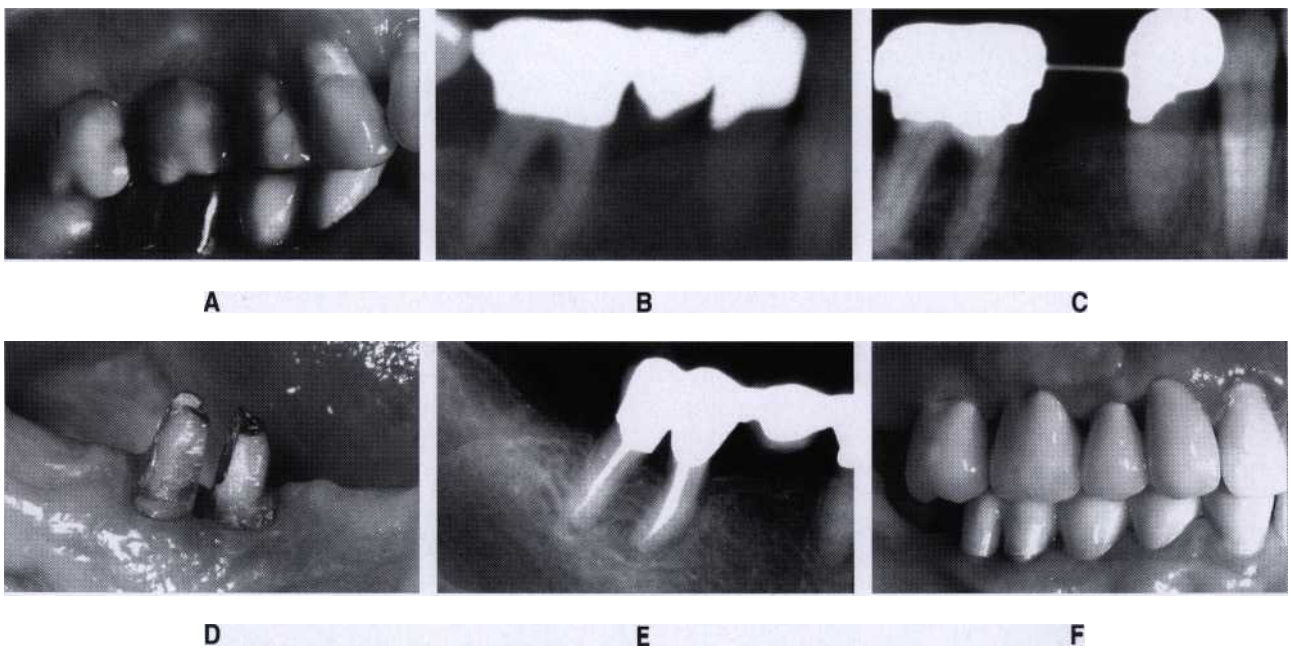

Fig. 53-7 This patient had a Class III furcation defect before orthodontic treatment (A and B). Orthodontic treatment was performed (C), and the furcation defect was maintained by the periodontist on 2-month recalls until after orthodontic treatment. After appliance removal, the tooth was hemisected (D), and the roots were restored, and splinted together (E). The final periapical radiograph (F) shows that the furcation defect has been eliminated by hemisecting and restoring the two root fragments.

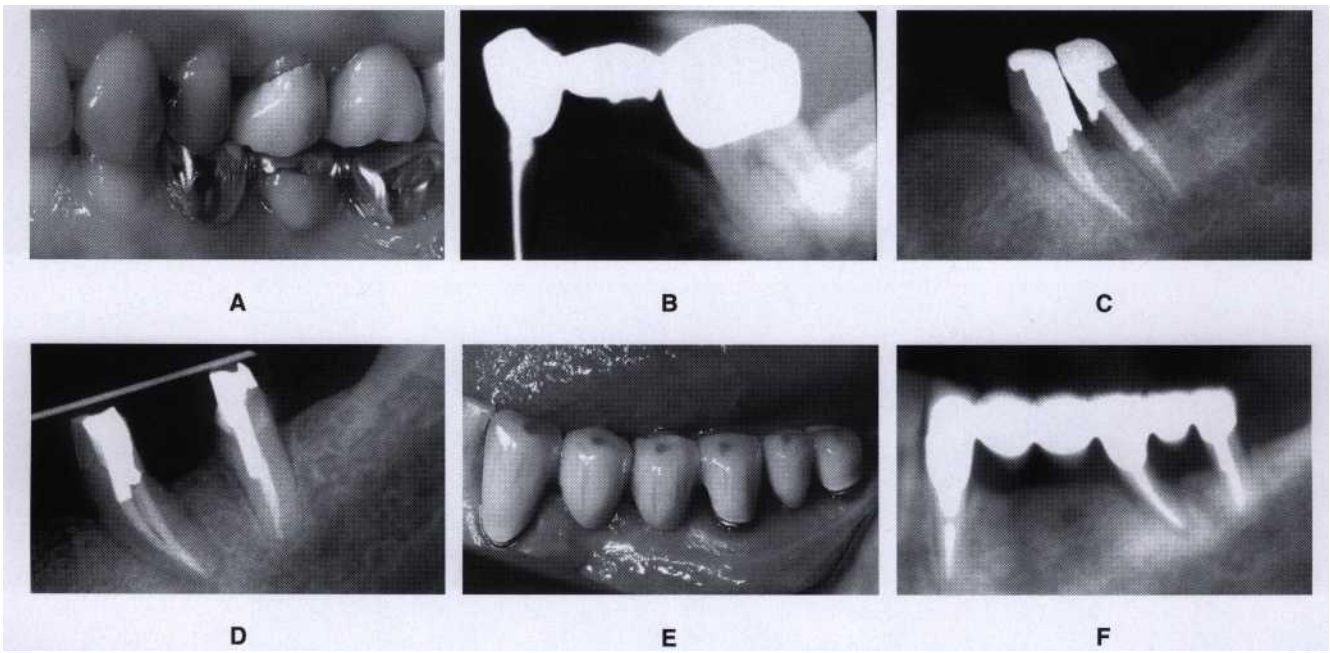

Fig. 53-8 Before orthodontic treatment, this patient had a Class III furcation defect in the mandibular left second molar (A and B). Because the patient had an edentulous space mesial to the molar, the tooth was hemisected (C), and the root fragments were separated orthodontically (D). After orthodontic treatment, the root fragments were used as abutments to stabilize a multiunit posterior bridge (E and F).

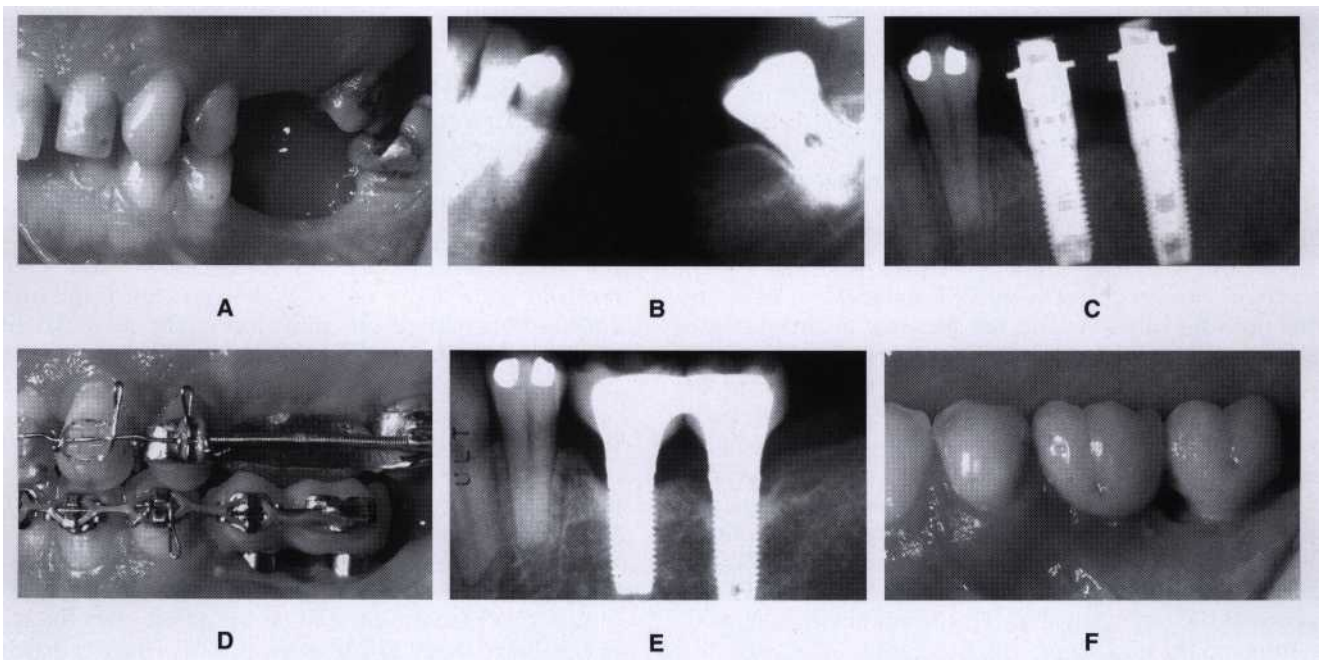

Fig. 53-9 This patient was missing several teeth in the mandibular left posterior quadrant (A). The mandibular left third molar had a Class III furcation defect and short roots (B). The third molar was extracted and two implants were placed in the mandibular left posterior quadrant (C). The implants were used as anchors to facilitate orthodontic treatment (D) and help reestablish the left posterior occlusion (E and F).

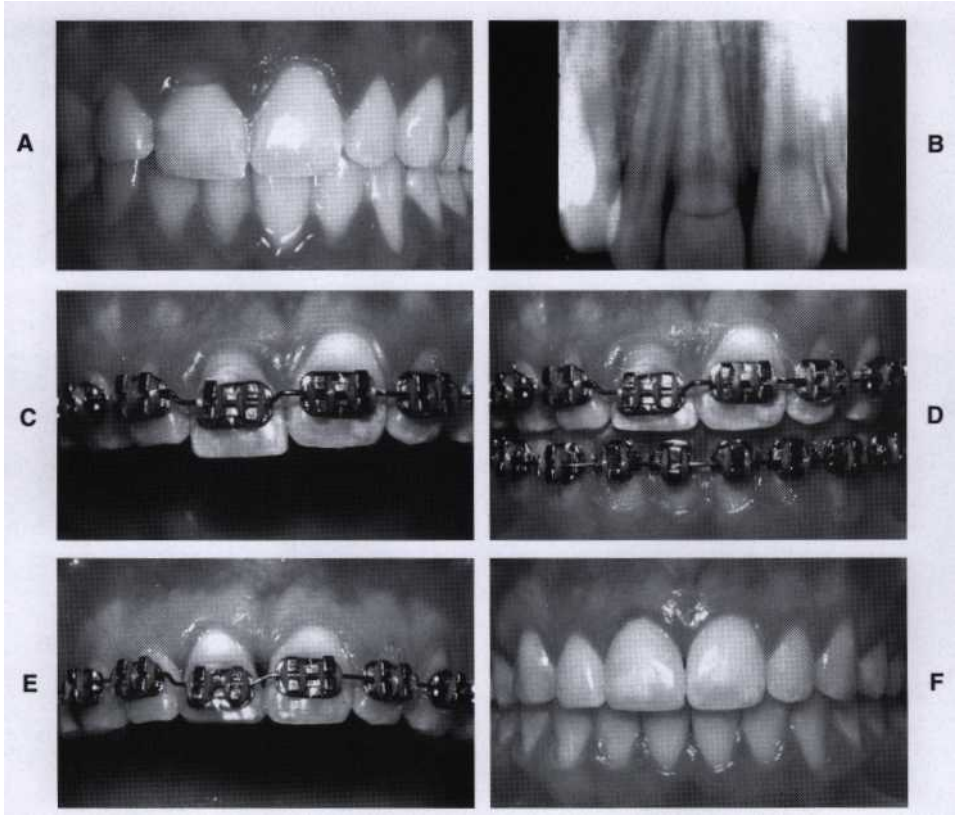

Fig. 53-10 This patient had a severe fracture of the maxillary right central incisor (A) that extended apical to the level of the alveolar crest on the lingual (I3). To restore the tooth adequately and avoid impinging on the periodontium, the fractured root was extruded 4 mm (C). As the tooth erupted, the gingival margin followed the tooth (D). Gingival surgery was required to lengthen the crown of the central incisor (E) so that the final restoration had sufficient ferrule for resistance and retention and the appropriate gingival margin relationship with the adjacent central incisor (F).

This generally improves the periodontal health of this area.

If orthodontic treatment will be used to move roots apart, this plan must be known before bracket placement. It is advantageous to place the brackets so that the orthodontic movement to separate the roots will begin with the initial archwires (see Fig. 53-5). Therefore brackets must be placed obliquely to facilitate this process. To determine the progress of orthodontic root separation, radiographs are needed to monitor the status. Generally, 2 to 3 mm of root separation provides adequate bone and embrasure space to improve periodontal health. During this time, the patient should be maintained to ensure that a favorable bone response occurs as the roots are moved apart. In addition, these patients need occasional occlusal adjustment to recontour the crown because the roots are moving apart. As this occurs, the crowns may develop an unusual occlusal contact with the opposing arch. This should be equilibrated to improve the occlusion.

Fractured Teeth/Forced Eruption

Occasionally, children and adolescents may fall and accidentally injure their anterior teeth. If the injuries are minor and result in small fractures of enamel, these can be restored with light-cured composite or porcelain veneers. However, in some situations, the fracture may extend beneath the level of the gingival margin and terminate at the level of the alveolar ridge (Fig. 53-10). In these situations, restoration of the fractured crown is impossible because the tooth preparation would extend to the level of the bone. This overextension of the crown margin could result in an invasion of the biologic width of the tooth and cause persistent inflammation of the marginal gingiva. It may be beneficial in such cases to erupt the fractured root out of the bone and move the fracture margin coronally so that it can be properly restored.' However, if the fracture extends too far apically, it may be better to extract the tooth and replace it with an implant or bridge. Six criteria determine whether the tooth should be forcibly erupted or extracted.

1. *Root length:* Is the root long enough so that a one-to-one crown-root ratio will be preserved after the root has been erupted? To determine the answer to this question, the clinician must know how far to erupt the root. If a tooth fracture extends to the level of the bone, it must be erupted 4 mm. The first 2.5 mm moves the fracture margin far enough away from the bone to prevent a biologic width problem. The other 1.5 mm provides the proper amount of ferrule for

adequate resistance form of the crown preparation. Therefore if the root is fractured to the bone level and must be erupted 4 mm, the periapical radiograph must be evaluated (see Fig. 53-10) and 4 mm subtracted from the end of the fractured tooth root. The length of the residual root should be compared with the length of the eventual crown on this tooth. The root-to-crown ratio should be about 1:1. If the root-to-crown ratio is less than this amount, there may be too little root remaining in the bone for stability. In the latter situation, it may be prudent to extract the root and place a bridge or implant.

2. *Root form:* The shape of the root should be broad and nontapering, rather than thin and tapered. A thin, tapered root provides a narrower cervical region after the tooth has been erupted 4 mm. This could compromise the esthetic appearance of the final restoration. The internal root form is also important. If the root canal is wide, the distance between the external root surface and root canal filling will be narrow. In these situations, the walls of the crown preparation are thin, which could result in early fracture of the restored root. The root canal should not be more than one third of the overall width of the root. In this way, the root could still provide adequate strength for the final restoration.
3. *Level of the fracture:* If the entire crown is fractured 2 to 3 mm apical to the level of the alveolar bone, it is difficult, if not impossible, to attach to the root to erupt it.
4. *Relative importance of the tooth:* If the patient were 70 years of age and both adjacent teeth had prosthetic crowns, then it could be more prudent to construct a fixed bridge. However, if the patient is 15 years of age and the adjacent teeth were unrestored, then forced eruption would be much more conservative and appropriate.
5. *Esthetics:* If the patient has a high lip line and displays 2 to 3 mm of gingiva when smiling, then any type of restoration in this area will be more obvious. In this situation, keeping the patient's own tooth would be much more esthetic than any type of implant or prosthetic replacement.
6. *Endo/perio prognosis:* If the tooth has a significant periodontal defect, it may not be possible to retain the root. In addition, if the tooth root has a vertical fracture, the prognosis would be poor and extraction of the tooth would be the proper course of therapy.

If all these factors are favorable, then forced eruption of the fractured root is indicated. The orthodontic mechanics necessary to erupt the tooth can vary from elastic traction to orthodontic banding and bracketing. If a large portion of the tooth is still present, then orthodontic bracketing is necessary. If the entire crown has fractured, leaving only the root, then elastic traction from a bonded bar may be possible. The root may be erupted rapidly or slowly. If the movement is performed rapidly, the alveolar bone will be left behind temporarily and a circumferential fiberotomy may be performed to prevent bone from following the erupted root. However, if the root is erupted slowly, the bone follows the tooth. In this situation, the erupted root requires crown lengthening to expose the correct amount of tooth to create the proper ferrule, resistance form, and retention for the final restoration.

After the tooth root has been erupted, it must be stabilized to prevent it from intruding back into the alveolus. The reason for reintrusion is the orientation of the principal fibers of the periodontium. During forced eruption, the periodontal fibers become oriented obliquely and stretched as the root moves coronally. These fibers eventually reorient themselves after about 6 months. Before this occurs, the root can reintrude significantly. Therefore if this type of treatment is performed, an adequate period of stabilization is necessary to avoid significant relapse and reintrusion of the root.

As the root erupts, the gingiva move coronally with the tooth. As a result, the clinical crown length becomes shorter after extrusion (see Fig. 53-10). In addition, the gingival margin may be positioned more incisally than the adjacent teeth. In these situations, gingival surgery is necessary to create ideal gingival margin heights. The type of surgery varies depending on whether bone removal is necessary. If bone has followed the root during eruption, a flap is elevated and the appropriate amount of bone is removed to match the bone height of the adjacent teeth. If the bone level is flat between adjacent teeth, a simple excisional gingivectomy corrects the gingival margin discrepancy.

After gingival surgery, an open gingival embrasure may exist between the erupted root and adjacent teeth (see Fig. 53-10). The space occurs because the narrower root portion of the erupted tooth has been moved into the oral cavity. This space may be closed in two different ways. One method involves overcontouring of the replacement restoration. The other method involves reshaping of the crown of the tooth and movement of the root to close the space. This latter method often helps improve the overall shape of the final crown on the restored tooth.

Hopeless Teeth Maintained for Orthodontic Anchorage

Patients with advanced periodontal disease may have specific teeth diagnosed as hopeless, which would be extracted before orthodontics (Fig. 53-11). However, these teeth can be useful for orthodontic anchorage if the periodontal inflammation can be controlled. In moderate to advanced cases, some periodontal surgery may be indicated around a hopeless tooth. Flaps are reflected for debridement of the roots to control inflammation around the hopeless tooth during the orthodontic process. The important factor is to maintain the health of the bone around the adjacent teeth. Periodontal recall is imperative during the process.

After orthodontic treatment, there is a six-month period of stabilization before reevaluating the periodontal status. Occasionally, the hopeless tooth may be so improved after orthodontic treatment that it is retained. However, in most cases, the hopeless tooth requires extraction, especially if other restorations are planned in the segment. Again, these decisions require reevaluation by the clinician.

Fig. 53-11 This patient had an impacted mandibular right second molar (A). The mandibular right first molar was periodontally hopeless because of an advanced Class III furcation defect. The impacted second molar was extracted, but the first molar was maintained as an anchor to help upright the third molar orthodontically (B, C, and D). After orthodontic uprighting of the third molar, the first molar was extracted and a bridge was placed to restore the edentulous space (E and F).

ORTHODONTIC TREATMENT OF GINGIVAL DISCREPANCIES

Uneven Gingival Margins

The relationship of the gingival margins of the six maxillary anterior teeth plays an important role in the esthetic appearance of the crowns. Four factors contribute to ideal gingival form.

1. The gingival margins of the two central incisors should be at the same level.
2. The gingival margins of the central incisors should be positioned more apically than the lateral incisors and at the same level as the canines.13
3. The contour of the labial gingival margins should mimic the CEJs of the teeth.
4. A papilla should exist between each tooth, and the height of the tip of the papilla is usually halfway between the incisal edge and the labial gingival height of contour over the center of each anterior tooth. Therefore the gingival papilla occupies half of the interproximal contact, and the adjacent teeth form the other half of the contact.

However, some patients may have gingival margin discrepancies between adjacent teeth (Fig. 53-12). These discrepancies could be caused by abrasion of the incisal edges or delayed migration of the gingival margins. When gingival margin discrepancies are present, the proper solution for the problem must be determined: orthodontic movement to reposition the gingival margins or surgical correction of gingival margin discrepancies.

To make the correct decision, it is necessary to evaluate four criteria. First, the relationship between the gingival margin of the maxillary central incisors and the patient's lip line should be assessed when the patient smiles. If a gingival margin discrepancy is present but the discrepancy is not exposed, it does not require correction.

If a gingival margin discrepancy is apparent, the second step is to evaluate the labial sulcular depth over the two central incisors. If the shorter tooth has a deeper sulcus, excisional gingivectomy may be appropriate to move the gingival margin of the shorter tooth apically. However, if the sulcular depths of the short and long incisors are equivalent, gingival surgery does not correct the problem.

The third step is to evaluate the relationship between the shortest central incisor and the adjacent lateral incisors. If the shortest central is still longer than the lateral incisors, the other possibility is to extrude the longer central incisor and equilibrate the incisal edge. This moves the gingival margin coronally and eliminates the gingival margin discrepancy. However, if the shortest central is shorter than the laterals, this technique would

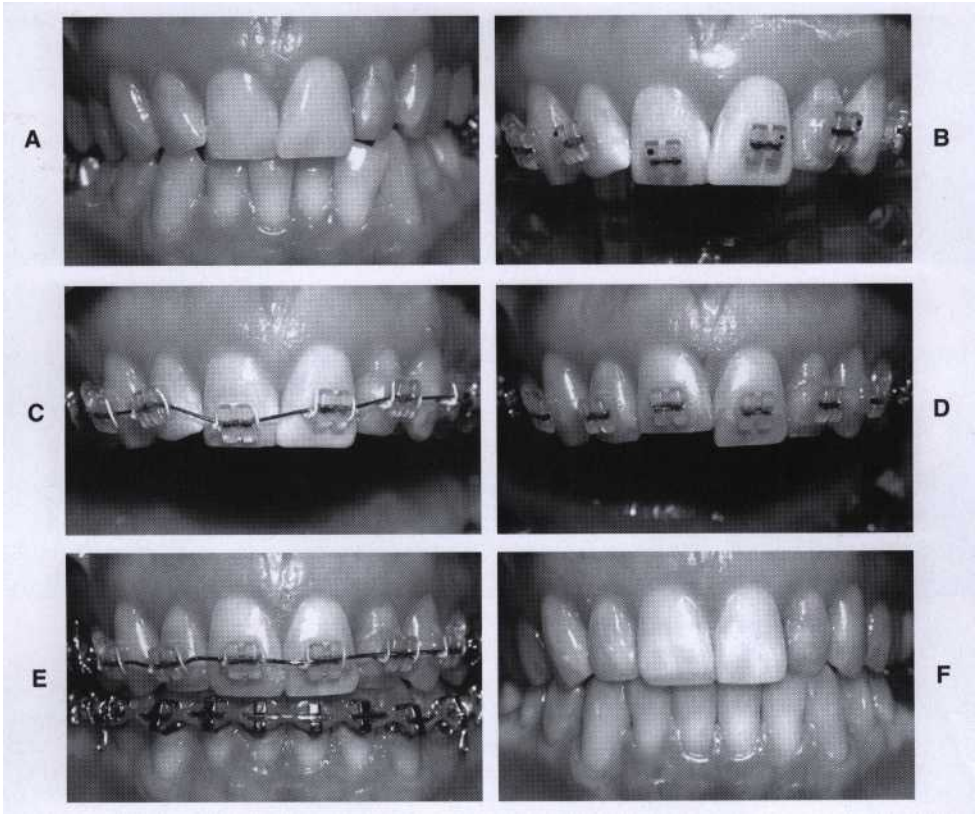

Fig. 53-12 This patient had a protrusive bruxing habit that had resulted in abrasion and overeruption of the maxillary right central incisor (A). The objective was to level the gingival margins during orthodontic therapy. Although gingival surgery was a possibility, the labial sulcular depth of the maxillary right central incisor was only 1 mm, and the CEJ was located at the bottom of the sulcus. Therefore the best solution involved positioning the orthodontic brackets to facilitate intrusion of the right central incisor (B, C, and D). This permitted the restorative dentist to restore the portion of the tooth that the patient had abraded (E), resulting in the correct gingival margin levels and crown lengths at the end of treatment (F).

produce an unaesthetic relationship between the gingival margins of the central and lateral incisors.

The fourth step is to determine whether the incisal edges have been abraded. This is best accomplished by evaluating the teeth from an incisal perspective. If one inaisal edge is thicker labiolingually than the adjacent tooth, this may indicate that it has been abraded and the tooth has overerupted. In such cases, the best method of correcting the gingival margin discrepancy is to intrude the short central incisor (see Fig. *53-12).* This method moves the gingival margin apically and permits restoration of the incisal edges .3,6,8-10 The intrusion should be accomplished at least 6 months before appliance removal. This allows reorientation of the principal fibers of the periodontium and avoids reextrusion of the central incisor(s) after appliance removal.

Significant Abrasion and Overeruption

Occasionally, patients have destructive dental habits such as a protrusive bruxing habit that could result in significant wear of the maxillary and mandibular incisors and compensatory overeruption of these teeth (Fig. *53-13).* The restoration of these abraded teeth is often impossible because of the lack of crown length to achieve adequate retention and resistance form for the crown preparations. Two options are available. One option is extensive crown lengthening by elevating a flap, removing sufficient bone, and apically positioning the flap to expose adequate tooth length for crown preparation. However, this type of procedure is contraindicated in the patient with short tapered roots because it could adversely affect the final root to crown ratio and potentially open gingival embrasures between the anterior teeth.

The other option for improving the restorability of these short abraded teeth is to orthodontically intrude the teeth and move the gingival margins apically (see Fig. *53-13).* It is possible to intrude up to four maxillary incisors by using the posterior teeth as anchorage during the intrusion process. This process is accomplished by placing the orthodontic brackets as close to the incisal edges of the maxillary incisors as possible. The brackets are placed in their normal position on the canines and remaining posterior teeth. The patient's posterior occlusion resists the eruption of the posterior teeth, and the incisors gradually intrude and move the gingival margins and the crowns apically. This creates the restorative space necessary to temporarily restore the incisal edges of these teeth and then eventually place the final crowns.

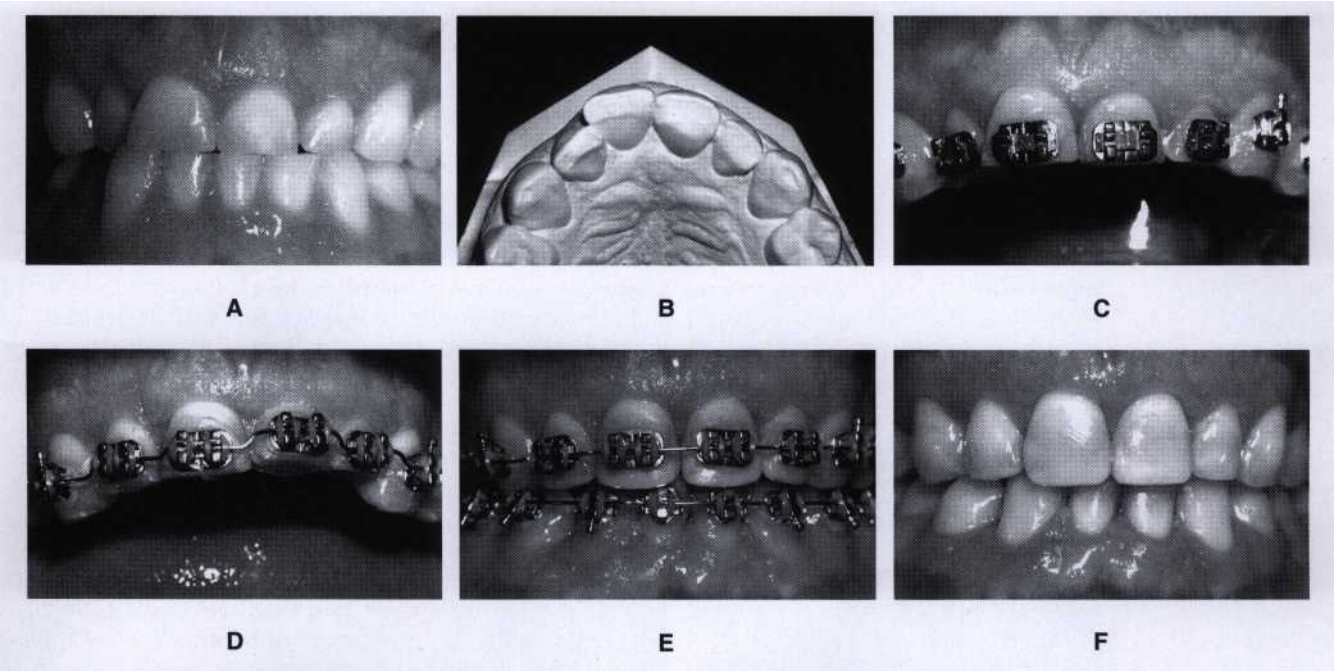

Fig. 53-13 This patient had a protrusive bruxing habit that had caused severe abrasion of the maxillary anterior teeth, resulting in the loss of over half of the crown length of the incisors (A and B). Two possible options existed for gaining crown length to restore the incisors. One possibility was an apically positioned flap with osseous recontouring, which would expose the roots of the teeth. The less destructive option was to intrude the four incisors orthodontically, level the gingival margins (C and D), and allow the dentist to restore the abraded incisal edges (E and F). The orthodontic option was clearly successful and desirable in this patient.

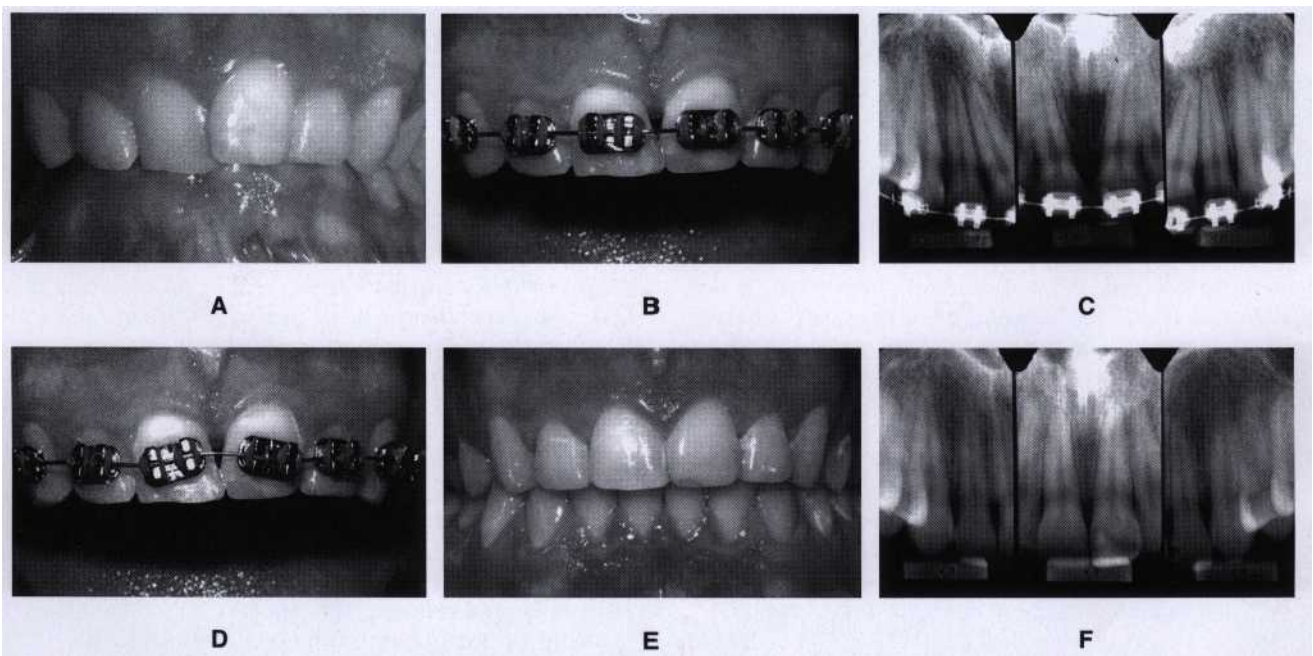

Fig. 53-14 This patient initially had overlapped maxillary central incisors (A), and after initial orthodontic alignment of the teeth, an open gingival embrasure appeared between the centrals (B). A radiograph showed that the open embrasure was caused by divergence of the central incisor roots (C). To correct the problem, the central incisor brackets were repositioned (D), and the roots were moved together. This required restoration of the incisal edges after orthodontics (E) because these teeth had worn unevenly before orthodontic therapy. As the roots were paralleled (F), the tooth contact moved gingivally and the papilla moved incisally, resulting in the elimination of the open gingival embrasure.

When abraded teeth are significantly intruded, it is necessary to hold these teeth for at least 6 months in the intruded position with either the orthodontic brackets, archwires, or both, or some type of bonded retainer. The principal fibers of the periodontium must accommodate to the new intruded position, a process that could take a minimum of 6 months in most adult patients. Orthodontic intrusion of severely abraded and overerupted teeth is usually a distinct advantage over periodontal crown lengthening unless the patient has extremely long and broad roots or has had extensive horizontal periodontal bone loss.

Open Gingival Embrasures

The presence of a papilla between the maxillary central incisors is a key esthetic factor in any individual. Occasionally, adults have open gingival embrasures or lack gingival papillae between their central incisors. These unaesthetic areas are often difficult to resolve with periodontal therapy. However, orthodontic treatment can correct many of these open gingival embrasures. This open space is usually due to one of three causes: tooth shape, root angulation, or periodontal bone loss.'

The interproximal contact between the maxillary central incisors consists of two parts. One portion is the tooth contact, and the other is the papilla. The ratio of papilla to contact is 1:1. Half of the space is occupied by papilla, and half is formed by the tooth contact. If the patient has an open embrasure, the first aspect that must be evaluated is whether the problem is due to the papilla or the tooth contact. If the papilla is the problem, then the cause is usually a lack of bone support due to an underlying periodontal problem.

In some situations, a deficient papilla can be improved with orthodontic treatment. By closing open contacts, the interproximal gingiva can be squeezed and moved incisally. This type of movement may help create a more esthetic papilla between two teeth despite alveolar bone loss. Another possibility is to erupt adjacent teeth when the interproximal bone level is positioned apically.

Most open embrasures between the central incisors are due to problems with tooth contact. The first step in the diagnosis of this problem is to evaluate a periapical radiograph of the central incisors. If the root angulation is divergent, then the brackets should be repositioned so the root position can be corrected (Fig. 53-14). In these situations, the incisal edges may be uneven and require restoration with either composite or porcelain restorations. If the periapical radiograph shows that the roots are in their correct relationship, then the open gingival embrasure is due to a triangular tooth shape (Fig. 53-15).

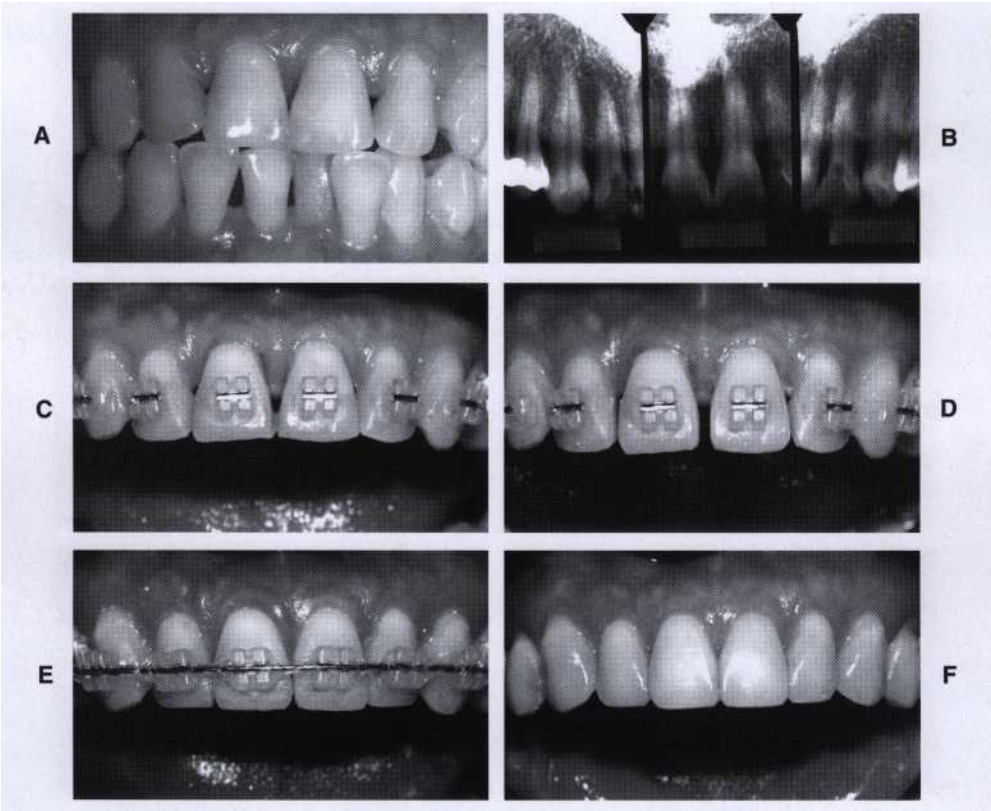

Fig. 53-15 This patient initially had triangular-shaped central incisors (A and B), which produced an open gingival embrasure after orthodontic alignment (C). Because the roots of the central incisors were parallel with one another, the appropriate solution for the open gingival embrasure was to recontour the mesial surfaces of the central incisors (D). As the diastema was closed (E), the tooth contact moved gingivally and the papilla moved incisally, resulting in the elimination of the open gingival embrasure (F).

If the shape of the tooth is the problem, two solutions are possible. One possibility is to restore the open gingival embrasure. The other option is to reshape the tooth by flattening the incisal contact and closing the space (see Fig. 53-15). This results in lengthening of the contact until it meets the papilla. In addition, if the embrasure space is large, closing the space squeezes the papilla between the central incisors. This helps create a 1:1 ratio between the contact and papilla and restores uniformity to the heights between the midline and adjacent papillae.

SUMMARY

This chapter has discussed and illustrated the benefits of integrating orthodontics and periodontics in the management of adult patients with underlying periodontal defects. The key to treating these types of patients is communication and proper diagnosis before orthodontic therapy as well as continued dialogue during orthodontic treatment. Not all periodontal problems are treated in the same way. This chapter has provided a framework for the integration of orthodontics to solve periodontal problems.

METHODS OF POCKET THERAPY
Criteria for Method Selection

Although in a strict sense, all instrumental therapy can be considered surgical, this chapter refers only to those techniques that include the intentional severing or incising of gingival tissue* with the following purposes:

- Controlling or eliminating periodontal disease.
- Correcting anatomic conditions that may favor periodontal disease, impair esthetics, or impede the placement of correct prosthetics.
- Placing implants to replace lost teeth and improving the environment for their placement and function.

* **Scaling and root planing are not included because these procedures do not *intentionally* act on the gingival tissue.**

OBJECTIVES OF THE SURGICAL PHASE

The surgical phase of periodontal therapy seeks the following:

1. Improvement of the prognosis of teeth and their replacements.
2. Improvement of esthetics.

The surgical phase consists of techniques performed for pocket therapy and for the correction of related morphologic problems, namely mucogingival defects. In many cases, procedures are combined so that one surgical intervention fulfills both objectives.

The purpose of surgical pocket therapy is to eliminate the pathologic changes in the pocket walls; to create a stable, easily maintainable state; and, if possible, to promote periodontal regeneration. To fulfill these objectives, surgical techniques 1) increase accessibility to the

BOX 54-1

Periodontal Surgery

Pocket Reduction Surgery

Resective (gingivectomy, apically displaced flap and undisplaced flap with or without osseous resection)

Regenerative (flaps with grafts, membranes, etc.)

Correction of Anatomic/Morphologic Defects

Plastic surgery techniques to widen attached gingiva (free gingival grafts, and other techniques, etc.)

Esthetic surgery (root coverage, re-creation of gingival papillae)

Preprosthetic techniques (crown lengthening, ridge augmentation, vestibular deepening)

Placement of dental implants, including techniques for site development for implants (guided bone regeneration, sinus grafts)

root surface, making it possible to remove all irritants; 2) reduce or eliminate pocket depth, making it possible for the patient to maintain the root surfaces free of plaque; and 3) reshape soft and hard tissues to attain a harmonious topography. Pocket reduction surgery seeks to reduce pocket depth by either resective or regenerative means or often by a combination of both methods. Chapters 60 to 64 describe the different techniques used for these purposes.

The second objective of the surgical phase of periodontal therapy is the correction of anatomic morphologic defects that may favor plaque accumulation and pocket recurrence or impair esthetics. It is important to understand that these procedures are not directed to treat disease but aim to alter the gingival and mucosal tissues to correct defects that may predispose to disease. They are performed on noninflamed tissues and in the absence of periodontal pockets.

Three types of techniques fall into this category: the *plastic surgery techniques* used to create or widen the attached gingiva by placing grafts of various types, the *esthetic surgery techniques* used to cover denuded roots and to recreate lost papillae, and the *preprosthetic techniques,* the purpose of which is the adaptation of the periodontal and neighboring tissues to receive prosthetic replacements and which include crown lengthening, ridge augmentation, and vestibular deepening. The plastic and esthetic surgery techniques are presented in Chapter 66 and the preprosthetic techniques in Chapter 74.

In addition, periodontal surgical techniques for the placement of dental implants are available. These involve not only the implant placement techniques but also a variety of surgical procedures to adapt the neighboring tissues, such as the sinus floor or the mandibular nerve canal, for subsequent placement of the implant (Box 54-1). These methods are discusssed in Chapters 70 and 71.

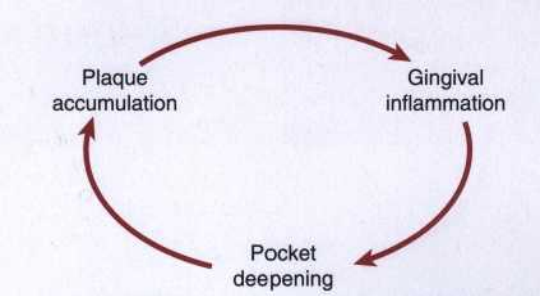

Fig. 54-1 Accumulation of plaque leads to gingival inflammation and pocket deepening, which in turn increases the area of plaque accumulation.

Surgical Pocket Therapy

Surgical pocket therapy can be directed toward 1) access surgery to ensure the removal of irritants from the tooth surface or 2) elimination, or reduction of the depth of, the periodontal pocket.

The effectiveness of periodontal therapy is predicated on success in completely eliminating calculus, plaque, and diseased cementum from the tooth surface. Numerous investigations have shown that the difficulty of this task increases as the pocket becomes deeper. The presence of irregularities on the root surface also increase the difficulty of the procedure. As the pocket gets deeper, the surface to be scaled increases, more irregularities appear on the root surface, and accessibility is impaired" , "; the presence of furcation involvements sometimes creates insurmountable problems (see Chapter 64).

All these problems can be reduced by resecting or displacing the soft tissue wall of the pocket, thereby increasing the visibility and accessibility of the root surface.3 The flap approach and the gingivectomy technique attain this result.

The need to eliminate or reduce the depth of the pocket is another important consideration. Pocket elimination consists of reducing the depth of periodontal pockets to that of a physiologic sulcus to enable cleansing by the patient. By proper case selection, both resective techniques and regenerative techniques can be used to accomplish this goal. The presence of a pocket produces areas that are impossible for the patient to keep clean, and therefore the vicious circle depicted in Fig. 54-1 is established.

Results of Pocket Therapy

A periodontal pocket can be in an active state or a period of inactivity or quiescence. An active pocket is one under which bone is being lost (Fig. 54-2, top *left).* It often can be diagnosed clinically by bleeding, either spontaneously or on probing. After Phase I therapy, the inflammatory changes in the pocket wall subside, rendering the pocket inactive and reducing its depth (see Fig. 54-2, *top center).* The extent of this reduction depends on the depth before treatment and the degree to which the depth is the result of the edematous and inflammatory component of the pocket wall.

Whether the pocket remains inactive depends on its depth and the individual characteristics of the plaque components and the host response. Recurrence of the initial activity is likely.

Inactive pockets can sometimes heal with a long junctional epithelium (see Fig. 54-2, *top right).* However, this condition also may be unstable, and the chance of recurrence and reformation of the original pocket is always present because the epithelial union to the tooth is weak. However, one study in monkeys has shown that the long junctional epithelial union may be as resistant to plaque infection as a normal connective tissue attachment.

Studies have shown that inactive pockets can be maintained for long periods with little loss of attachment by means of frequent scaling and root planing procedures. A more reliable and stable result is obtained, however, by transforming the pocket into a healthy sulcus. The bottom of the healthy sulcus can be located either where the bottom of the pocket was localized or coronal to it. In the first case, there is no gain of attachment (see Fig. 54-2, *bottom left)* and the area of the root that was previously the tooth wall of the pocket becomes exposed. This does not mean that the periodontal treatment has caused recession, but rather that it has uncovered the recession previously induced by the disease.

The healthy sulcus can also be located coronal to the bottom of the preexistent pocket (Fig. 54-2, *bottom center* and *right).* This is conducive to a restored marginal periodontium; the result is a sulcus of normal depth with gain of attachment. The creation of a healthy sulcus and a restored periodontium is termed *regeneration* and entails a total restoration of the status that existed before periodontal disease began. This is, of course, the ideal result of treatment.

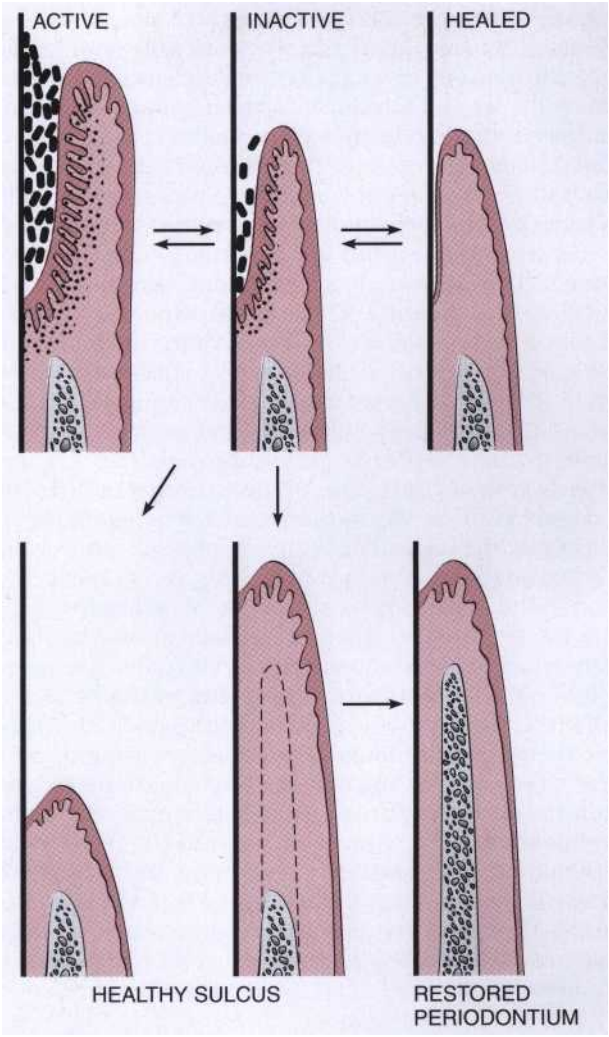

Fig. 54-2 Possible results of pocket therapy. An active pocket can become inactive and heal by means of a long junctional epithelium. Surgical pocket therapy can result in a healthy sulcus, with or without gain of attachment. Improved gingival attachment promotes restoration of bone height, with reformation of periodontal ligament fibers and layers of cementum.

POCKET ELIMINATION VERSUS POCKET MAINTENANCE

Pocket elimination (depth reduction to gingival sulcus levels) has traditionally been considered one of the main goals of periodontal therapy. It was considered vital because of the need to improve accessibility to root surfaces for the therapist during treatment and for the patient after healing. It is now the prevalent opinion that while in general the presence of deep pockets after therapy represents a greater risk of disease progression than shallow sites, individual probing depths per se are not good predictors of future clinical attachment loss.' The absence of deep pockets in treated patients is, on the other hand, an excellent predictor of a stable periodontium.

Longitudinal studies of different therapeutic modalities, carried out in the last quarter century, have given somewhat conflicting results, [7,16] probably because of inherent problems created by the "split-mouth" design. In general, however, after surgical therapy, pockets that rebound to a shallow or moderate depth can be maintained in a healthy state and without radiographic evidence of advancing bone loss by maintenance visits consisting of scaling and root planing, with oral hygiene reinforcement performed at regular intervals of not more than 3 months. In these cases the residual pocket can be examined with a thin periodontal probe, but no pain, exudate, or bleeding results; this appears to indicate that no plaque has formed on the subgingival root surfaces.

These findings do not alter the indications for periodontal surgery because the results obtained are based on surgical exposure of the root surfaces for a thorough and complete elimination of irritants. They do, however, emphasize the importance of the maintenance phase and the close monitoring of both level of attachment and pocket depth, together with the other clinical variables (bleeding, exudation, and tooth mobility). *The transformation of the initial deep, active pocket into a shallower, inactive, maintainable one requires some form of definitive pocket therapy and constant supervision thereafter.*

Pocket depth is an extremely useful and widely employed clinical determination, but it must be evaluated

together with level of attachment and the presence of bleeding, exudation, and pain. The most important variable for evaluating whether a pocket (or deep sulcus) is progressive is the level of attachment, which is measured in millimeters from the cementoenamel junction; it is the apical displacement of the level of attachment that places the tooth in jeopardy, not the increase in pocket depth, which may be due to coronal displacement of the gingival margin.

Pocket depth remains an important clinical variable on which decisions about treatment selection can be based in part. Lindhe and colleagues compared the effect of root planing alone and in conjunction with a modified Widman flap on the resultant level of attachment and in relation to initial pocket depth.' They reported that scaling and root planing procedures induce loss of attachment if performed in pockets shallower than *2.9* mm, whereas gain of attachment occurs in deeper pockets. The modified Widman flap induces loss of attachment if done in pockets shallower than 4.2 mm but results in a greater gain of attachment than root planing in pockets deeper than 4.2 mm. The loss is a true loss of connective tissue attachment, whereas the gain can be considered a false gain owing to reduced penetrability of connective tissues apical to the bottom of the pocket after treatment.[9,17]

Furthermore, probing depths established following active therapy and healing (approximately 6 months after treatment) can be maintained unchanged or reduced even further during a maintenance care period involving careful prophylaxis once every 3 months.'

Ramfjord and associates and Rosling and colleagues[13] showed that, regardless of the surgical technique used for pocket therapy, a certain pocket depth recurs. *Therefore maintenance of this depth without any further loss of attachment becomes the goal.*

REEVALUATION AFTER PHASE I THERAPY

The longitudinal studies mentioned previouslys have noted that all patients should be treated initially with scaling and root planing and that a final decision on the need for periodontal surgery should be made only after a thorough evaluation of the effects of Phase I therapy. The assessment is generally made no less than 1 to 3 months and sometimes as much as *9* months after the completion of Phase I therapy.' This reevaluation of the periodontal condition should include reprobing the entire mouth, with rechecking for the presence of calculus, root caries, defective restorations, and all signs of persistent inflammation.

CRITICAL ZONES IN POCKET SURGERY

Criteria for the selection of one of the different surgical techniques for pocket therapy are based on clinical findings in the soft tissue pocket wall, tooth surface, underlying bone, and attached gingiva.

Zone 1: The Soft Tissue Wall

The morphologic features, thickness, and topography of the soft tissue pocket wall and persistence of inflammatory changes in it should be determined.

Zone 2: The Tooth Surface

The presence of deposits and alterations on **the cementum surface and the accessibility** of the root surface to instrumentation should be identified. Phase I therapy should have solved many, if not all, of the problems on the tooth surface. Evaluation of the results of Phase I therapy should determine the need for further therapy and the method to be used.

Zone 3: The Bone

The shape and height of the alveolar bone next to the pocket wall should be established by careful probing and clinicoradiographic examination. Bony craters, horizontal or angular bone losses, and other bone deformities are important criteria for the selection of the treatment technique.

Zone 4: The Attached Gingiva

The presence or absence of an adequate band of attached gingiva is a factor to be considered when selecting the pocket treatment method. Diagnostic techniques for mucogingival problems are described in Chapter 66. An inadequate attached gingiva may be due to a high frenum attachment, marked gingival recession, or a deep pocket that reaches the level of the mucogingival junction. All of these possible conditions should be explored and their influence on pocket therapy determined.

INDICATIONS FOR PERIODONTAL SURGERY

The following findings may indicate the need for a surgical phase of therapy:

1. Areas with irregular bony contours, deep craters, and other defects usually require a surgical approach.
2. Pockets on teeth in which a complete removal of root irritants is not considered clinically possible may call for surgery. This occurs frequently in molar and premolar areas.
3. In cases of furcation involvement of Grade II or III, a surgical approach ensures the removal of irritants; any necessary root resection or hemisection also requires surgical intervention.
4. Intrabony pockets on distal areas of last molars, frequently complicated by mucogingival problems, are usually unresponsive to nonsurgical methods.
5. Persistent inflammation in areas with moderate to deep pockets may require a surgical approach. In areas with shallow pockets or normal sulci, persistent inflammation may point to the presence of a mucogingival problem that needs a surgical solution.

METHODS OF POCKET THERAPY

The methods for pocket therapy can be classified under three main headings:

1. New attachment techniques offer the ideal result because they eliminate pocket depth by reuniting the gingiva to the tooth at a position coronal to the bottom of the preexisting pocket. New attachment is

usually associated with filling in of bone and regeneration of periodontal ligament and cementum.

2. Removal of the pocket wall is the most common method. The wall of the pocket consists of soft tissue and may also include bone in the case of intrabony pockets. It can be removed by the following:
   - Retraction or shrinkage, in which scaling and root planing procedures resolve the inflammatory process and the gingiva therefore shrinks, reducing the pocket depth.
   - Surgical removal performed by the gingivectomy technique or by means of an undisplaced flap.
   - Apical displacement with an apically displaced flap.
3. Removal of the tooth side of the pocket, which is accomplished by tooth extraction or by partial tooth extraction (hemisection or root resection).

The techniques, what they accomplish, and the factors governing their selection are presented in Chapters 58 to 64.

Criteria for Method Selection

Scientific criteria to establish the indications for each technique are difficult to determine. Longitudinal studies following a significant number of cases over a number of years, standardizing multiple factors and many variables, would be needed. Clinical experience, however, has suggested the criteria for selecting the method to be used to treat the pocket in individual cases. The selection of a technique for treatment of a particular periodontal lesion is based on a number of considerations.

1. Characteristics of the pocket: depth, relation to bone, and configuration.
2. Accessibility to instrumentation, including presence of furcation involvements.
3. Existence of mucogingival problems.
4. Response to Phase I therapy.
5. Patient cooperation, including ability to perform effective oral hygiene and, for smokers, willingness to stop their habit at least temporarily (i.e., a few weeks).
6. Age and general health of the patient.
7. Overall diagnosis of the case: various types of gingival enlargement and types of periodontitis (chronic marginal periodontitis, localized aggressive periodontitis, generalized aggressive periodontitis, and so forth).
8. Esthetic considerations.
9. Previous periodontal treatments.

Each of these variables is analyzed in relation to the pocket therapy techniques available, and a specific technique is selected. Of the many techniques, the one that would most successfully solve the problems with the fewest undesirable effects should be chosen. Clinicians who adhere to one technique to solve all problems do not use to the advantage of the patient the wide repertoire of techniques at their disposal.

Therapy for Gingival Pockets. Two factors are taken into consideration: 1) the character of the pocket wall and 2) the pocket accessibility. The pocket wall can be either edematous or fibrotic. Edematous tissue shrinks after the elimination of local factors, thereby reducing or totally eliminating pocket depth. Therefore scaling and root planing is the technique of choice in these cases.

Pockets with a fibrotic wall are not appreciably reduced in depth after scaling and root planing. They therefore are eliminated surgically. Until recently, gingivectomy was the only technique available, it solves the problem successfully, but in cases of marked gingival enlargement (e.g., severe phenytoin enlargement), it may leave a large wound that goes through a painful and prolonged healing process. In these cases, a modified flap technique can adequately solve the problem with fewer postoperative problems (see Chapter 59).

Therapy for Slight Periodontitis. In slight or incipient periodontitis, bone loss has occurred to a small degree and pockets are shallow to moderate. In these cases, a conservative approach and adequate oral hygiene generally suffice to control the disease. Incipient periodontitis occurring as recurrence in previously treated sites may require a thorough analysis of the causes for the recurrence and, on occasions, a surgical approach to correct them.

Therapy for Moderate to Severe Periodontitis in the Anterior Sector. The anterior teeth are important esthetically; therefore the techniques that induce the least amount of visual root exposure should be considered first. However, the importance of esthetics may be different for different patients, and nonelimination of the pocket may place the tooth in jeopardy. The final decision may have to be a compromise between health and esthetics, not attaining ideal results in either respect.

Anterior teeth offer some advantages to a conservative approach. First, they are all single rooted and easily accessible; second, patient's compliance and thoroughness in plaque control are easier to attain. Therefore scaling and root planing is the technique of choice for the anterior teeth.

Sometimes, however, a surgical technique may be necessary owing to the need for improved accessibility for root planing or regenerative surgery of osseous defects. The papilla preservation flap can be used for both purposes and also offers a better postoperative result with less recession and reduced soft tissue crater formation interproximally.[14] It is the first choice when a surgical approach is needed.

When the teeth are too close interproximally, the papilla preservation technique may not be feasible, and a technique that splits the papilla will have to be used. The sulcular incision flap offers good esthetic results and is the next choice.

When esthetics are not the primary consideration, the so-called modified Widman flap can be chosen. This technique uses an internal bevel incision about 1 to 2 mm from the gingival margin without thinning the flap and may result in some small recession.

In some infrequent cases, bone contouring may be needed despite the resultant root exposure. The technique of choice is the apically displaced flap with bone contouring.

Therapy for Moderate to Severe Periodontitis in the Posterior Area. Treatment for premolars and molars usually poses no esthetic problem but frequently involves difficult accessibility. Bone defects are more frequent than in the anterior sector, and root morphologic features, particularly in relation to furcations, may offer unsurmountable problems for instrumentation in a close field. Therefore surgery is frequently indicated in this region.

The purpose of surgery in the posterior area is either enhanced accessibility or the need for definitive pocket reduction requiring osseous surgery. Accessibility can be obtained by either the undisplaced or apically displaced flap.

Most cases of moderate to severe periodontitis have developed osseous defects that require some degree of osseous remodeling or regenerative procedures. When osseous defects amenable to regeneration are present, the papilla preservation flap is the technique of choice because it better protects the interproximal areas where defects are frequently present. Second and third choices are the sulcular flap and the modified Widman flap, maintaining as much of the papilla as possible.

When osseous defects with no possibility of reconstruction, such as interdental craters, are present, the technique of choice is the flap with osseous contouring.

Surgical Techniques for Correction of Morphologic Defects. The objectives and rationale for the techniques performed to correct morphologic defects (mucogingival, esthetic and preprosthetic) are given in Chapter 66.

Surgical Techniques for Implant Placement and Related Problems. The objectives and rationale for these techniques are described in Chapter 70.

HOSPITAL PERIODONTAL SURGERY
- **Indications**
- **The Operation**
- **Postoperative Instructions**

All surgical procedures should be very carefully planned. The patient should be adequately prepared medically, psychologically, and practically for all aspects of the intervention. This chapter covers the preparation of the patient and the general considerations common to all periodontal surgical techniques. Complications that may occur during or after surgery are also discussed.

Surgical periodontal procedures are usually performed in the dental office. Hospital periodontal surgery is discussed at the end of this chapter.

OUTPATIENT SURGERY

Preparation of the Patient

Reevaluation after Phase I Therapy. Almost every patient undergoes the so-called initial or preparatory phase of therapy, which basically consists of thorough scaling and root planing and removing all irritants responsible for the periodontal inflammation. These procedures 1) eliminate some lesions entirely, 2) render the tissues more firm and consistent, thus permitting a more accurate and delicate surgery; and 3) acquaint the patient with the office and the operator and assistants, thereby reducing the patient's apprehension and fear.

The reevaluation phase consists of reprobing and reexamining all the pertinent findings that previously indicated the need for the surgical procedure. Persistence of these findings confirms the indication for surgery. The number of surgical procedures, expected outcome, and postoperative care necessary are all decided beforehand. These are discussed with the patient and a final decision is made, incorporating any necessary adjustments to the original plan.

Premeditation." For patients who are not medically compromised, the value of administering antibiotics routinely for periodontal surgery has not been

* **Precautions to be taken with medically compromised patients can be found in Chapter 38.**

clearly demonstrated,[27] although some studies have reported reduced postoperative complications including reduced pain and swelling when antibiotics are given before periodontal surgery and continuing for 4 to 7 days after surgery.[4,12,20,10]

The prophylactic use of antibiotics in patients who are otherwise healthy has been advocated for bone-grafting procedures and has been claimed to enhance the chances of new attachment. Although the rationale for such use appears logical, no research evidence is available to support it. In any case, the risks inherent in the administration of antibiotics should be evaluated together with the potential benefits.

Other presurgical medications include administration of a nonsteroidal, antiinflammatory drug such as ibuprofen (Motrin) 1 hour before the procedure and one oral rinse with *0.12%* chlorhexidine gluconate (Peridex or PerioGard).

Smoking. The deleterious effect of smoking on healing of periodontal wounds has been amply documented (see also Chapter 14). Patients should be clearly informed of this fact and requested to quit or stop smoking for a minimum of 3 to 4 weeks after the procedure. For patients who are unwilling to follow this advice, an alternate treatment plan not including highly sophisticated techniques such as regenerative procedures and mucogingival and esthetic techniques should be considered.

Informed Consent. The patient should be informed at the time of the initial visit about the diagnosis, prognosis, the different possible treatments with their expected results, and all pros and cons of each approach. At the time of surgery, the patient should again be informed, verbally and in writing, of the procedure to be performed, and he or she should indicate agreement by signing the consent form.

Emergency Equipment

The operator, all assistants, and office personnel should be trained to handle all the possible emergencies that may arise. Drugs and equipment for emergency use should be readily available at all times.

The most common emergency is *syncope* or a transient loss of consciousness due to a reduction in cerebral blood flow. The most common cause is fear and anxiety. Syncope is usually preceded by a feeling of weakness, and then the patient develops pallor, sweating, coldness of the extremities, dizziness, and slowing of the pulse. The patient should be placed in a supine position with the legs elevated; tight clothes should be loosened, and a wide-open airway ensured. Administration of oxygen is also useful. Unconsciousness persists for a few minutes. A history of previous syncopal attacks during dental appointments should be explored before treatment is begun, and, if these are reported, extra efforts to relieve the patient's fear and anxiety should be made. The reader is referred to other texts' for a complete analysis of this important topic.

Measures to Prevent Transmission of Infection

In recent years, the danger of transmitting infections to the dental team or other patients has become apparent, particularly with the threat of acquired immune deficiency syndrome (AIDS) and hepatitis B. Universal precautions, including protective attire, and barrier techniques are strongly recommended and often required by law. They include the use of disposable sterile gloves, surgical masks, and protective eyewear. All surfaces possibly contaminated with blood or saliva that cannot be sterilized (such as light handles and unit syringes) must be covered with aluminum foil or plastic wrap. Aerosol-producing devices, such as the Cavitron, should not be used on patients with suspected infections, and their use should be kept to a minimum in all other patients. Special care should be taken when using and disposing of sharp items such as needles and scalpel blades.

Sedation and Anesthesia

Periodontal surgery should be performed painlessly. The patient should be assured of this at the outset and throughout the procedure. The most reliable means of providing painless surgery is the effective administration of local anesthesia. The area to be treated should be thoroughly anesthetized by means of regional block and local infiltration injections. Injections directly into the interdental papillae may also be helpful.

Apprehensive and neurotic patients require special management with antianxiety or sedative hypnotic agents. Modalities for the administration of these agents include inhalation, oral, intramuscular, and intravenous routes. The specific agents and modality of administration selected is based on the desired level of sedation, anticipated length of the procedure, and overall condition of the patient. Specifically, the medical history and physical and emotional status of the patient should be taken into consideration when selecting agents and techniques to be employed.

Perhaps the simplest, least invasive method to alleviate anxiety in the dental office is nitrous oxide and oxygen inhalation sedation. For many individuals, this is quite effective. Advantages include a quick onset of action, the ability to adjust the level of sedation throughout the procedure, a rapid recovery, and little or no concern for postoperative impairment of sensory or motor function. Disadvantages are few. A small percentage of patients will not achieve the desired effect. This is especially true for the mentally impaired individual because nitrous oxide and oxygen sedation requires some level of patient cooperation. Overall, inhalation sedation with nitrous oxide and oxygen is a safe, effective and reliable means of reducing mild anxiety.

For individuals with mild to moderate anxiety, oral administration of a benzodiazepine can be effective in decreasing anxiety and producing a level of relaxation. Oral administration of a sedative agent can be more effective than inhalation anesthesia because the level of sedation achieved may be more profound. Disadvantages of oral sedative administration include incomplete recovery, an

inability to control the level of sedation, and a prolonged period of impaired sensory and motor skills. A variety of benzodiazepine agents are available for oral administration. See Table 55-1 for a brief description of commonly used benzodiazepine agents, including dosage, onset of action, and duration of effect (half-life).

Intravenous (IV) administration of a benzodiazepine, alone or in combination with other agents, can be used to achieve a greater level of sedation in individuals with moderate to severe levels of anxiety. Furthermore, the onset of action of intravenous sedation is almost immediate and the level of sedation can be titrated, on an individual basis, to the desired effect. The recovery period depends on the half-life of the agent used and the amount given. The operator should receive formal training in the techniques of sedation; this often is required by law. A thorough understanding of the indications, contraindications, and risks of these agents is required .[3] The reader is referred to other texts for a more detailed discussion of conscious sedation techniques .[25]

Tissue Management

1. *Operate gently and carefully*. In addition to being most considerate to the patient, this is also the most effective way to operate. Tissue manipulation should be precise, deliberate, and gentle. Thoroughness is essential, but roughness must be avoided because it produces excessive tissue injury, causes postoperative discomfort, and delays healing.
2. *Observe the patient at all times.* It is essential to pay careful attention to the patient's reactions. Facial expressions, pallor, and perspiration are some distinct signs that may indicate the patient is experiencing pain, anxiety, or fear. The doctor's responsiveness to these signs can be the difference between success and failure.
3. *Be certain the instruments are sharp.* Instruments must be sharp to be effective; successful treatment is not possible without sharp instruments. Dull instruments inflict unnecessary trauma due to poor cutting and excessive force applied to compensate for their ineffectiveness. A sterile sharpening stone should be available on the operating table at all times.

Scaling and Root Planing

Although scaling and root planing has been performed previously as part of Phase I therapy, all exposed root surfaces should be carefully explored and planed as needed as part of the surgical procedure. In particular, areas of difficult access such as furcations or deep pockets often have rough areas or even calculus that was undetected during the preparatory sessions. The assistant who is retracting the tissues and using the aspirator should also check for the presence of calculus and the smoothness of each surface from a different angle.

Hemostasis

Hemostasis is an important aspect of periodontal surgery because good intraoperative control of bleeding permits an accurate visualization of the extent of disease, pattern of bone destruction, and anatomy and condition of the root surfaces. It provides the operator with a clear view of the surgical site, which is essential for wound debridement and scaling and root planing. In addition, good hemostasis also prevents excessive loss of blood into the mouth, oropharynx, and stomach.

Periodontal surgery can produce profuse bleeding, especially during the initial incisions and flap reflection. After flap reflection and removal of granulation tissue, bleeding disappears or is considerably reduced. Typically, control of intraoperative bleeding can be managed with aspiration. Continuous suctioning of the surgical site with an aspirator is indispensable for performing periodontal surgery. Application of pressure to the surgical wound with moist gauze can be a helpful adjunct to control site specific bleeding. Intraoperative bleeding that is not controlled with these simple methods may indicate a more serious problem and require additional control measures.

Excessive hemorrhaging following initial incisions and flap reflection may be due to laceration of venules, arterioles, or larger vessels. Fortunately, the laceration of medium or large vessels is rare because incisions near highly vascular anatomic areas such as the posterior mandible (lingual and inferior alveolar arteries), and the posterior, mid-palatal regions (greater palatine arteries) are avoided in incision and flap design. Proper design of the flaps, taking into consideration these areas, avoids accidents (see Chapter 56). However, even when all anatomic precautions are taken, it is possible to cause bleeding from medium or large vessels because anatomic variations do occur and may result in inadvertent laceration. If a medium or large vessel is lacerated, a suture around the bleeding end may be necessary to control

TABLE 55-1

Oral Benzodiazepine Agents Commonly Used for Perioperative Antianxiety and Sedation

Generic	Proprietary	Adult Dose (mg)	Onset (Hours)	Half-Life (Hours)
Alprazolam	Xanax	0.25-0.5	1-2	12-15
Diazepam	Valium	2-10	0.5-2	30-70
Lorazepam	Ativan	1-4	1-6	10-18
Triazolam	Halcion	0.125-0.5	1-2	1.5-5.5

hemorrhage. Pressure should be applied through the tissue to determine the location that will stop blood flow in the severed vessel. Then a suture can be passed through the tissue and tied to restrict blood flow.

It is also possible to have excessive bleeding from a surgical wound due to incisions across a capillary plexus. Minor areas of persistent bleeding from capillaries can be stopped by applying cold pressure to the site with moist gauze (soaked in sterile ice water) for several minutes. The use of a local anesthetic with a vasoconstrictor may also be useful in controlling minor bleeding from the periodontal flap. Both of these methods act via vasoconstriction, thus reducing the flow of blood through incised small vessels and capillaries. This action is relatively short lived and should not be relied on for long-term hemostasis. It is important to avoid the use of vasoconstrictors to control bleeding prior to sending a patient home. If a more serious bleeding problem exists or a firm blood clot is not established, bleeding is likely to reoccur when the vasoconstrictor has metabolized and the patient is no longer in the office.

For slow, constant blood flow and oozing, hemostasis may be achieved with hemostatic agents. Table 55-2 describes available, absorbable hemostatic agents useful in the control of bleeding.

Absorbable gelatin sponge (Gelfoam), oxydized cellulose (Oxycel), oxidized regenerated cellulose (Surgicel Absorbable Hemostat), and microfibrillar collagen hemostat (Collacote, Collatape, Collaplug) are useful hemostatic agents for the control of capillaries, small blood vessels, and deep wound bleeding.

Absorbable gelatin sponge is a porous matrix prepared from pork skin that helps stabilize a normal blood clot. The sponge can be cut to the desired dimensions and either sutured in place or positioned within the wound (e.g., extraction socket). It is absorbed in 4 to 6 weeks.

Oxydized cellulose is a chemically modified form of surgical gauze that forms an artificial clot. The material is friable and can be difficult to keep in place. It absorbs in 1 to 6 weeks.

Oxydized regenerated cellulose is prepared from cellulose by reaction with alkali to form a chemically pure, more uniform structure than oxidized cellulose. The material is prepared in a cloth or thin gauze form that can be cut to the desired size and sutured or layered on the bleeding surface. It can be used as a surface dressing because it

TABLE 55-2

Absorbable Hemostatic Agents

Generic Name	Brand Name	Directions	Adverse Effects	Precautions
Absorbable gelatin sponge	Gelfoam	May be cut into various sizes and applied to bleeding surfaces.	May form nidus for infection or abscess.	Should not be overpacked into extraction site or wound-may interfere with healing.
Oxidized cellulose	Oxycel	Most effective when applied to wound dry as opposed to moistened.	May cause foreign body reaction.	Extremely friable and difficult to place; should not be used adjacent to bone-impairs bone regeneration; should not be used as a surface dressing-inhibits epithelialization.
Oxidized regenerated cellulose	Surgicel Absorbable Hemostat	May be cut to various shapes and positioned over bleeding sites; thick or excessive amounts should not be used.	Encapsulation, cyst formation, and foreign body reaction possible.	Should not be placed in deep wounds-may physically interfere with wound healing and bone formation.
Microfibrillar collagen hemostat	Collacote, Collatape, Collaplug	May be cut to shape and applied to bleeding surface.	May potentiate abscess formation, hematoma, and wound dehiscence; possible allergic reaction or foreign body reaction.	May interfere with wound healing; placement in extraction sockets has been associated with increased pain.
Thrombin	Thrombostat	May be applied topically to bleeding surface.	Allergic reaction can occur in patients with known sensitivity to bovine materials.	Must not be injected intc tissues or vasculature because it can cause severe (possibly fatal) clotting.

does not impair epithelialization, and it is bactericidal against many gram-negative and gram-positive microorganisms, both aerobic and anaerobic. Caution should be used when wounds are infected or have an increased potential to becoming infected (e.g., immunocompromised patients) because the absorbable hemostatic agents can serve as a nidus for infection.

Thrombin is a drug capable of hastening the process of blood clotting. It is intended for topical use only because is applied as a liquid or powder. Thrombin should never be injected into tissues because it can cause serious, even fatal intravascular coagulation. Also, because thrombin is a bovine-derived material, caution should be used for any patient with known allergic reaction to bovine products.

Finally, it is imperative to recognize that excessive bleeding may be due to systemic disorders, including but not limited to platelet deficiencies, coagulation defects, medications, and hypertension. As a precaution, all surgical patients should be asked about current medications that may contribute to bleeding, any family history of bleeding disorders, and hypertension. All patients, regardless of health history, should have their blood pressure evaluated prior to surgery, and anyone diagnosed with hypertension must be advised to see a physician before surgery. Patients with known or suspected bleeding deficiencies or disorders must be carefully evaluated before any surgical procedure. A consultation with the patient's physician is recommended and laboratory tests should be done to assess the risk of bleeding. It may be necessary to refer the patient to a hematologist for a comprehensive work-up.

Periodontal Dressings (Periodontal Packs)

In most cases, after the surgical periodontal procedures are completed, the area is covered with a surgical pack. In general, dressings have no curative properties; they assist healing by protecting the tissue rather than providing "healing factors." The pack minimizes the likelihood of postoperative infection and hemorrhage, facilitates healing by preventing surface trauma during mastication, and protects against pain induced by contact of the wound with food or the tongue during mastication. For a complete literature review on this subject, the reader is referred to the work by Sachs et alas

Zinc Oxide-Eugenol Packs. Packs based on the reaction of zinc oxide and eugenol include the Wondr-Pak developed by Ward in 1923 and several others that modified Ward's original formula. The addition of accelerators such as zinc acetate gives the dressing a better working time.

Zinc oxide-eugenol dressings are supplied as a liquid and a powder that are mixed prior to use. Eugenol in this type of pack may induce an allergic reaction that produces reddening of the area and burning pain in some patients.

Noneugenol Packs. The reaction between a metallic oxide and fatty acids is the basis for Coe-Pak, which is the most widely used dressing in the U.S. This is supplied in two tubes, the contents of which are mixed immediately before use until a uniform color is obtained. One tube contains zinc oxide, an oil (for plasticity), a gum (for cohesiveness), and lorothidol (a fungicide); the other tube contains liquid coconut fatty acids thickened with colophony resin (or rosin) and chlorothymol (a bacteriostatic agent). This dressing does not contain asbestos or eugenol, thereby avoiding the problems associated with these substances.

Other noneugenol packs include cyanoacrylates6.8 ,21 and tissue conditioners (methacrylate gels) .2 However, these are not commonly used.

Retention of Packs. Periodontal dressings are usually kept in place mechanically by interlocking in interdental spaces and joining the lingual and facial portions of the pack.

In isolated teeth or when several teeth in an arch are missing, retention of the pack may be difficult. Numerous reinforcements and splints and stents for this purpose have been described.[16,17,44] Placement of dental floss tied loosely around the teeth enhances retention of the pack.

Antibacterial Properties of Packs. Improved healing and patient comfort with less odor and taste' have been obtained by incorporating antibiotics in the pack. Bacitracin,5 oxytetracycline (Terramycin),13 neomycin, and nitrofurazone have been tried, but all may produce hypersensitivity reactions. The emergence of resistant organisms and opportunistic infection have been reported.

Incorporation of tetracycline powder in Coe-Pak is generally recommended, particularly when long and traumatic surgeries are performed.

Allergy. Contact allergy to eugenol and rosin has been reported .32

Preparation and Application of the Periodontal Dressing. Zinc oxide packs are mixed with eugenol or noneugenol liquids on a wax paper pad with a wooden tongue depressor. The powder is gradually incorporated with the liquid until a thick paste is formed.

Coe-Pak is prepared by mixing equal lengths of paste from tubes containing the accelerator and the base until the resulting paste is a uniform color. A capsule of tetracycline powder can be added at this time. The pack is then placed in a cup of water at room temperature. In 2 to 3 minutes, the paste loses its tackiness (Fig. 55-1) and can be handled and molded; it remains workable for 15 to 20 minutes. Working time can be shortened by adding a small amount of zinc oxide to the accelerator (pink paste) before spatulating.

The pack is then rolled into two strips approximately the length of the treated area. The end of one strip is bent into a hook shape and fitted around the distal surface of the last tooth, approaching it from the distal surface (Fig. 55-2, A). The remainder of the strip is brought forward along the facial surface to the midline and gently pressed into place along the gingival margin and interproximally. The second strip is applied from the lingual surface. It is joined to the pack at the distal surface

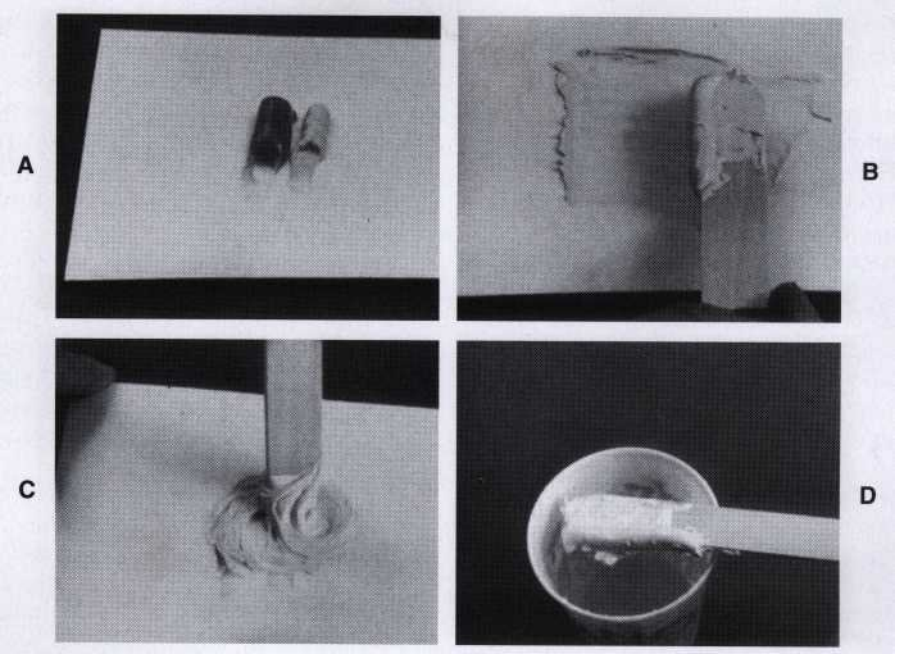

Fig. 55-1 Preparing the surgical pack (Coe-Pak). A, Equal lengths of the two pastes are placed on a paper pad. B, Pastes are mixed with a wooden tongue depressor for 2 or 3 minutes until the paste loses its tackiness (C). D, Paste is placed in a paper cup of water at room temperature. With lubricated fingers, it is then rolled into cylinders and placed on the surgical wound.

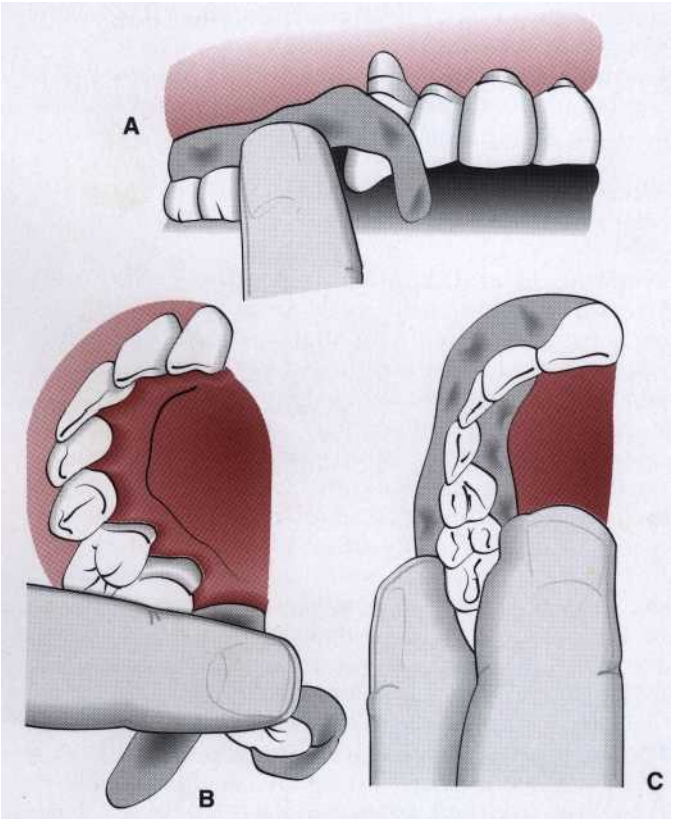

Fig. 55-2 Inserting the periodontal pack. A, A strip of pack is hooked around the last molar and pressed into place anteriorly. B, The lingual pack is joined to the facial strip at the distal surface of the last molar and fitted into place anteriorly. C, Gentle pressure on the facial and lingual surfaces joins the pack interproximally.

of the last tooth, then brought forward along the gingival margin to the midline (Fig. 55-2, B). The strips are joined interproximally by applying gentle pressure on the facial and lingual surfaces of the pack (Fig. 55-2, C. For isolated teeth separated by edentulous spaces, the pack should be made continuous from tooth to tooth, covering the edentulous areas (Fig. 55-3).

When split flaps have been performed, the area should be covered with tin foil to protect the sutures before placing the pack (see Chapter 60).

The pack should cover the gingiva, but overextensions onto uninvolved mucosa should be avoided. *Excess pack irritates the mucobuccal fold and floor of the mouth and interferes with the tongue.* Overextension also jeopardizes the remainder of the pack because the excess tends to break off, taking pack from the operated area with it. *Pack that interferes with the occlusion should be trimmed away before the patient is dismissed* (Fig. 55-4). Failure to do this causes discomfort and jeopardizes retention of the pack.

The operator should ask the patient to move the tongue forcibly out and to each side, and the cheek and lips should be displaced in all directions to mold the pack while it is still soft. After the pack has set, it should be trimmed to eliminate all excess.

As a general rule, the pack is kept on for 1 week after surgery. This guideline is based on the usual timetable of healing and clinical experience. It is not a rigid requirement; the period may be extended, or the area may be repacked for an additional week.

Fragments of the surface of the pack may come off during the week, but this presents no problem. If a portion of the pack is lost from the operated area and the

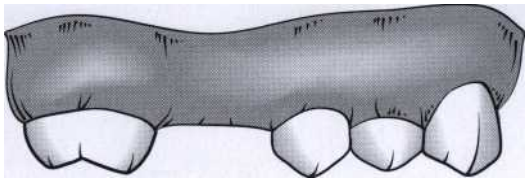

Fig. 55-3 Continuous pack covers the edentulous space.

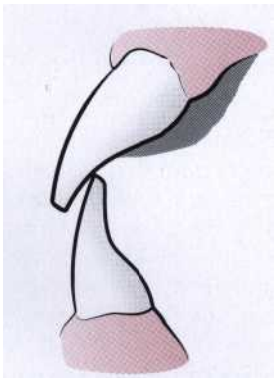

Fig. 55-4 The pack should not interfere with the occlusion.

patient is uncomfortable, it is usually best to repack the area. The clinician should remove the remaining pack, wash the area with warm water, and apply a topical anesthetic before replacing the pack, which is then retained for 1 week. Again, patients may develop pain from an overextended margin that irritates the vestibule, floor of the mouth, or tongue. The excess pack should be trimmed away, making sure that the new margin is not rough, before the patient is dismissed.

Instructions for the Patient after Surgery

After the pack is placed, printed instructions are given to the patient to be read before he or she leaves the chair (Box 55-1).

The First Postoperative Week

Properly performed, periodontal surgery presents no serious postoperative problems. Patients should be told to rinse with 0.12% chlorhexidine gluconate (Peridex, PerioGard) immediately after the surgical procedure and twice daily thereafter until normal plaque control technique can be resumed.[28-36,42] The following complications may arise in the first postoperative week, although they are the exception rather than the rule:

1. *Persistent bleeding after surgery.* The pack is removed, the bleeding points are located, and the bleeding is stopped with pressure, electrosurgery, or electrocautery. After the bleeding is stopped, the area is repacked.
2. *Sensitivity to percussion.* Sensitivity to percussion may be caused by the extension of inflammation into the periodontal ligament. The patient should be questioned regarding the progress of the symptoms. Gradually diminishing severity is a favorable sign. The pack should be removed and the gingiva checked for localized areas of infection or irritation, which should be cleaned or incised to provide drainage. Particles of calculus that may have been overlooked should be removed. Relieving the occlusion is usually helpful. Sensitivity to percussion may also be caused by excess pack, which interferes with the occlusion. Removal of the excess usually corrects the condition.
3. *Swelling.* Sometimes within the first 2 postoperative days, patients report a soft, painless swelling of the cheek in the area of operation. Lymph node enlargement may occur, and the temperature may be slightly elevated. The area of operation itself is usually symptom free. This type of involvement results from a localized inflammatory reaction to the operative procedure. It generally subsides by the fourth postoperative day, without necessitating removal of the pack. If swelling persists, becomes worse, or is associated with increased pain, then amoxyicillin, 500 mg should be taken every 8 hours for 1 week, and the patient should also be instructed to apply moist heat intermittently over the area. The antibiotic should also be used as a prophylactic measure after the next operation, starting before the surgical appointment.
4. *Feeling of weakness.* Occasionally, patients report having experienced a "washed-out," weakened feeling for about 24 hours after the operation. This represents a systemic reaction to a transient bacteremia induced by the operative procedure. It is prevented by premedication with amoxycillin, 500 mg every 8 hours, beginning 24 hours before the next operation and continuing for a 5-day postoperative period.

Removal of the Periodontal Pack and Return Visit Care

When the patient returns after 1 week, the pack is taken off by inserting a surgical hoe along the margin and exerting gentle lateral pressure. Pieces of pack retained interproximally and particles adhering to the tooth surfaces are removed with scalers. Particles may be enmeshed in the cut surface and should be carefully picked off with fine cotton pliers. The entire area is rinsed with peroxide to remove superficial debris.

Findings at Pack Removal. The following are usual when the pack is removed:

If a *gingivectomy* has been performed, the cut surface is covered with a friable meshwork of new epithelium, which should not be disturbed. If calculus has not been completely removed, red, beadlike protuberances of granulation tissue will persist. The granulation tissue must be removed with a curette, exposing the calculus so that it can be removed and the root can be planed. Removal of the granulation tissue without removal of calculus is followed by recurrence.

After a *flap operation,* the areas corresponding to the incisions are epithelialized but may bleed readily when touched; they should not be disturbed. Pockets should not be probed.

BOX 55-1

Patient Instructions after Surgery

Instructions for (Patient's Name)

The following information on your gum operation has been prepared to answer questions you may have about how to take care of your mouth. Please read the instructions carefully; our patients have found them very helpful.

Although there will be little or no discomfort when the anesthesia wears off, you should take two acetaminophen (Tylenol) tablets every 6 hours for the first 24 hours. After that, take the same medication if you have some discomfort. Do not take aspirin, as this may increase bleeding.

We have placed a periodontal pack over your gums to protect them from irritation. The pack prevents pain, aids healing, and enables you to carry on most of your usual activities in comfort. The pack will harden in a few hours, after which it can withstand most of the forces of chewing without breaking off. It may take a little while to become accustomed to it.

The pack should remain in place until it is removed in the office at the next appointment. If particles of the pack chip off during the week, do not be concerned as long as you do not have pain. If a piece of the pack breaks off and you are in pain, or if a rough edge irritates your tongue or cheek, please call the office. The problem can be easily remedied by replacing the pack.

For the first 3 hours after the operation, avoid hot foods to permit the pack to harden. It is also convenient to avoid hot liquids during the first 24 hours. You can eat anything you can manage, but try to chew on the nonoperated side of your mouth. Semisolid or finely minced foods are suggested. Avoid citrus fruits or fruit juices, highly spiced foods, and alcoholic beverages; these will cause pain. Food supplements, or vitamins are generally not necessary.

Do not smoke. The heat and smoke will irritate your gums, and the immunologic effects of nicotine will delay healing and prevent a completely successful outcome of the procedure performed. If at all possible, use this opportunity to give up smoking. In addition to all other well-known health risks, smokers have more gum disease than nonsmokers.

Do not brush over the pack. Brush and floss the areas of the mouth not covered by the pack, as normal. Use chlorhexidine (Peridex, PerioGard) mouthrinses after brushing (the prescription for this mouthrinse has been given to you).

During the first day, apply ice intermittently on the face over the operated area. It is also beneficial to suck on ice chips intermittently during the first 24 hours. These methods will keep tissues cool and reduce inflammation and swelling.

You may experience a slight feeling of weakness or chills during the first 24 hours. This should not be cause for alarm but should be reported at the next visit. Follow *your regular daily activities, but avoid excessive exertion of any type.* Golf, tennis, skiing, bowling, swimming, or sunbathing should be postponed for a few days after the operation.

Swelling is not unusual, particularly in areas that required extensive surgical procedures. The swelling generally begins 1 to 2 days after the operation and subsides gradually in 3 or 4 days. If this occurs, apply moist heat over the operated area. If the swelling is painful or appears to become worse, please call the office.

Occasional blood stains in the saliva may occur for the first 4 or 5 hours after the operation. This is not unusual and will correct itself. If there is considerable bleeding beyond this, take a piece of gauze, form it into the shape of a U, hold it in the thumb and index finger, apply it to both sides of the pack, and hold it there under pressure for 20 minutes. Do not remove it during this period to examine it. If the bleeding does not stop at the end of 20 minutes, please contact the office. *Do not try to stop bleeding by rinsing.*

After the pack is removed, the gums most likely will bleed more than they did before the operation. This is perfectly normal in the early stage of healing and will gradually subside. Do not stop cleaning because of it.

If any other problems arise, please call the office.

The facial and lingual mucosa may be covered with a grayish-yellow or white granular layer of food debris that has seeped under the pack. This is easily removed with a moist cotton pellet. The root surfaces may be sensitive to a probe or to thermal changes, and the teeth may be stained.

Fragments of calculus delay healing. Each root surface should be rechecked visually to be certain that no calculus is present. Sometimes the color of the calculus is similar to that of the root. The grooves on proximal root surfaces and the **furcations are areas in which calculus** is likely to be overlooked.

Repacking. After the pack is removed, it is usually not necessary to replace it. However, it is advisable to repack for an additional week for patients with 1) a low pain threshold who are particularly uncomfortable when the pack is removed, 2) unusually extensive periodontal involvement, or 3) slow healing. Clinical judgement helps in deciding whether to repack the area or leave the initial pack on longer than 1 week.

Tooth Mobility. Tooth mobility is increased immediately after surgery,' but it diminishes below the pretreatment level by the fourth week.24

Care of the Mouth between Periodontal Surgery Procedures

Care of the mouth by the patient between the treatment of the first and the final areas, as well as after surgery is completed, is extremely important.[45] These measures should begin after the pack is removed from the first operation. The patient has been through a presurgical period of instructed plaque control and should be reinstructed at this time.

Vigorous brushing is not feasible during the first week after the pack is removed. However, the patient is informed that plaque and food accumulation retard healing and is advised to try to keep the area as clean as possible by the gentle use of soft toothbrushes and light water irrigation. Rinsing with a chlorhexidine mouthwash or its topical application with cotton-tipped applicators (Q-tips) is indicated for the first few postoperative weeks, particularly in advanced cases. Brushing is introduced when healing of the tissues permits it; the vigor of the overall hygiene regimen is increased as healing progresses. Patients should be told that there be more gingival bleeding will most likely occur than before the operation, that it is perfectly normal and will subside as healing progresses, and that it should not deter them from following their oral hygiene regimen.

Management of Postoperative Pain

Periodontal surgery performed following the basic principles outlined here should produce only minor pain and discomfort.38 One study of 304 consecutive periodontal surgical interventions revealed that 51.3% of the patients reported minimal or no postoperative pain, and only 4.6% reported severe pain. Of these, only 20.1% took five or more doses of analgesic.11 The same study showed that mucogingival procedures result in six times more discomfort and osseous surgery in 3.5 times more discomfort than plastic gingival surgery. In the few cases in which severe pain may be present, its control then becomes an important part of patient management.27

A common source of postoperative pain is overextension of the periodontal pack onto the soft tissue beyond the mucogingival junction or onto the frena. Overextended packs cause localized areas of edema, usually noticed 1 to 2 days after surgery. Removal of excess pack is followed by resolution in about 24 hours. Extensive and excessively prolonged exposure and dryness of bone also induce severe pain.

For most healthy patients, a preoperative dose of ibuprofen (600 to 800 mg) followed by one tablet every 8 hours for 24 to 48 hours is very effective in reducing discomfort after periodontal therapy. Patients are advised to continue taking ibuprofen or change to acetaminophen if needed thereafter. If pain persists, acetaminophen plus codeine (Tylenol #3) can be prescribed.

Caution should be used in prescribing or dispensing ibuprofen to patients with hypertension controlled by medications because it can interfere with the effectiveness of the medication.

When severe postoperative pain is present, the patient should be seen at the office on an emergency basis. The area is anesthetized by infiltration or topically, the pack is removed, and the wound is examined. Postoperative pain related to infection is accompanied by localized lymphadenopathy and a slight elevation in temperature. It should be treated with systemic antibiotics and analgesics.

Treatment of Sensitive Roots. Root hypersensitivity is a relatively common problem in periodontal practice. It may occur spontaneously when the root becomes exposed as a result of gingival recession or pocket formation, or it may appear after scaling and root planing and surgical procedures.* It is manifested as pain induced by cold or hot temperature, more commonly cold; by citrus fruits or sweets; or by contact with a toothbrush or a dental instrument.

Root sensitivity occurs more frequently in the cervical area of the root, where the cementum is extremely thin. Scaling and root planing procedures remove this thin cementum, inducing the hypersensitivity.

Transmission of stimuli from the surface of the dentin to the nerve endings located in the dental pulp or in the pulpal region of the dentin could occur through the odontoblastic process or owing to a hydrodynamic mechanism (displacement of dentinal fluid). The latter process seems more likely and would explain the importance of burnishing desensitizing agents to obturate the dentinal tubule.

An important factor for reducing or eliminating hypersensitivity is adequate plaque control. However, hypersensitivity may prevent plaque control, and therefore a vicious circle of escalating hypersensitivity and plaque accumulation may be created.

* For a complete review of the literature, see Curro FA: Tooth hypersensitivity. Dent Clin North Am 1990; 34(3):403.'°

DESENSITIZING AGENTS. A number of agents have been proposed to control root hypersensitivity. Clinical evaluation of the many agents proposed is difficult because 1) measuring and comparing pain between different persons is difficult, 2) hypersensitivity disappears by itself after a time, and 3) desensitizing agents usually take a few weeks to act.

The patient should be informed about the possibility of root hypersensitivity before treatment is undertaken. The following information on how to cope with the problem should also be given to the patient:

1. Hypersensitivity appears as a result of the exposure of dentin, which is inevitable if calculus and plaque and their products, buried in the root, are to be removed.
2. Hypersensitivity slowly disappears over a few weeks.
3. Plaque control is important for the reduction of hypersensitivity.
4. Desensitizing agents do not produce immediate relief. They have to be used for several days or even weeks to produce results.

Desensitizing agents can be applied by the patient at home or by the dentist or hygienist in the dental office. The most likely mechanism of action is the reduction in the diameter of the dentinal tubules so as to limit the displacement of fluid in them. According to Trowbridge and Silver,[40] this can be attained by 1) formation of a smear layer produced by burnishing the exposed surface, 2) topical application of agents that form insoluble precipitates within the tubules, 3) impregnation of tubules with plastic resins, or 4) sealing of the tubules with plastic resins.

Agents used by the Patient. The most common agents used by the patient for oral hygiene are dentifrices. Although many dentifrice products contain fluoride, additional active ingredients for desensitization are strontium chloride, potassium nitrate and sodium citrate. The following dentifrices have been approved by the American Dental Association for desensitizing purposes: Sensodyne, and Thermodent, which contain strontium chloride Crest Sensitivity Protection, Denquel, and Promise, which contain potassium nitrate[1-9]; and Protect, which contains sodium citrate. Fluoride rinsing solutions and gels can also be used after the usual plaque control procedures.[39]

Patients should be aware that several factors must be considered in the treatment of tooth hypersensitivity, including the history and severity of the problem as well as the physical findings of the tooth or teeth involved. A proper diagnosis is required before any treatment can be initiated so that pathologic causes of pain (e.g., caries, cracked tooth, pulpitis) can be ruled out before attempting to treat hypersensitivity. Desensitizing agents act via the precipitation of crystalline salts on the dentin surface, which block dentinal tubules. Patients must be aware that their use will not prove to be effective unless used continuously for a period of at least 2 weeks.

Agents used in the Dental Office. Box 55-2 lists various office treatments for the desensitization of hypersensitive dentin. These products and treatments aim to decrease hypersensitivity via blocking dentinal tubules with either a crystalline salt precipitation or an applied coating (varnish or bonding agent) on the root surface. The reader is again referred to the Towbridge and Silver" for a more detailed consideration of these methods.

Several agents have been used to precipitate crystalline salts on the dentin surface in an attempt to occlude the dentinal tubules. Fluoride solutions and pastes historically have been the agents of choice. In addition to their antisensitivity properties, they have the advantage of anticaries activity, which is particularly important for patients with a tendency to develop root caries. However, certain agents such as chlorhexidine, decrease the ability of fluoride to bind with calcium on the root surfaces.' Thus it is important to advise patients not to rinse or eat for 1 hour after a desensitizing treatment. Currently, potassium and ferric oxalate solutions are the preferred agents. They form insoluble calcium oxalate crystals that occlude the dentinal tubules.[26,28] Potassium oxalate is available under the name *Protect* and ferric oxalate under the name *Sensodyne Sealant.* Special applicators have been developed for their use.

A newer method of treatment for hypersensitive dentin is the use of varnishes or dentin bonding agents to occlude dentinal tubules. Newer restorative materials, such as glass-ionomer cements and dentine bonding agents, are still under investigation, but when the tooth needs recontouring or difficult cases do not respond to other treatments, the dentist may choose to use a restorative material. Resin primers alone could be promising, but the effects are not permanent and investigations are ongoing.[14]

Despite some successes in decreasing dentin hypersensitivity, it is important to note that these "dental office" treatments have not been a predictable means of solving hypersensitivity and the success achieved is often short lived. The crystalline salts and/or varnishes and

  - Fluoride compounds
    - Sodium fluoride
    - Stannous fluoride
  - Iontophoresis
  - Strontium chloride
  - Potassium oxalate
- Restorative resins
- Dentin bonding agents

From Trowbridge HO, Silver DR: A review of current approaches to in-office management of tooth hypersensitivity. Dent Clin North Am 1990; 34(3):566.

sealants can be washed away over time, and hypersensitivity may return. When this occurs, patients can have sensitive root surfaces treated again.

Recently, attempts have been made to improve the success and longevity of these treatments using lasers. Low-level laser "melting" of the dentin surface appears to seal dentinal tubules without damage to the pulp. Finally, in a combined treatment modality, the Nd:YAG laser has been used to congeal fluoride varnish on root surfaces. This in vitro study demonstrated that the laser treated fluoride varnish resisted removal by electric toothbrushing, with 90% of tubules remaining blocked while in the controls (no laser treatment) the fluoride varnish was almost completely brushed away.22 Despite these convincing preliminary results, more research is needed before laser treatment can be considered an effective and predictable means of desensitization. Furthermore, laser treatment is expensive and has the potential to cause pulp damage.

HOSPITAL PERIODONTAL SURGERY

Ordinarily, periodontal surgery is an office procedure performed in quadrants or sextants, usually at biweekly or longer intervals. Under certain circumstances, however, it is in the best interest of the patient to treat the mouth in one operation with the patient treated in a hospital operating room under general anesthesia. Indications for hospital periodontal surgery include optimal control and management of apprehension, convenience for individuals who cannot endure multiple visits to complete surgical treatment, and patient protection.

Indications

The Apprehensive Patient. Gentleness, understanding, and preoperative sedation usually suffice to calm the fears of most patients. For some patients, however, the prospect of a series of surgical procedures is sufficiently stressful to trigger disturbances that jeopardize the well-being of the patient and hamper treatment. Explaining that the treatment at the hospital will be performed painlessly and that it will be accomplished by a level of anesthesia that is neither practical nor safe for patients in a dental office is an important step in allaying their fears. The thought of completing the necessary surgical procedures in one session rather than in repeated visits is an added comfort to the patient because it eliminates the prospect of repeated anxiety in anticipation of each treatment.

Patient Convenience. With complete mouth surgery, there is less stress for the patient and less time involved in postoperative care. For patients whose occupation entails considerable contact with the public, surgery performed at biweekly intervals sometimes presents a special problem. It means that for a period of several weeks, some area of the mouth will be covered by a periodontal pack. With the complete mouth technique, the pack is ordinarily retained for only 1 week. Patients find this an acceptable alternative to several weeks of discomfort in different areas of the mouth and multiple dressing applications. For a variety of other reasons, patients may desire to attend to their surgical needs in one session under optimal conditions.

Patient Protection. Some patients have systemic conditions that are not severe enough to contraindicate elective surgery but may require special precautions best provided in a hospital setting. This includes some patients with cardiovascular disease, abnormal bleeding tendencies, or hyperthyroidism; those undergoing prolonged steroid therapy; and those with a history of rheumatic fever.

The purpose o f hospitalization is to protect patients by anticipating their special needs, not to perform periodontal surgery when it is contraindicated by the patient's general condition. For some patients, elective surgery is contraindicated regardless of whether it is performed in the dental office or hospital. When consultation with the patient's physician leads to this decision, palliative periodontal therapy, in the form of scaling and root planing if permissible, is the necessary compromise.

Premedication. Patients should be given a sedative the night before surgery. Benzodiazepines work well for most patients, allowing the patient to sleep well the night before surgery. If the patient is extremely nervous about the procedure, it is also helpful to advise them to take a benzodiazepine on the morning of surgery. This ensures that they will be rested and as relaxed as possible before surgery.

Patients with systemic problems (history of rheumatic fever, cardiovascular problems, etc.) are premedicated as needed (see Chapter 38).

Anesthesia. Local or general anesthesia25 may be used. Local anesthesia is the method of choice, except for especially apprehensive patients. It permits unhampered movement of the head, which is necessary for optimal visibility and accessibility to the various root surfaces. Local anesthesia is used in the same manner as for routine periodontal surgery.

When general anesthesia is indicated, it is administered by an anesthesiologist. It is important that the patient also receive local anesthesia, administered as for routine periodontal surgery, to ensure comfort for the patient and reduced bleeding during the procedure. The judicious use of local anesthetics to block regional nerves allows the level of sedation or general anesthesia to be lighter. Hence the entire operation is performed with a wider margin of safety.

The Operation

Surgery in the operating room is performed on the operating table with the patient lying down and the table either positioned flat or with the head inclined up to 30 degrees. Some operating rooms are equipped with dental chairs that can be used either flat or up to 30 degrees. When general anesthesia is used, it is advisable to delay placing the periodontal dressing until the patient has recovered sufficiently to have a demonstrable cough reflex. Periodontal dressings placed before the end of general

anesthesia can be displaced during the recovery period and pose serious risks of blocking the airway.

Postoperative Instructions

After a full recovery from general anesthesia, most patients can be discharged home with a responsible adult. The effects of general anesthesia and sedative agents make the patient drowsy for hours, recommending adult supervision at home for up to 24 hours after surgery. The typical postoperative instructions should be given to the responsible adult and the patient should be scheduled for a postoperative visit in 1 week.

Surgical Anatomy of the Periodontium and Related Structures

Fermin A. Carranza

CHAPTER OUTLINE

MANDIBLE
MAXILLA
MUSCLES
ANATOMIC SPACES

A sound knowledge of the anatomy of the periodontium and the hard and soft structures that surround it is essential to determine the scope and possibilities of surgical periodontal procedures and minimize their risks. Bones, muscles, blood vessels, and nerves, as well as the anatomic spaces located in the vicinity of the periodontal surgical field, are particularly important. Only those features of periodontal relevance are mentioned in this chapter; the reader is referred to books on oral anatomy [4] for a more comprehensive description of these structures.

MANDIBLE

The mandible is a horseshoe-shaped bone connected to the skull by the temporomandibular joints. It presents several landmarks of great surgical importance.

The *mandibular canal,* occupied by the inferior alveolar nerve and vessels, begins at the mandibular foramen on the medial surface of the mandibular ramus and curves downward and forward, becoming horizontal below the apices of the molars (Fig. 56-1). The distance from the canal to the apices of the molars is shorter in the third molar area and increases as it goes forward. In the premolar area, the canal divides in two: the incisive canal, which continues horizontally to the midline, and the mental canal, which turns upward and opens in the mental foramen.

The author is grateful to Dr. Andrew D. Dixon for his constructive analysis of this chapter.

The *mental foramen,* from which the mental nerve and vessels emerge, is located on the buccal surface of the mandible below the apices of the premolars, sometimes closer to the second premolar and usually halfway between the lower border of the mandible and the alveolar margin (Fig. 56-2). The opening of the mental foramen faces upward and distally, with its posterosuperior border slanting gradually to the bone surface. As it emerges, the mental nerve divides into three branches. One branch of the nerve turns forward and downward to supply the skin of the chin. The other two branches course anteriorly and upward to supply the skin and mucous membrane of the lower lip and the mucosa of the labial alveolar surface.

Surgical trauma to the mental nerve can produce paresthesia of the lip, which recovers slowly. Familiarity with the location and appearance of the mental nerve reduces the likelihood of injury (Fig. 56-3).

In partially or totally edentulous jaws, the disappearance of the alveolar portion of the mandible brings the mandibular canal closer to the superior border. When these patients are evaluated for placement of implants, the distance between the canal and the superior surface of the bone must be carefully determined to avoid surgical injury to the nerve.

The *lingual nerve,* along with the inferior alveolar nerve, is a branch of the posterior division of the mandibular nerve and descends along the mandibular ramus medial to and in front of the inferior alveolar nerve. It lies close to the surface of the oral mucosa in the third molar area and goes deeper as it goes forward

(Fig. 56-4; see also Fig. 56-18). It can be damaged during anesthetic injections and during oral surgery procedures such as third molar extractions.[7] Less commonly, it may be injured when a periodontal partial thickness flap is raised in the third molar region or releasing incisions are made.

The *alveolar process,* which provides the supporting bone to the teeth, has a narrower distal curvature than the body of the mandible (Fig. 56-5), creating a flat surface in the posterior area between the teeth and the anterior border of the ramus. This results in the formation of the *external oblique ridge,* which runs downward and forward to the region of the second or first molar (Fig. 56-6), creating a shelflike bony area. Resective osseous therapy may be difficult or impossible in this area owing to the amount of bone that would have to be removed.

Distal to the third molar, the external oblique ridge circumscribes the *retromolar triangle* (see Fig. 56-6). This region is occupied by glandular and adipose tissue covered by unattached nonkeratinized mucosa. If sufficient space exists distal to the last molar, a band of attached gingiva may be present; only in such a case can a distal wedge operation be performed.

The inner side of the body of the mandible is traversed obliquely by the *mylohyoid ridge,* which starts close to the alveolar margin in the third molar area and continues anteriorly, increasing its distance from the osseous margin as it goes forward (Fig. 56-7). The mylohy-

old muscle, inserted at this ridge, separates the sublingual space, located more anteriorly and superiorly, from the submandibular space, located more posteriorly and inferiorly (see Fig. 56-18).

MAXILLA

The maxilla is a paired bone that is hollowed out by the maxillary sinus and has four processes: the *alveolar process,* which contains the sockets for the upper teeth; the *palatine process,* which extends horizontally to meet its counterpart from the other maxilla at the midline intermaxillary suture, and posteriorly with the horizontal plate of the palatine bone to form the hard palate; the *zygomatic process,* which extends laterally from the area of the first molar and determines the depth of the vestibular fornix; and the *frontal process,* which extends in an ascending direction and articulates with the frontal bone at the frontomaxillary suture.

The terminal branches of the nasopalatine nerve and vessels pass through the *incisive canal,* which opens in the midline anterior area of the palate (Fig. 56-8). The mucosa overlying the incisive canal presents a slight protuberance called the *incisive papilla.* Vessels emerging through the incisive canal are of small caliber, and their surgical interference is of little consequence.

The *greater palatine foramen* opens 3 to 4 mm anterior to the posterior border of the hard palate (Fig. 56-9). The

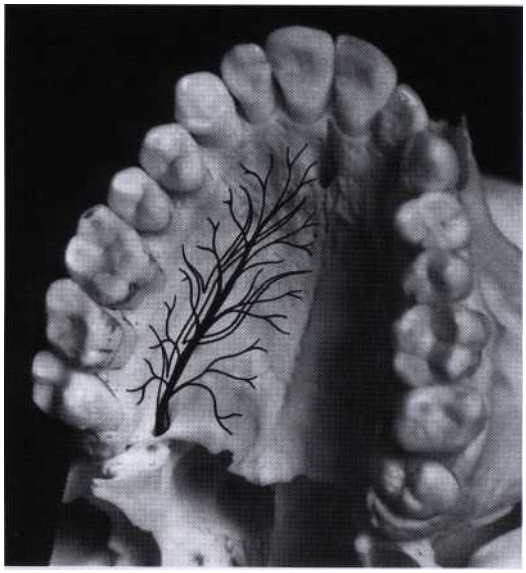

Fig. 56-9 Occlusolateral view of palate showing nerves and vessels emerging from the greater palatine foramen and continuing anteriorly on the palate.

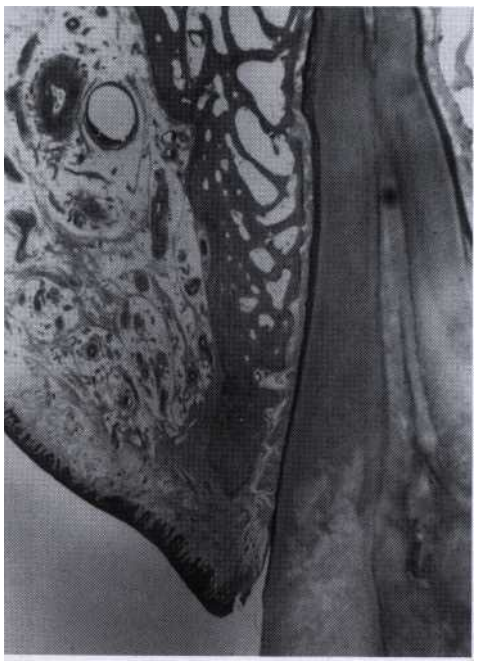

Fig. 56-10 Histologic frontal section of human palate at the level of the first molar, showing the location of vessels and nerve, surrounded by adipose and glandular tissue.

greater palatine nerve and vessels emerge through this foramen and run anteriorly in the submucosa of the palate, between the palatal and alveolar processes (Fig. 56-10). Palatal flaps and donor sites for gingival grafts should be carefully performed and selected to avoid invading these areas, as profuse hemorrhages may ensue, particularly if vessels are damaged at the palatine foramen.

Fig. 56-11 Radiograph of upper molars and premolars, with the maxillary sinus apparently near the apices.

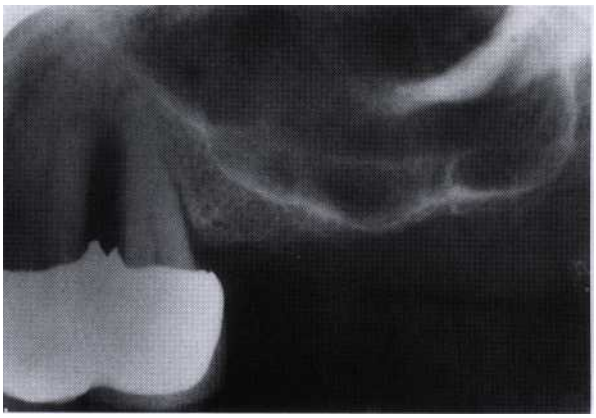

Fig. 56-12 Radiograph of edentulous molar maxillary area, with the sinus very close to the surface.

The mucous membrane covering the hard palate is firmly attached to the underlying bone. The submucous layer of the palate posterior to the first molars contains the palatal glands, which are more compact in the soft palate and extend anteriorly, filling the gap between the mucosal connective tissue and the periosteum and protecting the underlying vessels and nerve (see Fig. 56-17).

The area distal to the last molar is called the maxillary *tuberosity* and consists of the posteroinferior angle of the infratemporal surface of the maxilla; medially it articulates with the pyramidal process of the palatine bone. It is covered by fibrous connective tissue and contains the terminal branches of the middle and posterior palatine nerves. Excision of the area for distal wedge surgery may reach medially to the tensor palati muscle, which comes from the greater wing of the sphenoid bone and ends in a tendon that forms the palatine aponeurosis, which expands, fanlike, to attach to the posterior border of the hard palate.

The body of the maxilla is occupied by the maxillary sinus or antrum, which is a hollow pyramidal area with its base toward the nose and lined by respiratory epithelium. The inferior wall of the maxillary sinus is

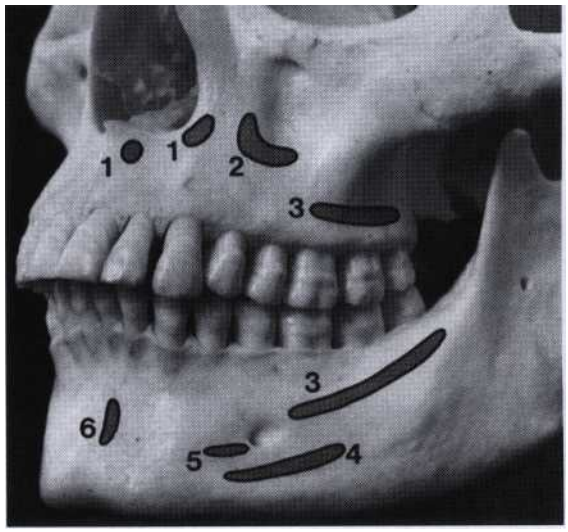

Fig. 56-16 Muscle attachments that may be encountered in mucogingival surgery. 7, Nasalis; 2, levator anguli oris; 3, buccinator; 4, depressor anguli oris; 5, depressor labii inferioris; 6, mentalis.

frequently separated from the apices and roots of the maxillary posterior teeth by a thin, bony plate (Fig. 56-11). In edentulous posterior areas the maxillary sinus bony wall may be only a thin plate in intimate contact with the alveolar mucosa (Fig. 56-12). Adequate determination of the extension of the maxillary sinus into the surgical site is important to avoid creating an oroantral communication, particularly in relation to the placement of implants. In edentulous jaws, determining the amount of available bone in the anterior area, below the floor of the nasal cavity, is also critical.

Both the maxilla and the mandible may have exostoses or tori, which are considered to be within the normal range of anatomic variation. Sometimes they may hinder the removal of plaque by the patient and may have to be removed to improve the prognosis of neighboring teeth. The most common location of a *mandibular torus is* in the lingual area of canine and premolars, above the mylohyoid muscle (Fig. 56-13). *Maxillary tori* are usually located in the midline of the hard palate (Fig. 56-14); smaller tori may be seen over the palatal roots of the molars (Fig. 56-15).

MUSCLES

Several muscles may be encountered when performing periodontal flaps, particularly in mucogingival surgery. These are the *mentalis, incisivus labii in ferioris, depressor labii inferioris, depressor anguli oris (triangularis), incisivus labii superioris,* and *buccinator.* Their bony attachment is shown in Fig. 56-16, and they provide mobility to the lips and cheeks.

ANATOMIC SPACES

Several anatomic spaces or compartments are found close to the operative field of periodontal surgery. These spaces contain loose connective tissue but can be easily distended by inflammatory fluid and infection.

Surgical invasion of these areas may result in dangerous infections and should be carefully avoided. Some of

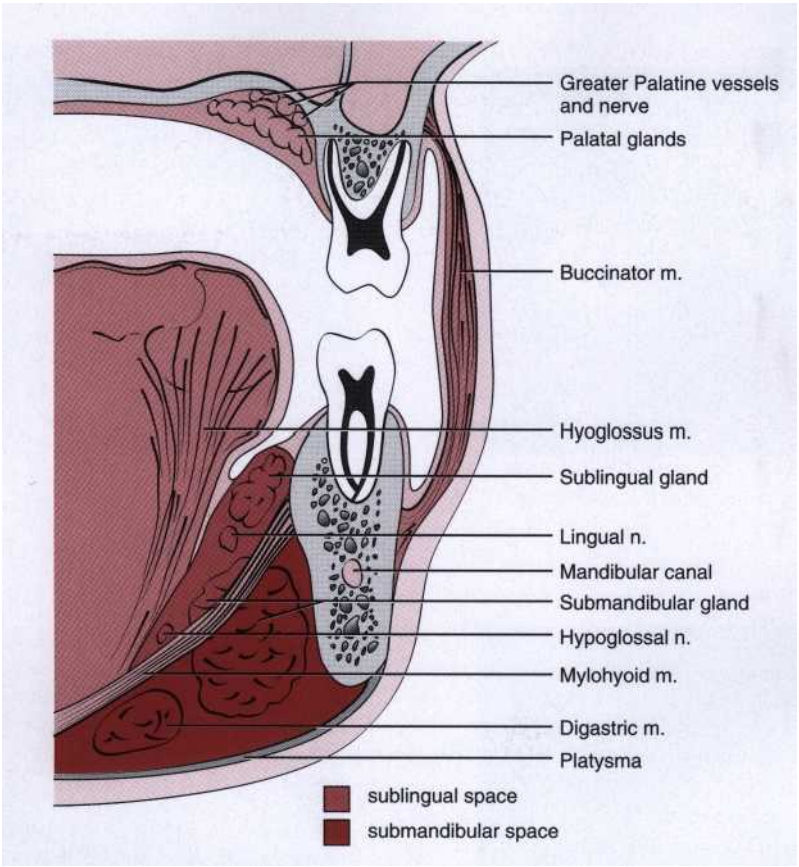

Fig. 56-17 Diagram of a frontal section of the human head at the level of the first molars, depicting the most important structures in relation to periodontal surgery. Note the location of the sublingual space, submandibular space, and greater palatine nerve and vessels.

these spaces are briefly described here. For further information, the reader is referred to other sources [2,6,9,10]

The *canine fossa* contains varying amounts of connective tissue and fat and is bounded superiorly by the quadratus labii superioris muscle, anteriorly by the orbicularis oris, and posteriorly by the buccinator. Infection of this area results in swelling of the upper lip, obliterating the nasolabial fold, and of the upper and lower eyelids, closing the eye.

The *buccal space is* located between the buccinator and the masseter muscles. Infection of this area results in swelling of the cheek but may extend to the temporal space or the submandibular space, with which the buccal space communicates.

The *mental* or *mentalis space is* located in the region of the mental symphysis, where the mental muscle, depressor muscle of the lower lip, and depressor muscle of the corner of the mouth are attached. Infection of this area results in large swelling of the chin, extending downward.

The *masticator space* contains the masseter muscle, pterygoid muscles, tendon of insertion of the temporalis muscle, and mandibular ramus and posterior part of the body of the mandible. Infection of this area results in swelling of the face and severe trismus and pain. If the abscess occupies the deepest part of this compartment, facial swelling may not be obvious but the patient may complain of pain and trismus. Patients may also have difficulty and discomfort when moving the tongue and swallowing.

The *sublingual space is* located below the oral mucosa in the anterior part of the floor of the mouth and contains the sublingual gland and its excretory duct, the submandibular or Wharton's duct, and is traversed by the lingual nerve and vessels and hypoglossal nerve (Fig. 56-17). Its boundaries are the geniohyoid and genioglossus muscles medially and the lingual surface of the mandible and below the mylohyoid muscle laterally and anteriorly (Fig. 56-18). Infection of this area raises the floor of the mouth and displaces the tongue, resulting in pain and difficulty in swallowing but little facial swelling.

The *submental space is* found between the mylohyoid muscle superiorly and the platysma inferiorly. It is bounded laterally by the mandible and posteriorly by the hyoid bone, and it is traversed by the anterior belly of the digastric muscle. Infections of this area arise from the region of the mandibular anterior teeth and result in swelling of the submental region; they become more dangerous as they proceed posteriorly.

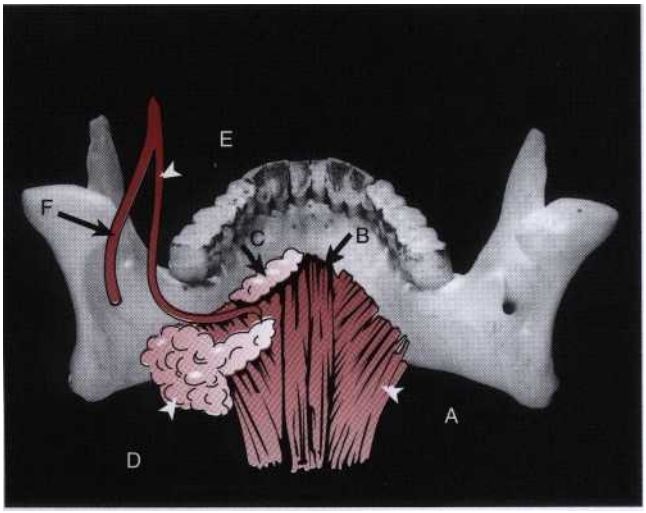

Fig. 56-18 Posterior view of mandible, showing the attachment of the mylohyoid muscles (A); geniohyoid muscles (8); sublingual gland (C); submandibular gland (D), which extends below and also to some extent above the mylohyoid muscle; and sublingual (E) and inferior alveolar (F) nerves.

The *submandibular space is* found external to the sublingual space, below the mylohyoid and hyoglossus muscles (see Figs. 50-17 and 50-18). This space contains the submandibular gland, which extends partially above the mylohyoid muscle, thus communicating with the sublingual space, and numerous lymph nodes. Infections of this area originate in the molar or premolar area and result in swelling that obliterates the submandibular line and pain when swallowing. Ludwig's angina is a severe form of infection of this space that may extend to the sublingual and submental spaces; it results in hardening of the floor of the mouth and may lead to asphyxiation from edema of the neck and glottis. Although the bacteriology of these infections has not been completely determined, they are presumed to be mixed infections with an important anaerobic component.

Gingival Curettage

Fermin A. Carranza and Henry H. Takei

CHAPTER OUTLINE

RATIONALE
Curettage and Esthetics
INDICATIONS
PROCEDURE
Basic Technique
Other Techniques
HEALING AFTER SCALING AND CURETTAGE
CLINICAL APPEARANCE AFTER SCALING AND CURETTAGE

The word *curettage is* used in periodontics to mean the scraping of the gingival wall of a periodontal pocket to separate diseased soft tissue. *Scaling* refers to the removal of deposits from the root surface, whereas *planing* means smoothing the root to remove infected and necrotic tooth substance. Scaling and root planing may inadvertently include various degrees of curettage. However, they are different procedures, with different rationales and indications, and should be considered separate parts of periodontal treatment.

A differentiation has been made between gingival and subgingival curettage (Fig. 57-1). *Gingival curettage* consists of the removal of the inflamed soft tissue lateral to the pocket wall, whereas *subgingival curettage* refers to the procedure that is performed apical to the epithelial attachment, severing the connective tissue attachment down to the osseous crest.

It should also be understood that some degree of curettage is done unintentionally when scaling and root planing is performed. This is called *inadvertent curettage.* This chapter refers to the purposeful curettage performed during the same visit as scaling and root planing or as a separate operation; its aim is to reduce pocket depth by enhancing gingival shrinkage, new connective tissue attachment, or both.

RATIONALE

Curettage accomplishes the removal of the chronically inflamed granulation tissue that forms in the lateral wall of the periodontal pocket. This tissue, in addition to the usual components of granulation tissues (fibroblastic and angioblastic proliferation), contains areas of chronic inflammation and may also have pieces of dislodged calculus and bacterial colonies. The latter may perpetuate the pathologic features of the tissue and hinder healing.

This inflamed granulation tissue is lined by epithelium, and deep strands of epithelium penetrate into the tissue. The presence of this epithelium is construed as a barrier to the attachment of new fibers in the area.

When the root is thoroughly planed, the major source of bacteria disappears and the pocket pathologic changes resolve with no need to eliminate the inflamed granulation tissue by curettage. The existing granulation tissue is slowly resorbed; the bacteria present, in the absence of replenishment of their numbers by the pocket plaque,

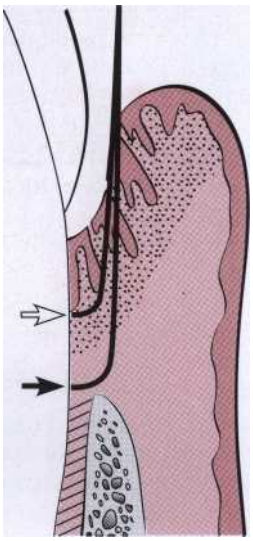

Fig. 57-1 Extent of gingival curettage *(white arrow)* **and subgingival curettage** *(black arrow).*

are destroyed by the defense mechanisms of the host. *Therefore the need for curettage just to eliminate the inflamed granulation tissue appears questionable.** It has been shown that scaling and root planing with additional curettage does not improve the condition of the periodontal tissues beyond the improvement caused by scaling and root planing alone.

Curettage may also eliminate all or most of the epithelium that lines the pocket wall and the underlying junctional epithelium. This purpose of curettage is still valid, particularly when an attempt is made at new attachment, as occurs in intrabony pockets. However, opinions differ regarding whether scaling and curettage consistently remove the pocket lining and the junctional epithelium. Some investigators report that scaling and root planing tear the epithelial lining of the pocket without removing either it or the junctional epithelium,[15] but both epithelial structures,[3,4,14] sometimes including underlying inflamed connective tissue,[16] are removed by curettage. Other investigators report that the removal of the pocket lining and junctional epithelium by curettage is not complete.[23,21,26]

Curettage and Esthetics

The awareness of esthetics in periodontal therapy has become an integral part of care in the modern practice of periodontics. In the past, pocket elimination was the primary goal of therapy, and little regard was given to the esthetic result. Maximal, rapid shrinkage of gingival tissue was the aim to eliminate the pocket. Currently, esthetics is a major consideration of therapy, particularly in the anterior maxilla (teeth #6 to 11), and *requires preservation of the interdental papilla.*

When regenerative therapy is not possible, every effort should be made to minimize shrinkage or loss of the interdental papilla. A compromise therapy that is feasible in the anterior maxilla, where access is not difficult, consists of thorough subgingival root planing, attempting not to detach the connective tissue beneath the pocket and *avoiding gingival curettage.* The granulation tissue in the lateral wall of the pocket, in an environment free of plaque and calculus, becomes connective tissue, thereby minimizing shrinkage. Thus although complete pocket elimination is not accomplished, the inflammatory changes are reduced or eliminated while the interdental papilla and the esthetic appearance of the area are preserved.

Surgical techniques specially designed to preserve the interdental papilla, such as the papilla preservation technique (see Chapter 60), result in better esthetic appearance of the anterior maxilla than do aggressive scaling and curettage of the area.

Another important precaution refers to root planing apical to the base of the pocket. The removal of the junctional epithelium and disruption of the connective tissue attachment exposes the nondiseased portion of the cementum. Root planing in this area of nondiseased cementum may result in excessive shrinkage of the gingiva, increasing recession or requiring "new attachment" where no disease previously existed.

INDICATIONS

Indications for curettage are very limited. It can be used after scaling and root planing for the following purposes:

1. Curettage can be performed as part of new attachment attempts in moderately deep intrabony pockets located in accessible areas where a type of "closed" surgery is deemed advisable. However, technical difficulties and inadequate accessibility frequently contraindicate such surgery.
2. Curettage can be done as a nondefinitive procedure to reduce inflammation prior to pocket elimination using other methods or in patients in whom more aggressive surgical techniques (e.g., flaps) are contraindicated owing to age, systemic problems, psychologic problems, and so forth. It should be understood that in these patients, the goal of pocket elimination is compromised and prognosis is impaired. The clinician should resort to this approach only when the indicated surgical techniques cannot be performed, and both the clinician and the patient must have a clear understanding of its limitations.
3. Curettage is also frequently performed on recall visits[20] as a method of maintenance treatment for areas of recurrent inflammation and pocket depth, particularly where pocket reduction surgery has previously been performed. Careful probing should establish the

* **This should not be confused with elimination of granulation tissue during flap surgery. The reason for the latter is to remove the bleeding tissue that obstructs the view and does not allow the necessary examination of the root surface and the bone morphology. Thus removal of granulation tissue during surgery is done for technical rather than biologic reasons.**

extent of the required root planing and curettage to avoid unnecessary shrinkage, pocket formation, or both.

PROCEDURE

Basic Technique

Curettage does not eliminate the causes of inflammation (i.e., bacterial plaque and deposits). *Therefore it should always be preceded by scaling and root planing, which is the basic periodontal therapy procedure.*

Scaling and root planing is described in detail in Chapters 42 and 47. The use of local infiltrative anesthesia for this procedure is optional. However, gingival curettage always requires some type of local anesthesia.

The curette is selected so that the cutting edge will be against the tissue (e.g., the Gracey No. 13-14 is used for mesial surfaces and the Gracey No. 11-12 for distal surfaces). Curettage can also be performed with a 4R-4L Columbia Universal curette. The instrument is inserted so as to engage the inner lining of the pocket wall and is carried along the soft tissue, usually in a horizontal stroke (Fig. 57-2). The pocket wall may be supported by gentle finger pressure on the external surface. The curette is then placed under the cut edge of the functional epithelium to undermine it.

In subgingival curettage, the tissues attached between the bottom of the pocket and the alveolar crest are removed with a scooping motion of the curette to the tooth surface (Fig. 57-3). The area is flushed to remove debris, and the tissue is partly adapted to the tooth by gentle finger pressure. Sometimes suturing of separated papillae and application of a periodontal pack may be indicated.

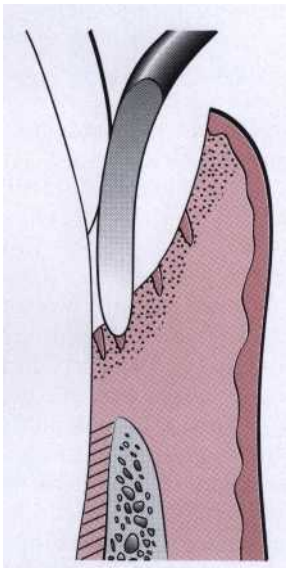

Fig. 57-2 Gingival curettage performed with a horizontal stroke of the curette.

Other Techniques

Other techniques for gingival curettage include the excisional new attachment procedure, ultrasonic curettage, and the use of caustic drugs:

Excisional New Attachment Procedure (ENAP). ENAP has been developed and used by the U.S. Naval Dental Corps.[19,29,10] It is a definitive subgingival curettage procedure performed with a knife. The technique is as follows:

1. After adequate anesthesia, an internal bevel incision is made from the margin of the free gingiva apically to a point below the bottom of the pocket (Fig. 57-4). The incision is carried interproximally on both the facial and **the lingual sides, attempting to retain** as much interproximal tissue as possible. The intention is to cut the inner portion of the soft tissue wall of the pocket, all around the tooth.
2. Remove the excised tissue with a curette, and carefully root plane all exposed cementum to a smooth, hard consistency. Preserve all connective tissue fibers that remain attached to the root surface.
3. Approximate the wound edges; if they do not meet passively, recontour the bone until good adaptation of the wound edges is achieved. Place sutures and a periodontal dressing.

Ultrasonic Curettage. The use of ultrasonic devices has been recommended for gingival curettage.[17] When applied to the gingiva of experimental animals, ultrasonic vibrations disrupt tissue continuity, lift off epithelium, dismember collagen bundles, and alter the morphologic features of fibroblast nuclei." Ultrasound is effective for debriding the epithelial lining of periodontal pockets'°; it results in a narrow band of necrotic tissue (microcauterization), which strips off the inner lining of the pocket.

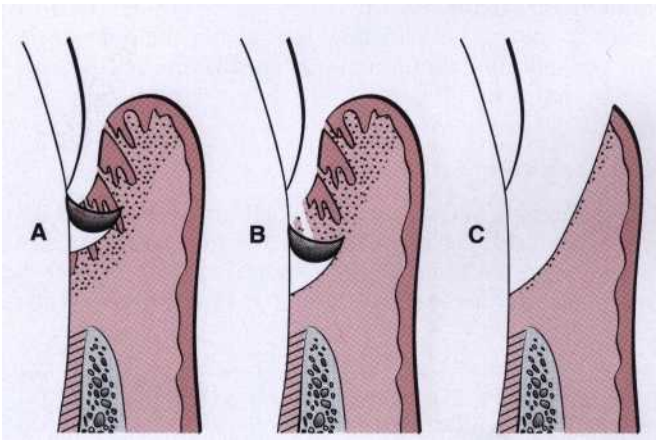

Fig. 57-3 Subgingival curettage. A, Elimination of pocket lining. B, Elimination of junctional epithelium and granulation tissue. C, Procedure completed.

The Morse scaler-shaped and rod-shaped ultrasonic instruments are used for this purpose. Some investigators found ultrasonic instruments to be as effective as manual instruments for curettage[17,22,11] but resulted in less inflammation and less removal of underlying connective tissue. The gingiva can be made more rigid for ultrasonic curettage by injecting anesthetic solution directly into it.[7]

Caustic Drugs. Since early in the development of periodontal procedures,[24,28] the use of caustic drugs has been recommended to induce a chemical curettage of the lateral wall of the pocket or even the selective elimination of the epithelium. Drugs such as sodium sulfide, alkaline sodium hypochlorite solution (Antiformin),[1 1,12] and phenol have been proposed and then discarded after studies showed their ineffectiveness.[2,9,12] The extent of tissue destruction with these drugs cannot be controlled, and they may increase rather than reduce the amount of tissue to be removed by enzymes and phagocytes.

HEALING AFTER SCALING AND CURETTAGE

Immediately after curettage, a blood clot fills the pocket area, which is totally or partially devoid of epithelial lining. Hemorrhage is also present in the tissues with dilated capillaries, and abundant polymorphonuclear leukocytes appear shortly thereafter on the wound surface. This is followed by a rapid proliferation of granulation tissue, with a decrease in the number of small blood vessels as the tissue matures.

Restoration and epithelialization of the sulcus generally require from 2 to 7 days,[13,16,18,26] and restoration of the junctional epithelium occurs in animals as early as 5 days after treatment. Immature collagen fibers appear within 21 days. Healthy gingival fibers inadvertently severed from the tooth and tears in the epithelium[1-5,21] are repaired in the healing process. Several investigators have reported that in monkeys[8,29] and humans[27] treated by scaling procedures and curettage, healing results in the formation of a long, thin junctional epithelium with no new connective tissue attachment. Sometimes this long epithelium is interrupted by "windows" of connective tissue attachment.[8]

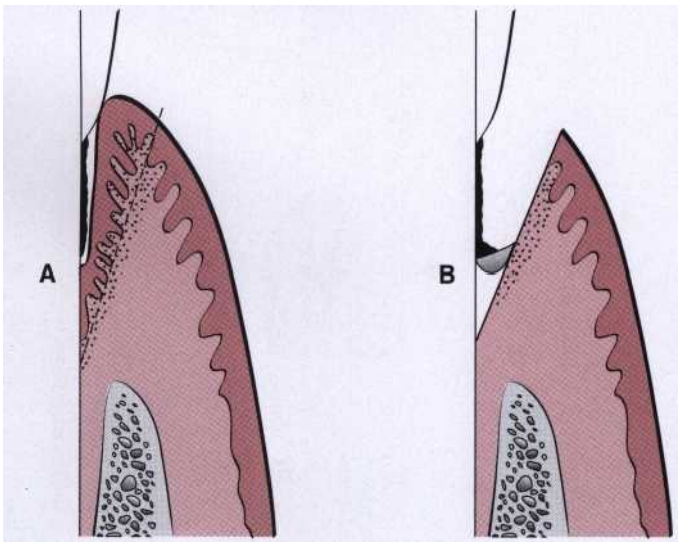

Fig. 57-4 Excisional new attachment procedure. A, Internal bevel incision to point below bottom of pocket. B, After excision of tissue, scaling and root planing are performed.

CLINICAL APPEARANCE AFTER SCALING AND CURETTAGE

Immediately after scaling and curettage, the gingiva appears hemorrhagic and bright red.

After 1 week, the gingiva appears reduced in height owing to an apical shift in the position of the gingival margin. The gingiva is also slightly redder than normal, but much less so than on previous days.

After 2 weeks and with proper oral hygiene by the patient, the normal color, consistency, surface texture, and contour of the gingiva are attained, and the gingival margin is well adapted to the tooth.

Disadvantages
Technique
Healing after Electrosurgery
LASER GINGIVECTOMY
GINGIVECTOMY BY CHEMOSURGERY

Gingivectomy means excision of the gingiva. By removing the pocket wall, gingivectomy provides visibility and accessibility for complete calculus removal and thorough smoothing of the roots (Fig. 58-1), creating a favorable environment for gingival healing and restoration of a physiologic gingival contour.

The gingivectomy technique was widely performed in the past. Improved understanding of healing mechanisms and the development of more sophisticated flap methods have relegated the gingivectomy to a lesser role in the current repertoire of available techniques. However, it remains an effective form of treatment when indicated (Fig. 58-2).

INDICATIONS AND CONTRAINDICATIONS

The gingivectomy technique may be performed for:

1. Elimination of suprabony pockets, regardless of their depth, if the pocket wall is fibrous and firm
2. Elimination of gingival enlargements
3. Elimination of suprabony periodontal abscesses'

Contraindications include the following:

1. The need for bone surgery or examination of the bone shape and morphology
2. Situations in which the bottom of the pocket is apical to the mucogingival junction
3. Esthetic considerations, particularly in the anterior maxilla

The gingivectomy technique may be performed by means of scalpels, electrodes, laser beams, or chemicals. All these techniques will be reviewed, although the surgical method is the only one recommended.

SURGICAL GINGIVECTOMY

Step 1: The pockets on each surface are explored with a periodontal probe and marked with a pocket marker (Figs. 58-3 and 58-4). Each pocket is marked in several areas to outline its course on each surface.

Step 2: Periodontal knives (e.g., Kirkland knives) are used for incisions on the facial and lingual surfaces and those distal to the terminal tooth in the arch. Orban periodontal knives are used for supplemental interdental incisions, if necessary, and Bard-Parker knives #11 and 12 and scissors are used as auxiliary instruments.

The incision is started apical to the points marking the course of the pockets[27,31] and is directed coronally to a point between the base of the pocket and the crest of the bone. It should be as close as possible to the bone without exposing it to remove the soft tissue coronal to the bone. Exposure of bone is undesirable. If it occurs, healing usually presents no problem if the area is adequately covered by the periodontal pack.

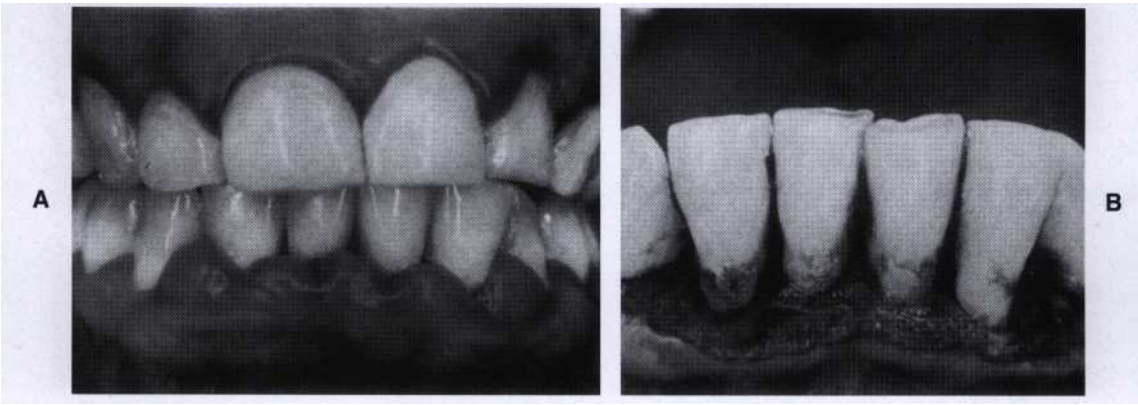

Fig. 58-1 Visibility and accessibility of calculus. A, Gingival enlargement. B, Removal of diseased gingiva exposes calculus. (Phase I therapy is sometimes omitted when the indication for a gingivectomy is obvious. It can never be omitted when a flap appears to be indicated.)

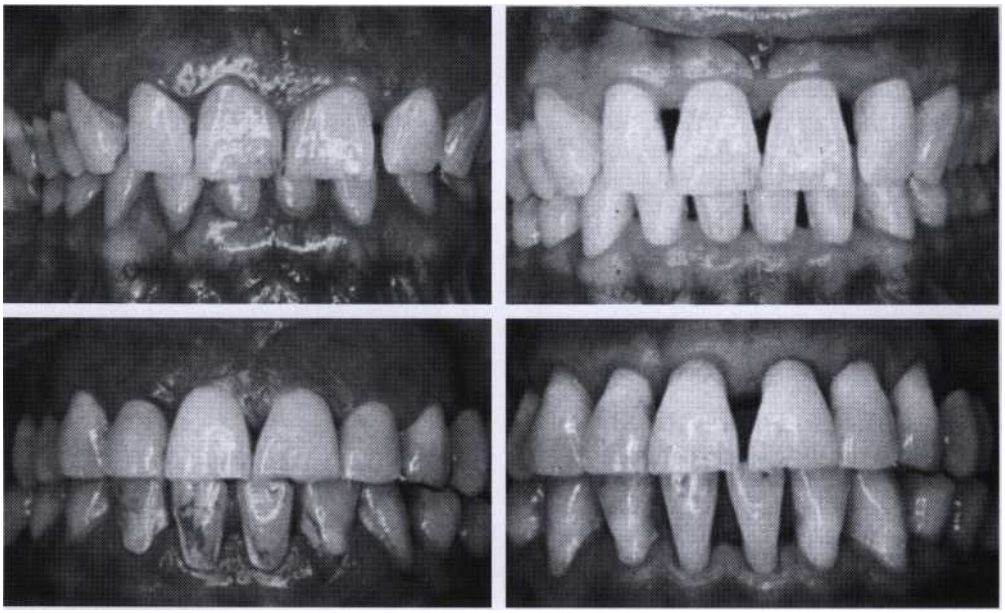

Fig. 58-2 Results obtained by treating suprabony pockets of different depths with gingivectomy. *Left,* **Before treatment.** *Right,* **After treatment.**

Discontinuous or continuous incisions may be used. Fig. 58-5 shows the design of each of these two incisions. *The incision should be beveled at approximately 45 degrees to the tooth surface and should recreate, as far as possible, the normal festooned pattern of the gingiva.* Failure to bevel leaves a broad, fibrous plateau that takes more time than is ordinarily required to develop a physiologic contour. In the interim, plaque and food accumulation may lead to recurrence of pockets.

Step 3: Remove the excised pocket wall, clean the area, and closely examine the root surface. The most apical zone consists of a bandlike light zone where the tissues were attached, and coronally to it some calculus remnants, root caries, or root resorption may be found. Granulation tissue may be seen on the excised soft tissue (Fig. 58-6).

Step 4: Carefully curette out the granulation tissue and remove any remaining calculus and necrotic cementum so as to leave a smooth and clean surface.

Step 5: Cover the area with a surgical pack (see Chapter 55).

Gingivoplasty

Gingivoplasty is similar to gingivectomy, but its purpose is different. Gingivectomy is performed to eliminate periodontal pockets and includes reshaping as part of the technique. Gingivoplasty is a reshaping of the gingiva to create physiologic gingival contours, with the sole purpose of recontouring the gingiva in the absence of pockets.

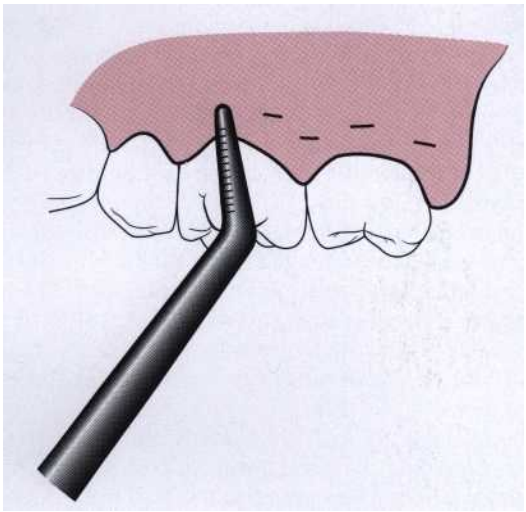

Fig. 58-3 Pocket marker makes pinpoint perforations that indicate pocket depth.

Gingival and periodontal disease often produce deformities in the gingiva that interfere with normal food excursion, collect plaque and food debris, and prolong and aggravate the disease process. Gingival clefts and craters, shelflike interdental papillae caused by acute necrotizing ulcerative gingivitis, and gingival enlargement are examples of such deformities.

Gingivoplasty may be done with a periodontal knife, a scalpel, rotary coarse diamond stones,[6] or electrodes.[7] It consists of procedures that resemble those performed in festooning artificial dentures; namely, tapering the gingival margin, creating a scalloped marginal outline, thinning the attached gingiva, and creating vertical interdental grooves and shaping the interdental papillae to provide sluiceways for the passage of food.

Healing after Surgical Gingivectomy

The initial response is the formation of a protective surface clot; the underlying tissue becomes acutely inflamed, with some necrosis. The clot is then replaced by granulation tissue. By 24 hours, there is an increase in new connective tissue cells, mainly angioblasts, just beneath the surface layer of inflammation and necrosis; by

the third day, numerous young fibroblasts are located in the area.[26] The highly vascular granulation tissue grows coronally, creating a new free gingival margin and sulcus.[22] Capillaries derived from blood vessels of the periodontal ligament migrate into the granulation tissue, and within 2 weeks they connect with gingival vessels.[32]

After 12 to 24 hours, epithelial cells at the margins of the wound start to migrate over the granulation tissue, separating it from the contaminated surface layer of the clot. Epithelial activity at the margins reaches a peak in 24 to 36 hours'; the new epithelial cells arise from the basal and deeper spinous layers of the wound edge epithelium and migrate over the wound over a fibrin layer that is later resorbed and replaced by a connective tissue bed." The epithelial cells advance by a tumbling action, with the cells becoming fixed to the substrate by hemidesmosomes and a new basement lamina."

Surface epithelization is generally complete after 5 to 14 days. During the first 4 weeks after gingivectomy, keratinization is less than it was prior to surgery. Complete epithelial repair takes about 1 month.[29] Vasodilation and vascularity begin to decrease after the fourth day of healing and appear to be almost normal by the 16th day.[19] Complete repair of the connective tissue takes about 7 weeks.[29]

The flow of gingival fluid in humans is initially increased after gingivectomy and diminishes as healing progresses.[1-28] Maximal flow is reached after 1 week, coinciding with the time of maximal inflammation.

Although the tissue changes that occur in postgingivectomy healing are the same in all individuals, the time required for complete healing varies considerably, depending on the area of the cut surface and interference from local irritation and infection. In patients with physiologic gingival melanosis, the pigmentation is diminished in the healed gingiva.

GINGIVECTOMY BY ELECTROSURGERY

Advantages

Electrosurgery permits an adequate contouring of the tissue and controls hemorrhage.[P,21]

Disadvantages

Electrosurgery cannot be used in patients who have noncompatible or poorly shielded cardiac pacemakers. The treatment causes an unpleasant odor. If the electrosurgery point touches the bone, irreparable damage can be done.[2,9,12,25] furthermore, the heat generated by injudicious use can cause tissue damage and loss of periodontal support when the electrode is used close to bone. When the electrode touches the root, areas of cementum burn are produced.[33] *Therefore the use of electrosurgery should be limited to superficial procedures such as removal of gingival enlargements, gingivoplasty, relocation of frenum and muscle attachments, and incision of periodontal abscesses and pericoronal flaps; extreme care should be exercised to avoid contacting the tooth surface. It should not be used for procedures that involve proximity to the bone, such as flap operations, or mucogingival surgery.*

Technique

The removal of gingival enlargements and gingivoplasty[21] is performed with the needle electrode, supplemented by the small ovoid loop or the diamond-shaped electrodes for festooning. A blended cutting and coagulating (fully rectified) current is used. In all reshaping procedures, the electrode is activated and moved in a concise "shaving" motion.

In the treatment of acute periodontal abscesses, the incision to establish drainage can be made with the needle electrode without exerting painful pressure. The incision remains open because the edges are sealed by the current. After the acute symptoms subside, the regular procedure for the treatment of the periodontal abscess is followed (see Chapter 46).

For hemostasis, the ball electrode is used. Hemorrhage must be controlled by direct pressure (via air, compress, or hemostat) first; then the surface is lightly touched with a coagulating current. Electrosurgery is helpful for the control of isolated bleeding points. Bleeding areas located interproximally are reached with a thin, bar-shaped electrode.

Frenum and muscle attachments can be relocated to facilitate pocket elimination using a loop electrode. For this purpose, the frenum or muscle is stretched and sectioned with the loop electrode and a coagulating current. For cases of acute pericoronitis, drainage may be obtained by incising the flap with a bent needle electrode. A loop electrode is used to remove the flap after the acute symptoms subside.

Healing after Electrosurgery

Some investigators report no significant differences in gingival healing after resection by electrosurgery and resection with periodontal knives; other researchers find delayed healing, greater reduction in gingival height, and more bone injury after electrosurgery.[25] There appears to be little difference in the results obtained after shallow gingival resection with electrosurgery and that with periodontal knives. *However, when used for deep resections close to bone, electrosurgery can produce gingival recession, bone necrosis and sequestration, loss of bone height, furcation exposure, and tooth mobility, which do not occur with the use of periodontal knives.*[2,9]

LASER GINGIVECTOMY

The lasers most commonly used in dentistry are the carbon dioxide (CO_2) and the neodymium:yttrium-aluminum-garnet (Nd:YAG), which have wavelengths of 10,600 nm and 1064 nm, respectively, both in the infrared range; they must be combined with other types of visible lasers for the beam to be seen and aimed.

The CO_2 laser beam has been used for the excision of gingival growths,[3,23] although healing is delayed when compared with healing after conventional scalpel gingivectomy.[11,17,24] The use of laser beam for oral surgery requires precautionary measures to avoid reflecting the beam on instrument surfaces, which could result in injury to neighboring tissues and the eyes of the operator.

At present, the use of lasers for periodontal surgery is not supported by research and is therefore discouraged. The use of lasers for other periodontal purposes, such as subgingival curettage is equally unsubstantiated and is also not recommended.

GINGIVECTOMY BY CHEMOSURGERY

Techniques to remove the gingiva using chemicals, such as 5% paraformaldehyde[20] or potassium hydroxide,[16] have been described in the past but are not currently used. They are presented here to provide a historical perspective.

The chemical gingivectomy has the following disadvantages:

1. The depth of action cannot be controlled, and therefore healthy attached tissue underlying the pocket may be injured.
2. Gingival remodeling cannot be accomplished effectively.
3. Epithelialization and reformation of the junctional epithelium and reestablishment of the alveolar crest fiber system are slower in chemically treated gingival wounds than in those produced by a scalpel.[30]

The use of chemical methods therefore is not recommended.

Treatment Options
TREATMENT OF LEUKEMIC GINGIVAL ENLARGEMENT
TREATMENT OF GINGIVAL ENLARGEMENT IN PREGNANCY
When to Treat
TREATMENT OF GINGIVAL ENLARGEMENT IN PUBERTY
RECURRENCE OF GINGIVAL ENLARGEMENT

Treatment of gingival enlargement is based on an understanding of the cause and underlying pathologic changes (see Chapter 18). Gingival enlargements are of special concern to the patient and the dentist because they pose problems in plaque control, function (including mastication, tooth eruption and speech), and esthetics. Because gingival enlargements differ in cause, treatment of each type is best considered individually.

TREATMENT OF CHRONIC INFLAMMATORY ENLARGEMENT

Chronic inflammatory enlargements, which are soft and discolored and are caused principally by edema and cellular infiltration, are treated by *scaling and root planing,* provided the size of the enlargement does not interfere with complete removal of deposits from the involved tooth surfaces.

When chronic inflammatory gingival enlargements include a significant fibrotic component that does not undergo shrinkage after scaling and root planing or are of such size that they obscure deposits on the tooth surfaces and interfere with access to them, *surgical removal is* the treatment of choice. Two techniques are available for this purpose: gingivectomy and flap operation.

Selection of the appropriate technique depends on the size of the enlargement and character of the tissue. When the enlarged gingiva remains soft and friable even after scaling and root planing, a gingivectomy is used to remove it because a flap requires a firmer tissue to adequately perform the incisions and other steps in the technique (Fig. 59-1). However, if the gingivectomy incision removes all the attached gingiva, creating a mucogingival problem, then a flap operation is indicated.

Tumorlike inflammatory enlargements are treated by gingivectomy as follows: Under local anesthesia, the tooth surfaces beneath the mass are scaled to remove calculus and other debris. The lesion is separated from the mucosa at its base with a #12 Bard-Parker blade. If the lesion extends interproximally, the interdental gingiva is included in the incision to ensure exposure of irritating root deposits. After the lesion is removed, the involved root surfaces are scaled and planed and the area is cleansed with warm water. A periodontal pack is applied and removed after a week, at which time the patient is instructed in plaque control (Fig. 59-2, A and B).

The Flap Operation

See Chapters 60 and 61 and the following discussion of the flap technique for drug-induced enlargements.

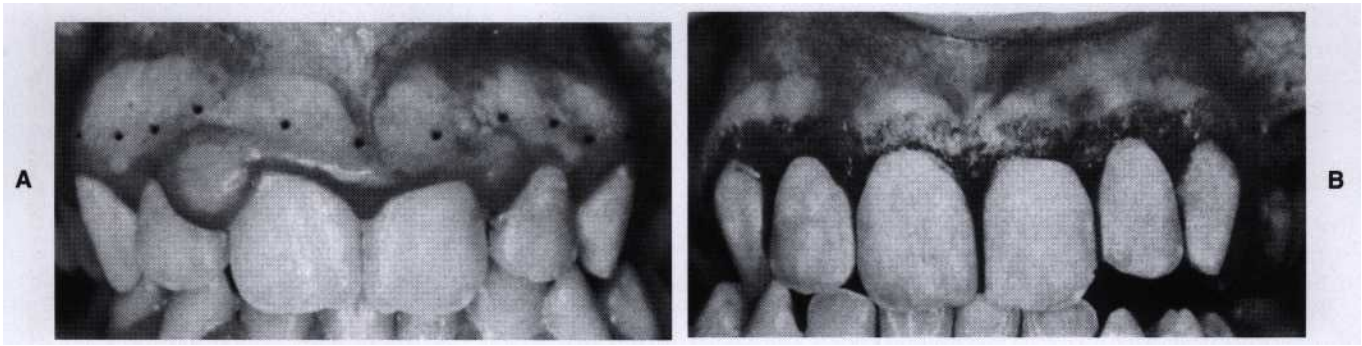

Fig. 59-1 Gingivectomy incision for gingival enlargement. A, Chronic inflammatory gingival enlargement with tumorlike area. Pinpoint markings outline the extent of the enlargement. Note the amount of attached gingiva remaining. B, Enlarged gingiva removed. Note the beveled incision.

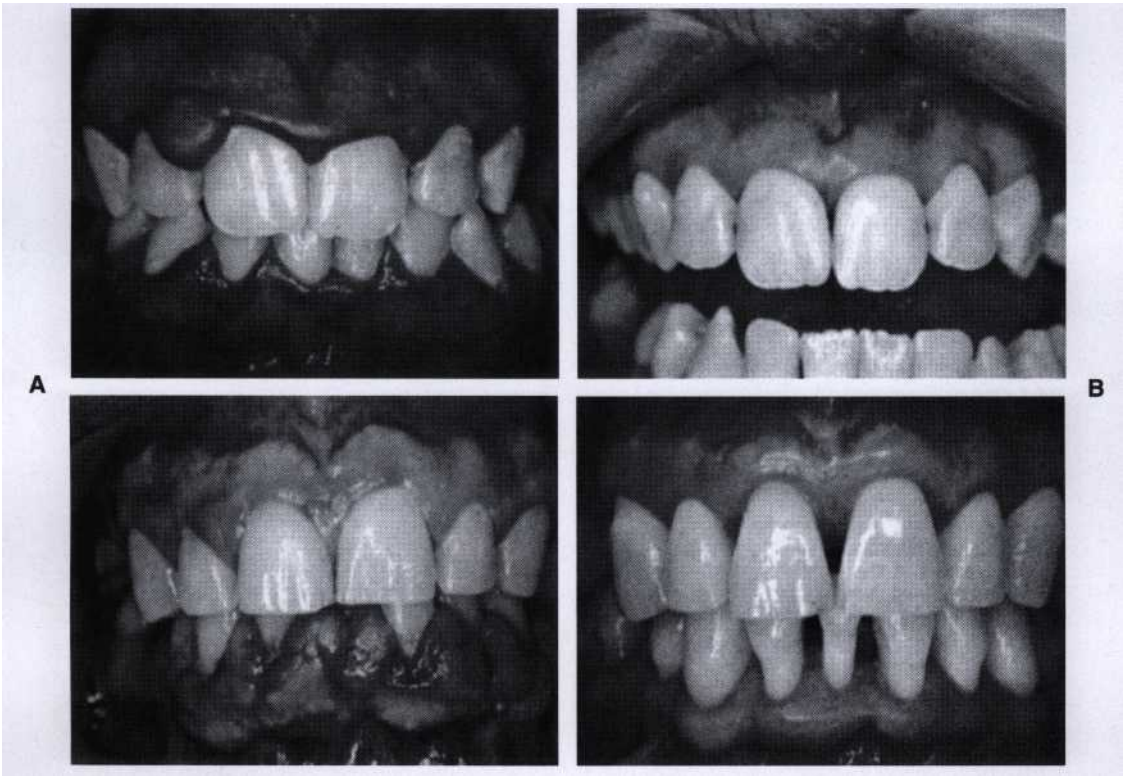

Fig. 59-2 A, Chronic inflammatory gingival enlargement associated with mouth breathing. B, Appearance after treatment.

TREATMENT OF PERIODONTAL AND GINGIVAL ABSCESSES

The reader is referred to Chapter 46, "Treatment of the Periodontal Abscess," for a more complete discussion of this topic.

TREATMENT OF DRUG-ASSOCIATED GINGIVAL ENLARGEMENT

Gingival enlargement has been associated with the administration of three different types of drugs: anticonvulsants, calcium channel blockers, and the immunosuppressant cyclosporine. A comprehensive review of the clinical and microscopic features, and pathogenesis of gingival enlargement induced by the above-mentioned drugs is provided in Chapter 18.

Examination of cases of drug-induced gingival enlargement reveals the overgrown tissues to have two components: a fibrotic one, which is caused by the drug, and an inflammatory one that is induced by bacterial plaque. Although the two components (fibrotic and inflammatory) present in the enlarged gingiva are the result of distinct pathologic processes, they almost always are observed in combination. The role of bacterial plaque in the overall pathogenesis of drug-induced gingival enlargement is not clear. Some studies indicate

that plaque is a prerequisite for gipgival enlargement,$ whereas others suggest that the presence of plaque is a consequence of its accumulation due to the enlarged gingiva.

Treatment Options

Treatment of drug-induced gingival enlargement should be based on the medication being used and the clinical features of the case.

First, consideration should be given to the possibility of discontinuing the drug or changing medication. These possibilities should be examined with the patient's physician. Simple discontinuation of the offending drug is usually not a practical option, but its substitution for another medication might be. If any drug substitution is attempted, it is important to allow for a 6- to 12-month period of time to elapse between discontinuation of the offending drug and the possible resolution of gingival enlargement before a decision to implement surgical treatment is made.

Alternative medications to phenytoin include carbamazepine5 and valproic acid, both of which have been reported to have a lesser impact in inducing gingival enlargement.

For patients on nifedipine, which has a reported prevalence of gingival enlargement of up to 44%, other calcium channel blockers such as diltiazem or verapamil

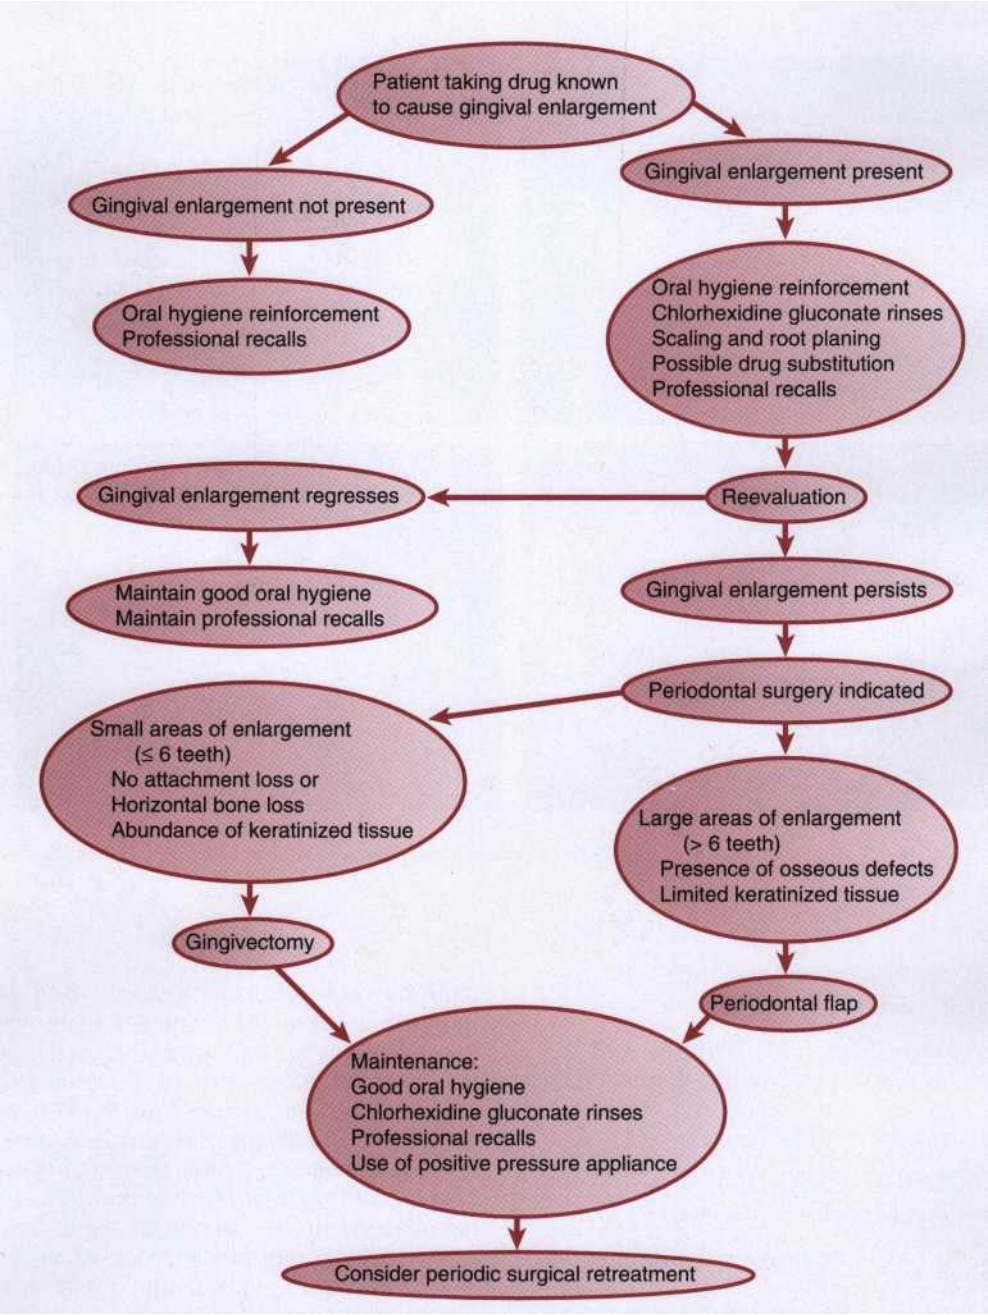

Fig. 59-3 Decision tree for treatment of drug-induced gingival enlargements.

may be viable alternatives, and their reported prevalence of gingival enlargement is 20% and 4%, respectively. [3,7,11] Also, consideration may be given to the use of another class of antihypertensive medications rather than calcium channel blockers, none of which are known to induce gingival enlargement.

Drug substitutions for cyclosporine are more limited. Recently, it has been shown that cyclosporine-induced gingival enlargement can spontaneously resolve if the drug is substituted by tracolimus.[10] There is also preliminary evidence that the antibiotic azithromycin may aid in decreasing the severity of cyclosporine-induced gingival enlargement.[17]

Second, the clinician should emphasize plaque control as the first step in the treatment of drug-induced gingival enlargement. Despite the fact that the exact role played by bacterial plaque is not well understood, there is evidence that good oral hygiene and frequent professional removal of plaque decreases the degree of gingival enlargement present and improves overall gingival health.[6,8,16] The presence of drug-induced enlargement is associated with pseudo-pocket formation, frequently with abundant plaque accumulation, which raises the possibility of periodontitis to develop; meticulous plaque control therefore helps maintain attachment levels. Also, adequate plaque control may aid in preventing or retarding the recurrence of gingival enlargement in surgically treated cases.

Third, in some cases, gingival enlargement persists after careful consideration of the above-mentioned approaches. These cases need to be treated by surgery, either gingivectomy or the periodontal flap. A decision tree outlining the sequence of events and options in the treatment of gingival enlargement is presented in Fig. 59-3.

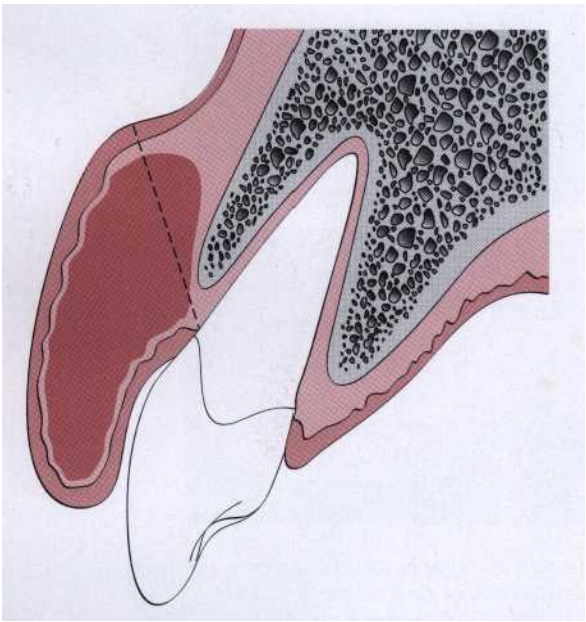

Fig. 59-4 The gingivectomy technique as used in treating drug-induced gingival enlargement cases. The dotted line represents the external bevel incision, and the shaded area corresponds to the tissue to be excised. Gingivectomy incision may not remove the entire hyperplastic tissue *(shaded area)* **and may leave a wide wound of exposed connective tissue.**

Gingivectomy has the advantage of simplicity and quickness but presents the disadvantages of more postoperative discomfort and increased chance of postoperative bleeding. It also sacrifices keratinized tissue and does not allow for osseous recontouring. The clinician's decision between the two surgical techniques available must consider the extension of the area to be operated, the presence of periodontitis and osseous defects, and the location of the base of the pockets in relation to the mucogingival junction.

In general, small areas (up to 6 teeth) of drug-induced gingival enlargement with no evidence of attachment loss (and therefore no anticipated need for osseous surgery) can be effectively treated with the gingivectomy technique. An important consideration is the amount of keratinized tissue present, remembering that at least 3 mm in the apicocoronal direction should remain after the surgery is completed.

The gingivectomy technique is described in detail in Chapter 58. Fig. 59-4 depicts diagrammatically the procedure, and Fig. 59-5 illustrates a case of cyclosporine-induced gingival enlargement treated with the gingivectomy technique.

Gingivectomy/gingivoplasty can also be performed via electrosurgery or a laser device. The advantages and disadvantages of these techniques are presented in Chapter 58.

The Flap Technique. Larger areas of gingival enlargement (more than 6 teeth) or areas where attachment loss and osseous defects are present should be treated by the flap technique, as should any situation in which the gingivectomy technique may create a mucogingival problem.

The periodontal flap technique used for the treatment of gingival enlargements is a simple variation of the one used to treat periodontitis, described in Chapters 60 and 61. Fig. 59-6 shows the basic steps in the technique, described as follows:

1. After anesthetizing the area, sounding of the underlying alveolar bone is performed with a periodontal probe to determine the presence and extent of osseous defects.
2. With a #15 Bard-Parker blade, the initial scalloped internal bevel incision is made at least 3 mm coronal to the mucogingival junction, including the creation of new interdental papillae.
3. The same blade is used to thin the gingival tissues in a buccolingual direction to the mucogingival junction. At this point the blade establishes contact with the alveolar bone, and a full-thickness or a split-thickness flap is elevated.
4. Using an Orban knife, the base of each papilla connecting the facial and the lingual incisions is incised.
5. The excised marginal and interdental tissue are removed with curettes.
6. Tissue tabs are removed, the roots are thoroughly scaled and planed, and the bone is recontoured as needed.
7. The flap is replaced and, if necessary, trimmed to exactly reach the bone-tooth junction. The flap is then

sutured with an interrupted or a continuous mattress technique, and the area is covered with periodontal dressing.

Sutures and pack are removed after 1 week, and the patient is instructed to start plaque control methods. Usually it is convenient to have the patient use chlorhexidine mouthrinses once or twice daily for 2 to 4 weeks.

Fig. 59-7 illustrates a case treated with the flap technique.

Recurrence of drug-induced gingival enlargements is a reality in surgically treated cases.[14] As stated previously, meticulous home care[4,12] chlorhexidine gluconate rinses, and professional cleanings can decrease the speed and the degree to which recurrence occurs. A hard, natural rubber, fitted bite guard worn at night sometimes assists in the control of recurrence.[1,2]

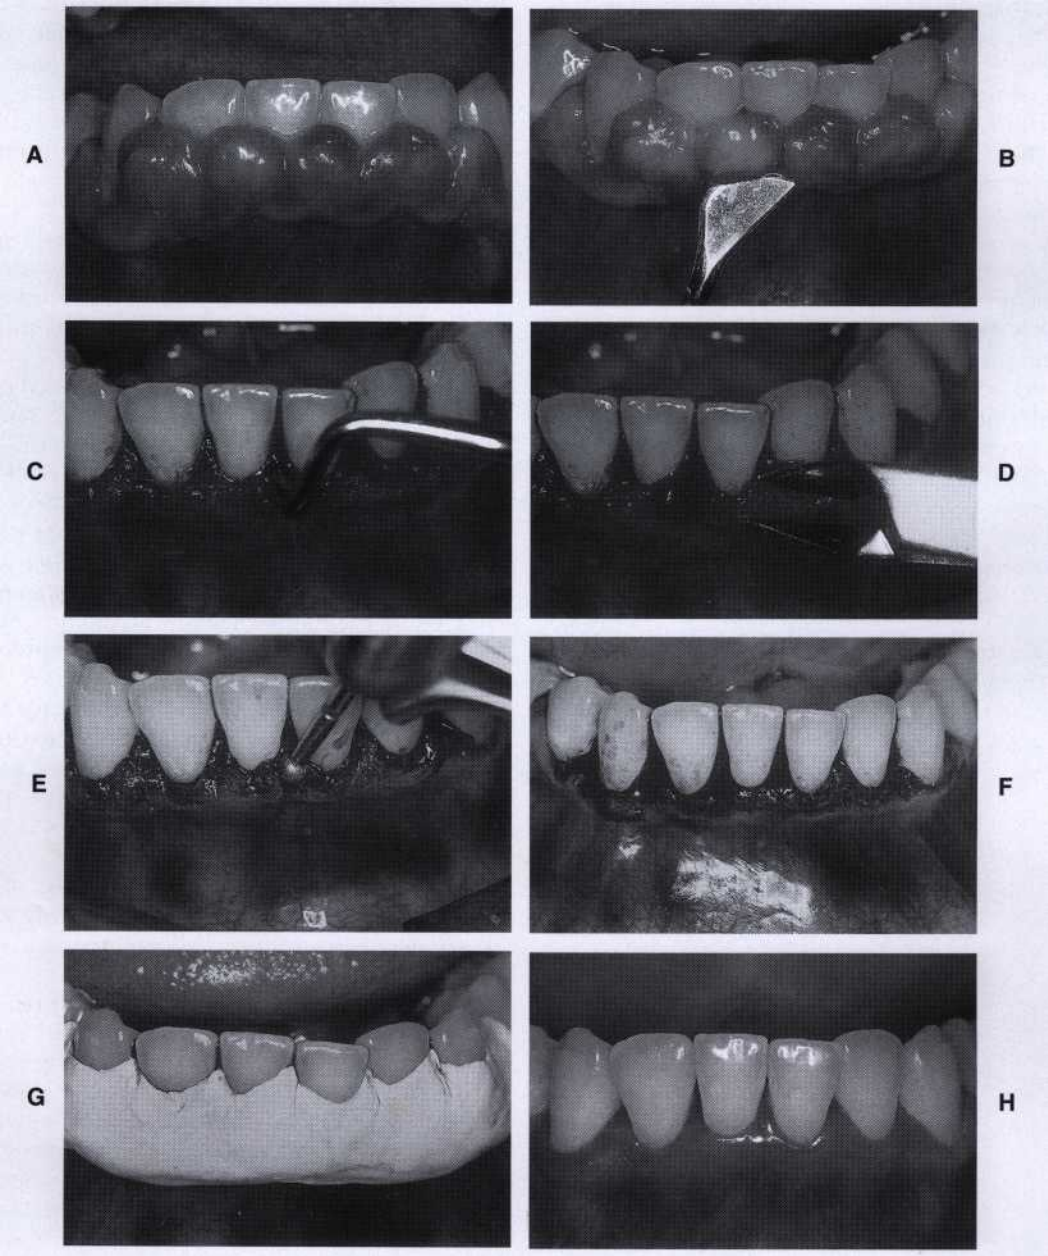

Fig. 59-5 Surgical treatment of cyclosporin-induced gingival enlargement using the gingivectomy technique on a 16-year-old girl who had received a kidney allograft 2 years previously. A, Presence of enlarged gingival tissues and pseudo-pocket formation; no attachment loss or evidence of vertical bone loss existed. B, Initial external bevel incision performed with a Kirkland knife. C, Interproximal tissue release achieved with an Orban knife. D and E, Gingivoplasty performed with tissue nippers and a round diamond at high speed with abundant refrigeration. F, Aspect of the surgical wound at the conclusion of the surgical procedure. G, Placement of noneugenol periodontal dressing. H, Surgical area 3 months postoperatively. Note the successful elimination of enlarged gingival tissue, restoration of a physiologic gingival contour, and maintenance of an adequate band of keratinized tissue.

Recurrence may occur as early as 3 to 6 months after the surgical treatment, but in general, surgical results are maintained for at least 12 months. One study" examined the recurrence of cyclosporine-induced gingival enlargement after treatment with the periodontal flap or gingivectomy and determined that increased pocket depth return is slower with the flap as revealed by 6-month postsurgical examination. Recurrence of periodontal tissue increased thickness, however, has not been objectively evaluated.

TREATMENT OF LEUKEMIC GINGIVAL ENLARGEMENT

Leukemic enlargement occurs in acute or subacute leukemia and is uncommon in the chronic leukemic state. The medical care of leukemic patients is often complicated by gingival enlargement with superimposed painful acute necrotizing ulcerative gingivitis, which interferes with eating and creates toxic systemic reactions. Bleeding and clotting times and platelet count of the patient should be checked and the hematologist consulted before periodontal treatment is instituted (see Chapter 38).

Treatment of acute gingival involvement is described in Chapter 45. After acute symptoms subside, attention is directed to correction of the gingival enlargement. The rationale is to remove the local irritating factors to control the inflammatory component of the enlargement.

The enlargement is treated by scaling and root planing carried out in stages under topical anesthesia. The initial treatment consists of gently removing all loose accumulations with cotton pellets, performing superficial scaling, and instructing the patient in oral hygiene for plaque control, which should include, at least initially, daily use of chlorhexidine mouthwashes. Oral hygiene procedures are extremely important in these cases and should be performed by the nurse if necessary.

Progressively deeper scalings are carried out at subsequent visits. Treatments are confined to a small area of the mouth to facilitate control of bleeding. Antibiotics are administered systemically the evening before and for 48 hours after each treatment to reduce the risk of infection.

B, After flap elevation, the enlarged portion of the gingival tissue is removed. C, The flap is placed on top of the alveolar bone and sutured.**

TREATMENT OF GINGIVAL ENLARGEMENT IN PREGNANCY

Treatment requires elimination of all local irritants responsible for precipitating the gingival changes in pregnancy. Elimination of local irritants early in pregnancy is a preventive measure against gingival disease, which is preferable to treatment of gingival enlargement after it occurs. Marginal and interdental gingival inflammation and enlargement are treated by scaling and curettage (see Chapters 42 and 47). Treatment of tumorlike gingival enlargements consists of surgical excision and scaling and planing of the tooth surface. The enlargement recurs unless all irritants are removed. Food impaction is frequently an inciting factor.

When to Treat

Gingival lesions in pregnancy should be treated as soon as they are detected, although not necessarily by surgical means. Scaling and root planing procedures and adequate oral hygiene measures may reduce the size of the enlargement. Gingival enlargements do shrink after pregnancy, but they usually do not disappear. After pregnancy, the entire mouth should be reevaluated, a full set of radiographs taken, and the necessary treatment undertaken.

Lesions should be removed surgically during pregnancy only if they interfere with mastication or produce an esthetic disfigurement that the patient wishes removed.

In pregnancy, the emphasis should be on 1) preventing gingival disease before it occurs and 2) treating existing gingival disease before it worsens. All patients should be seen as early as possible in pregnancy. Those without gingival disease should be checked for potential sources of local irritation and should be instructed in plaque control procedures. Those with gingival disease should be treated promptly, before the conditioning effect of pregnancy on the gingiva becomes manifest. Precautions necessary for periodontal treatment of pregnant women are presented in Chapter 37.

Every pregnant patient should be scheduled for periodic dental visits, the importance of which in the prevention of serious periodontal disturbances should be stressed.

TREATMENT OF GINGIVAL ENLARGEMENT IN PUBERTY

Gingival enlargement in puberty IS treated by performing scaling and curettage, removing all sources of irritation, and controlling plaque. Surgical removal may be required in severe cases. The problem in these patients is recurrence due to poor oral hygiene.

RECURRENCE OF GINGIVAL ENLARGEMENT

Recurrence after treatment is the most common problem in the management of gingival enlargement. Residual local irritation and systemic or hereditary conditions causing noninflammatory gingival hyperplasia are the responsible factors.

Recurrence of chronic inflammatory enlargement immediately after treatment indicates that all irritants have

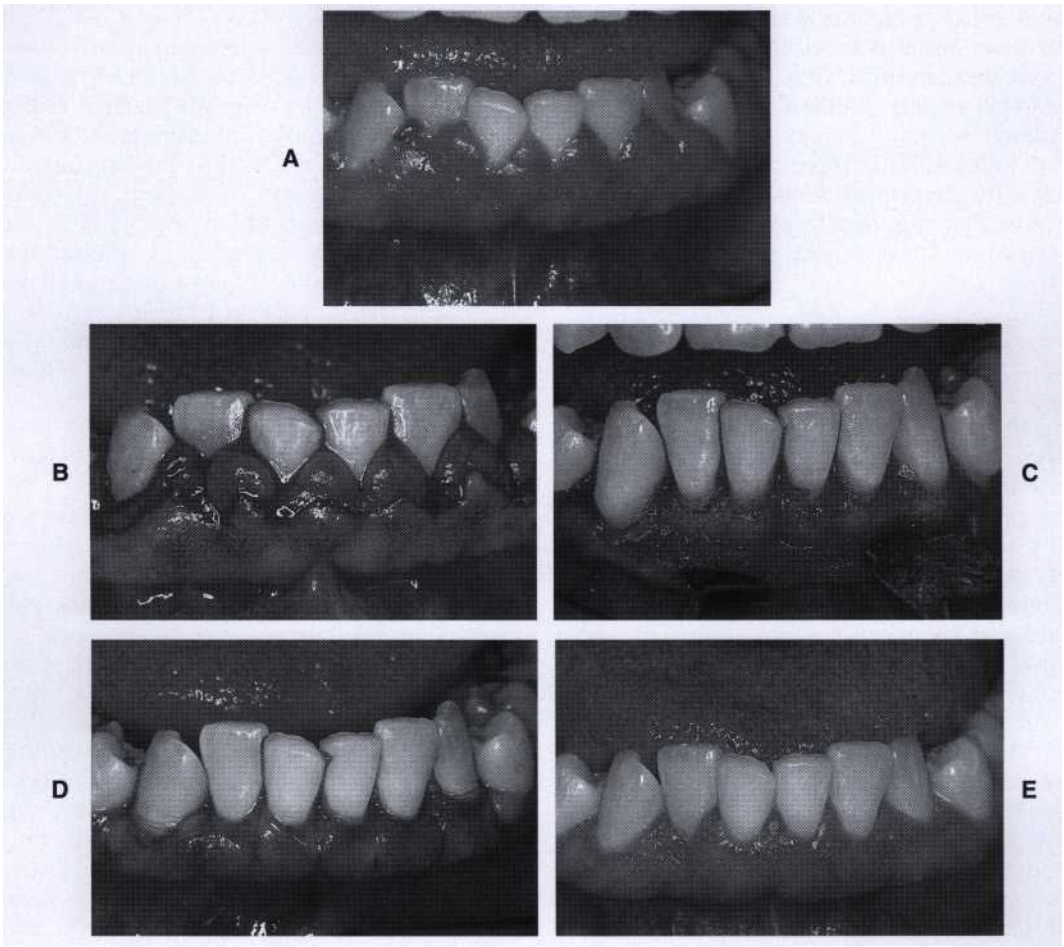

Fig. 59-7 Treatment of a case of a combined cyclosporin- and nifedipine-induced gingival enlargement with a periodontal flap on a 35-year-old female who had received a kidney allograft 31/2 years previously. A, Presurgical clinical aspect of the lower anterior teeth, showing severe gingival enlargement. B, Initial scalloped reverse bevel incision, including maintenance of keratinized tissue and creation of surgical papillae. C, Elevation of a full thickness flap and removal of the inner portion of the previously thinned gingival tissue; after scaling and root planing, osseous recontouring can be performed if necessary. D, The flap i5 positioned on top of the alveolar crest. E, Postsurgical aspect of the treated area at 12 months; note the reduction of enlarged tissue volume and acceptable gingival health.

not been removed. Contributory local conditions, such as food impaction and overhanging margins of restorations, are commonly overlooked. If the enlargement recurs after healing is complete and normal contour is attained, inadequate plaque control by the patient is the most common cause.

Recurrence during the healing period is manifested as red, beadlike, granulomatous masses that bleed on slight provocation. This is a proliferative vascular inflammatory response to local irritation, usually a fragment of calculus on the root. The condition is corrected by removing the granulation tissue and scaling and planing the root surface.

Familial, hereditary, or idiopathic gingival enlargement recurs after surgical removal, even if all local irritants have been removed. The enlargement can be maintained at minimal size by preventing secondary inflammatory involvement.

The use o f escharotic drugs has been recommended in the past for the removal of gingival enlargements, but its use is currently *not* recommended. The destructive action of the drugs is difficult to control; injury to healthy tissue and root surfaces, delayed healing, and excessive postoperative pain are complications that can be avoided when the gingiva is removed with periodontal knives and scalpels or by electrosurgery.

HEALING AFTER FLAP SURGERY

A periodontal flap is a section of gingiva and/or mucosa surgically separated from the underlying tissues to provide visibility of and access to the bone and root surface. The flap also allows the gingiva to be displaced to a different location in patients with mucogingival involvement (Color Fig. 60-1).

CLASSIFICATION OF FLAPS

Periodontal flaps can be classified based on the following:

- Bone exposure after flap reflection
- Placement of the flap after surgery
- Management of the papilla

Based on bone exposure after reflection, the flaps are classified as either full thickness (mucoperiosteal) or partial thickness (mucosal) flaps (Fig. 60-1).

In full thickness flaps, all the soft tissue, including the periosteum, is reflected to expose the underlying bone. This complete exposure of, and access to, the underlying bone is indicated when resective osseous surgery is contemplated.

The partial thickness flap includes only the epithelium and a layer of the underlying connective tissue. The bone remains covered by a layer of connective tissue, including the periosteum. This type of flap is also called the *split thickness flap.* The partial thickness flap is indicated when the flap is to be positioned apically or when the operator does not desire to expose bone.

There are conflicting data regarding the advisability of uncovering the bone when this is not actually needed. When bone is stripped of its periosteum, a loss of marginal bone occurs, and this loss is prevented when the periosteum is left on the bone.[4] The differences, however, are usually not clinically significant,[1] although sometimes they may be (Fig. 60-2). The partial thickness flap may be necessary in cases in which the crestal bone margin is thin and is exposed when the flap is placed apically, or when dehiscences or fenestrations are present. The periosteum left on the bone may also be used for suturing the flap when it is displaced apically.

Based on flap placement after surgery, flaps are classified as 1) *nondisplaced flaps,* when the flap is returned and sutured in its original position; or 2) *displaced flaps* that are placed apically, coronally, or laterally to their original position. Both full thickness and partial thickness flaps can be displaced, but to do so, the attached gingiva has to be totally separated from the underlying bone, thereby enabling the unattached portion of the gingiva to be moveable. However, palatal flaps cannot be displaced owing to the absence of unattached gingiva.

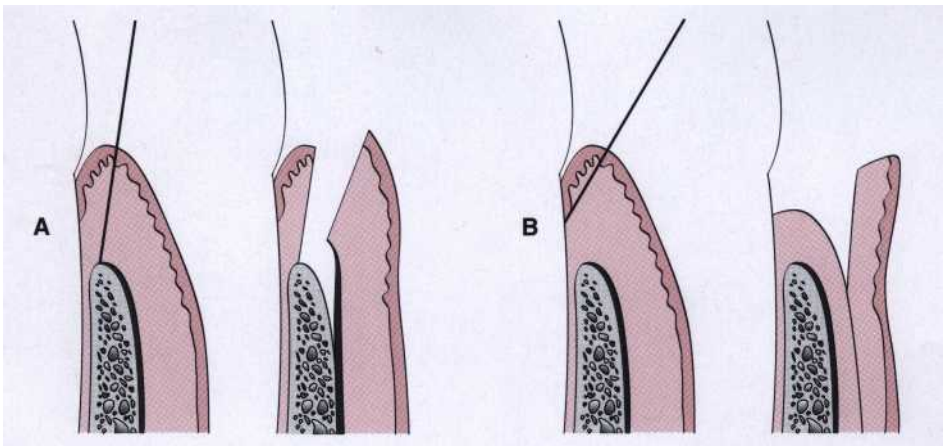

Fig. 60-1 A, Diagram of the internal bevel incision (first incision) to reflect a full thickness (mucoperiosteal) flap. Note that the incision ends on the bone to allow for the reflection of the entire flap. B, Diagram of the internal bevel incision to reflect a partial thickness flap. Note that the incision ends on the root surface to preserve the periosteum on the bone.

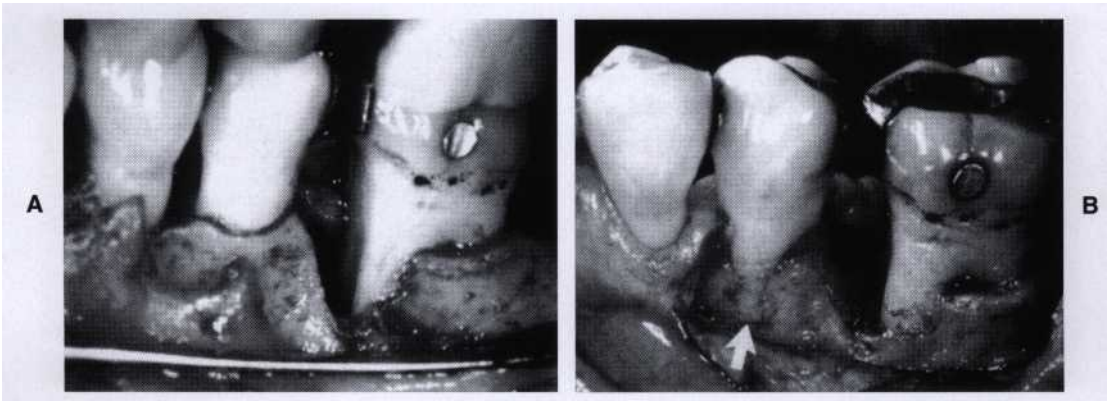

Fig. 60-2 Loss of marginal bone as a result of uncovering the osseous crest. A, Mucoperiosteal flap elevated as part of a clinical study. B, Reentry performed 6 months later reveals loss of marginal bone facial to second premolar (arrow). (Courtesy Dr. Silvia Oreamuno; San Jose, Costa Rica.)

Apically displaced flaps have the important advantage of preserving the outer portion of the pocket wall and transforming it into attached gingiva. Therefore they accomplish the double objective of eliminating the pocket and increasing the width of the attached gingiva.

Based on management of the papilla, flaps can be conventional or papilla preservation flaps. In the conventional flap the interdental papilla is split beneath the contact point of the two approximating teeth to allow reflection of buccal and lingual flaps. The incision is usually scalloped to maintain gingival morphology with as much papilla as possible. The conventional flap is used when 1) the interdental spaces are too narrow, thereby precluding the possibility of preserving the papilla, and 2) when the flap is to be displaced.

Conventional flaps include the modified Widman flap, the undisplaced flap, the apically displaced flap, and the flap for regenerative procedures. These techniques are described in detail in Chapter 61.

The papilla preservation flap incorporates the entire papilla in one of the flaps by means of crevicular interdental incisions to sever the connective tissue attachment and a horizontal incision at the base of the papilla, leaving it connected to one of the flaps.

DESIGN OF THE FLAP

The design of the flap is dictated by the surgical judgement of the operator and may depend on the objectives of the operation. The degree of access to the underlying bone and root surfaces necessary and the final position of the flap must be considered in designing the flap. Preservation of good blood supply to the flap is an important consideration.

Two basic flap designs are used. Depending on how the interdental papilla is dealt with, flaps can either split the papilla (conventional flap) or preserve it (papilla preservation flap).

In the conventional flap operation, the incisions for the facial and the lingual or palatal flap reach the tip of

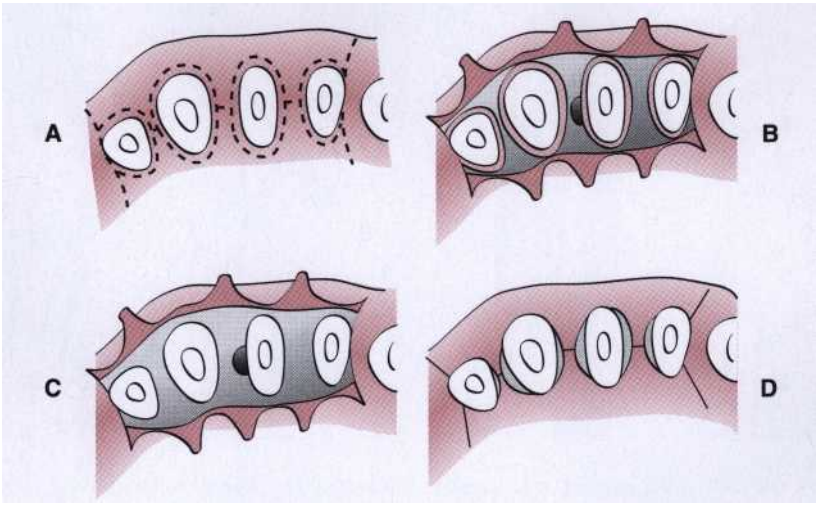

Fig. 60-3 Flap design for the conventional or traditional flap technique. A, Design of the incisions: the internal bevel incision, splitting the papilla, and the vertical incisions are drawn in interrupted lines. B, The flap has been elevated, and the wedge of tissue next to the tooth is still in place. C, All marginal tissue has been removed, exposing the underlying bone (see defect in one space). D, Tissue returned to its original positron. Proximal areas are not totally covered.

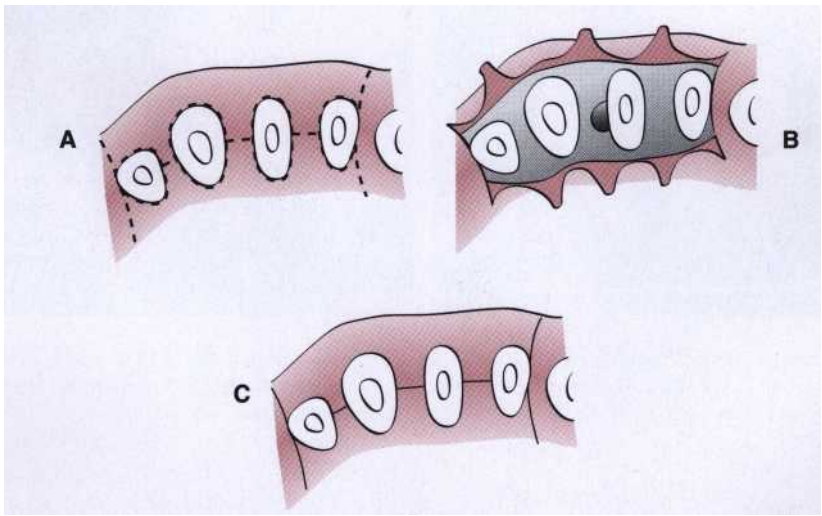

Fig. 60-4 Flap design for a sulcular incision flap. A, Design of the incisions: the sulcular incisions and the vertical incisions are depicted by interrupted lines. B, The flap has been elevated, exposing the underlying bone (see defect in one space). C, Tissue returned to its original position covers the entire interdental spaces.

the interdental papilla or its vicinity, thereby splitting the papilla into a facial half and a lingual or palatal half (Figs. 60-3 and 60-4).

The entire surgical procedure should be planned in every detail before the intervention is begun. This should include the type of flap, exact location and type of incisions, management of the underlying bone, and final closure of the flap and sutures. Although some details may be modified during the actual performance of the procedure, detailed planning allows for a better clinical result.

INCISIONS

Horizontal Incisions

Periodontal flaps use horizontal and vertical incisions. Horizontal incisions are directed along the margin of the gingiva in a mesial or a distal direction (Fig. 60-5). Two types of horizontal incisions have been recommended: the internal bevel incision,[6] which starts at a distance from the gingival margin and is aimed at the bone crest, and the crevicular incision, which starts at the bottom of the pocket and is directed to the bone margin. In

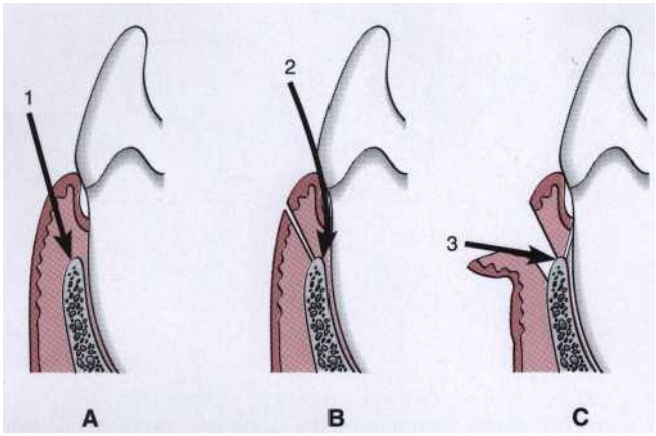

Fig. 60-5 A to C, The first (internal bevel), second (crevicular), and third (interdental) incisions are the three incisions necessary for flap surgery.

Fig. 60-6 Position of knife in performing internal bevel incision.

addition, the interdental incision is performed after the flap is elevated.

The *internal bevel incision is* basic to most periodontal flap procedures. It is the incision from which the flap is reflected to expose the underlying bone and root. The internal bevel incision accomplishes three important objectives: 1) it removes the pocket lining; 2) it conserves the relatively uninvolved outer surface of the gingiva, which, if apically positioned, becomes attached gingiva; and 3) it produces a sharp, thin flap margin for adaptation to the bone-tooth junction. This incision has also been termed the first incision because it is the initial incision in the reflection of a periodontal flap, and the reverse bevel incision, because its bevel is in reverse direction from that of the gingivectomy incision. The #11 or #15 surgical scalpel is used most commonly. That portion

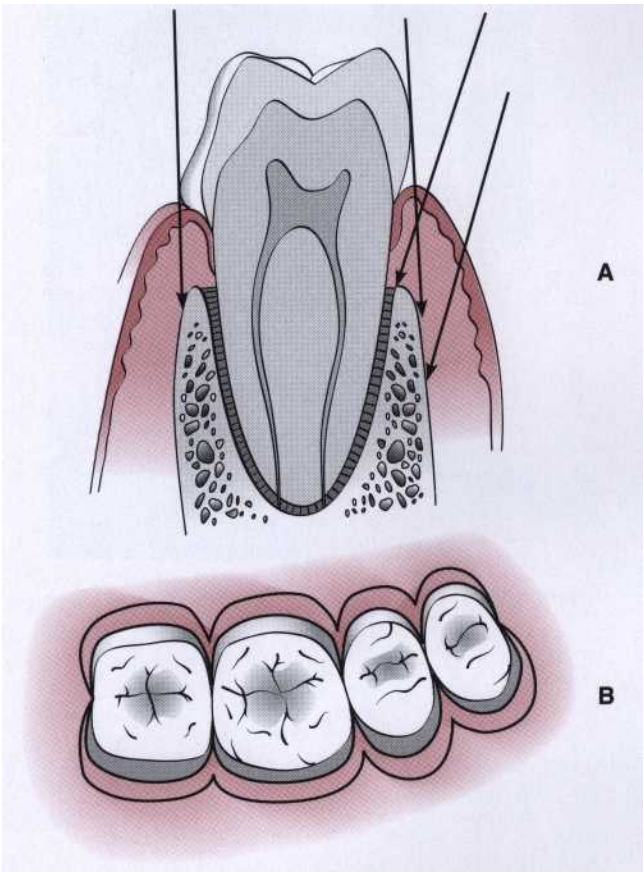

Fig. 60-7 A, The internal bevel (first) incision can be made at varying locations and angles according to the different anatomic and pocket situations. B, An occlusal view of the different locations where the internal bevel incision can be made. Note the scalloped shape of the incisions.

of the gingiva left around the tooth contains the epithelium of the pocket lining and the adjacent granulomatous tissue. It is discarded after the crevicular (second) and interdental (third) incisions are performed (see Fig. 60-5).

The internal bevel incision starts from a designated area on the gingiva and is directed to an area at or near the crest of the bone (Fig. 60-6). The starting point on the gingiva is determined by whether the flap is apically displaced or not displaced (Fig. 60-7).

The *crevicular incision,* also termed the second incision, is made from the base of the pocket to the crest of the bone (Fig. 60-8). This incision, together with the initial reverse bevel incision, forms a V-shaped wedge ending at or near the crest of bone; this wedge of tissue contains most of the inflamed and granulomatous areas that constitute the lateral wall of the pocket, as well as the junctional epithelium and the connective tissue fibers that still persist between the bottom of the pocket and the crest of the bone. The incision is carried around the entire tooth. The beak-shaped #12D blade is usually used for this incision.

Fig. *60-8* **Position of knife in performing crevicular incision.**

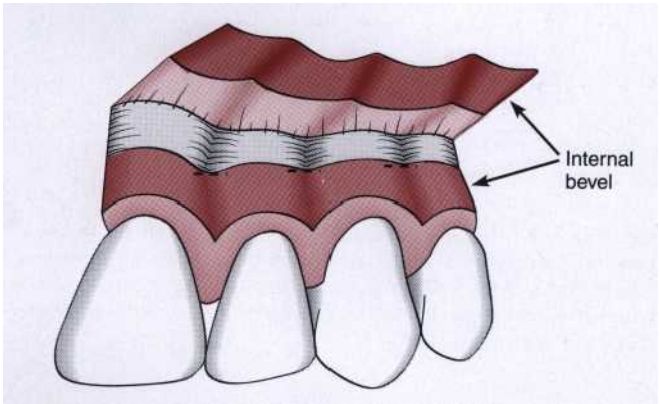

Fig. 60-9 After the flap has been elevated, a wedge of tissue remains on the teeth, attached by the base of the papillae. An interdental incision along the horizontal lines seen in the interdental spaces will sever these connections.

A periosteal elevator is inserted into the initial internal bevel incision, and the flap is separated from the bone. The most apical end of the internal bevel incision is more exposed and visible. With this access, the surgeon is able to make the third or *interdental incision* to separate the collar of gingiva that is left around the tooth. The Orban knife is usually used for this incision. The incision is made not only around the facial and lingual radicular area but also interdentally, connecting the facial and lingual segments, to completely free the gingiva around the tooth (Fig. 60-9; see Fig. 60-5).

These three incisions allow the removal of the gingiva around the tooth (i.e., the pocket epithelium and the adjacent granulomatous tissue). A curette or a large scaler (U15/30) can be used for this purpose. After removal of the large pieces of tissue, the remaining connective tissue in the osseous lesion should be carefully curetted out so that the entire root and the bone surface adjacent to the teeth can be observed.

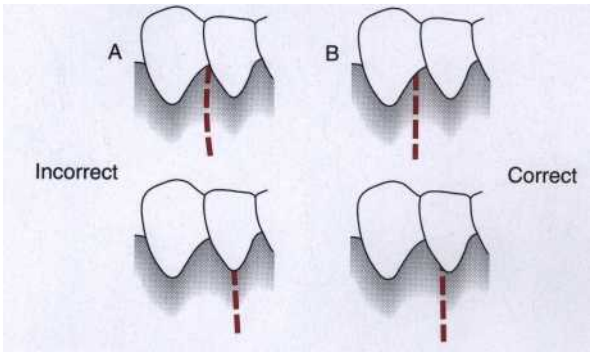

Fig. 60-10 Incorrect (A) and correct (B) locations of a vertical incision. This incision should be made at the line angles to prevent splitting of a papilla or incising directly over a radicular surface.

Flaps can be reflected using only the horizontal incision if sufficient access can be obtained by this means and if apical, lateral, or coronal displacement of the flap is not anticipated. If no vertical incisions are made, the flap is called an *envelope* flap.

Vertical Incisions

Vertical or oblique releasing incisions can be used on one or both ends of the horizontal incision, depending on the design and purpose of the flap. Vertical incisions at both ends are necessary if the flap is to be apically displaced. Vertical incisions must extend beyond the mucogingival line, reaching the alveolar mucosa, to allow for the release of the flap to be displaced (see Chapter 61).

In general, vertical incisions in the lingual and palatal areas are avoided. Facial vertical incisions should not be made in the center of an interdental papilla or over the radicular surface of a tooth. Incisions should be made at the line angles of a tooth either to include the papilla in the flap or to avoid it completely (Fig. 60-10). The vertical incision should also be designed so as to avoid short flaps (mesiodistal) with long, apically directed horizontal incisions because these could jeopardize the blood supply to the flap.

Several investigators[1,2,11,12] proposed the so-called interdental denudation procedure, which consists of horizontal, internal bevel, nonscalloped incisions to remove the gingival papillae and denude the interdental space. This technique completely eliminates the inflamed interdental areas, which heal by secondary intention, and results in excellent gingival contour. It is contraindicated when bone grafts are used.

ELEVATION OF THE FLAP

When a full thickness flap is desired, the reflection is accomplished by blunt dissection. A periosteal elevator is used to separate the mucoperiosteum from the bone by moving it mesially, distally, and apically until the desired reflection is accomplished (Fig. 60-11).

Sharp dissection is necessary to reflect a partial thickness flap. A surgical scalpel (#11 or #15) is used (Fig. 60-12).

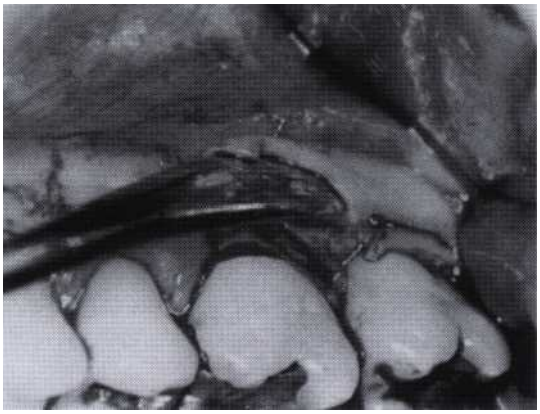

Fig. 60-11 Elevation of the flap with a periosteal elevator to obtain a full thickness flap.

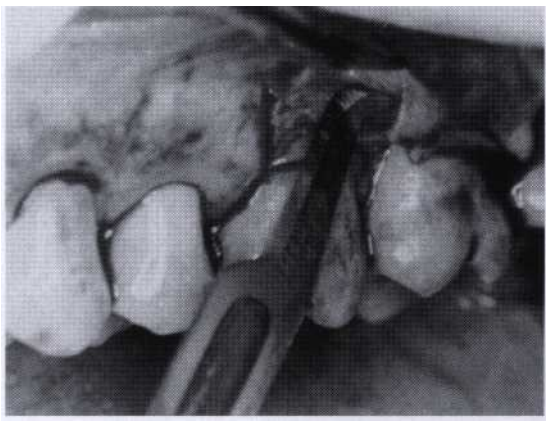

Fig. 60-12 Elevation of the flap with a Bard-Parker knife to obtain a split thickness flap.

A combination of full and partial thickness flaps can often be indicated to obtain the advantages of both. The flap is started as a full thickness procedure, and then a partial thickness flap is made at the apical portion. In this way the coronal portion of the bone, which may be subject to osseous remodeling, is exposed while the remaining bone remains protected by its periosteum.

SUTURING TECHNIQUES

After all the necessary procedures are completed, the area is reexamined and cleansed, and the flap is placed in the desired position, where it should remain without tension. It is convenient to keep it in place with light pressure with a piece of gauze so that a blood clot can form. The purpose of suturing is to maintain the flap in the desired position until healing has progressed to the point where sutures are no longer needed.

There are many types of sutures, suture needles, and materials.5,10 Suture materials may be either nonresorbable or resorbable, and they may be further categorized as braided or monofilaments. The resorbable sutures have gained popularity since they enhance patient comfort and eliminate suture removal appointments. The monofilament type of suture alleviates the "wicking effect" of braided sutures that may allow bacteria from the oral cavity to be drawn through the suture to the deeper areas of the wound. Box 60-1 is a classification of the sutures available today:

The nonresorbable, braided silk suture was the most commonly used in the past due to its ease of use and low cost. The expanded polytetrafluoroethylene synthetic monofilament is an excellent nonresorbable suture widely used today.

The most commonly used resorbable sutures are the natural, plain gut and the chromic gut. Both are monofilaments and are processed from purified collagen of either sheep or cattle intestines. The chromic suture is a plain gut suture processed with chromic salts to make it resistant to enzymatic resorption, thereby increasing the resorption time. The synthetic resorbable sutures are also often used.

BOX 60-1

Sutures for Periodontal Flaps

Nonabsorbable
Silk: braided
Nylon: monofilament (Ethilon)
EPTfe: monofilament (Gore-tex)
Polyester: braided (Ethibond)

Absorbable
Surgical: gut
Plain gut; monofilament (30 days)
Chromic gut; monofilament (45–60 days)

Synthetic
Polyglycolic: braided (16–20 days)
(Vicryl; Ethicon)
(Dexon; Davis & Geck)
Polyglecaprone: monofilament (90–120 days)
(Monocryl; Ethicon)
Polyglyconate: monofilament (Maxon)

Technique

The needle is held with the needle holder and should enter the tissues at right angles and no less than 2 to 3 mm from the incision. The needle is then carried through the tissue, following the needle's curvature. The knot should not be placed over the incision.

The periodontal flap is closed either with independent sutures or with continuous, independent sling sutures. The latter method eliminates the pulling of the buccal and lingual or palatal flaps together and instead, uses the teeth as an anchor for the flaps. There is less tendency for the flaps to buckle, and the forces on the flaps are better distributed.

Sutures of any kind placed in the interdental papillae should enter and exit the tissue at a point located below

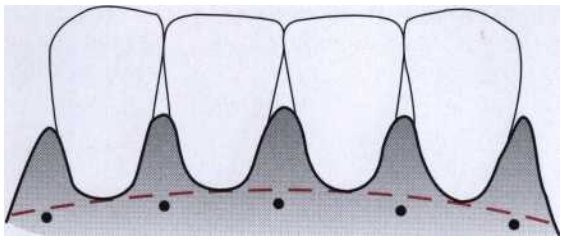

Fig. 60-13 Placement of suture in the interdental space below the base of an imaginary triangle in the papilla.

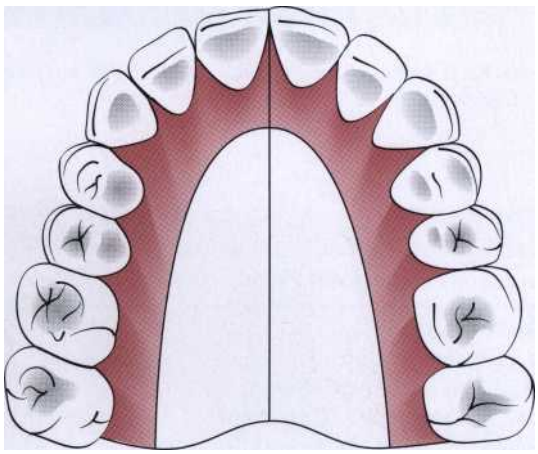

Fig. 60-14 Placement of sutures for closing a palatal flap. For slightly or moderately elevated flaps, the sutures are placed in shaded areas; for more substantial elevation of the flap, they are placed in the central (unshaded) area of their palate.

the imaginary line that forms the base of the triangle of the interdental papilla (Fig. 60-13). The location of sutures for closure of a palatal flap depend on the extent of flap elevation that has been performed. The flap is divided in four quadrants as depicted in Fig. 60-14. If the elevation of the flap is slight or moderate, the sutures can be placed in the quadrant closest to the teeth. If the flap elevation is substantial, the sutures should be placed in the central quadrants of the palate.

One may or may not use periodontal dressings. When the flaps are not apically displaced, it is not necessary to use dressings other than for patient comfort.

Ligation

Interdental Ligation. Two types of interdental ligation can be used: the director loop suture (Fig. 60-15) and the figure-eight suture (Fig. 60-16). In the figure-eight suture, there is thread between the two flaps. This suture is therefore used when the flaps are not in close apposition because of apical flap position or nonscalloped incisions. It is simpler to perform than the direct ligation. The direct suture permits a better closure of the interdental papilla and should be performed when bone grafts are used or when close apposition of the scalloped incision is required.

Sling Ligation. The sling ligation can be used for a flap on one surface of a tooth that involves two interdental spaces (Fig. 60-17).

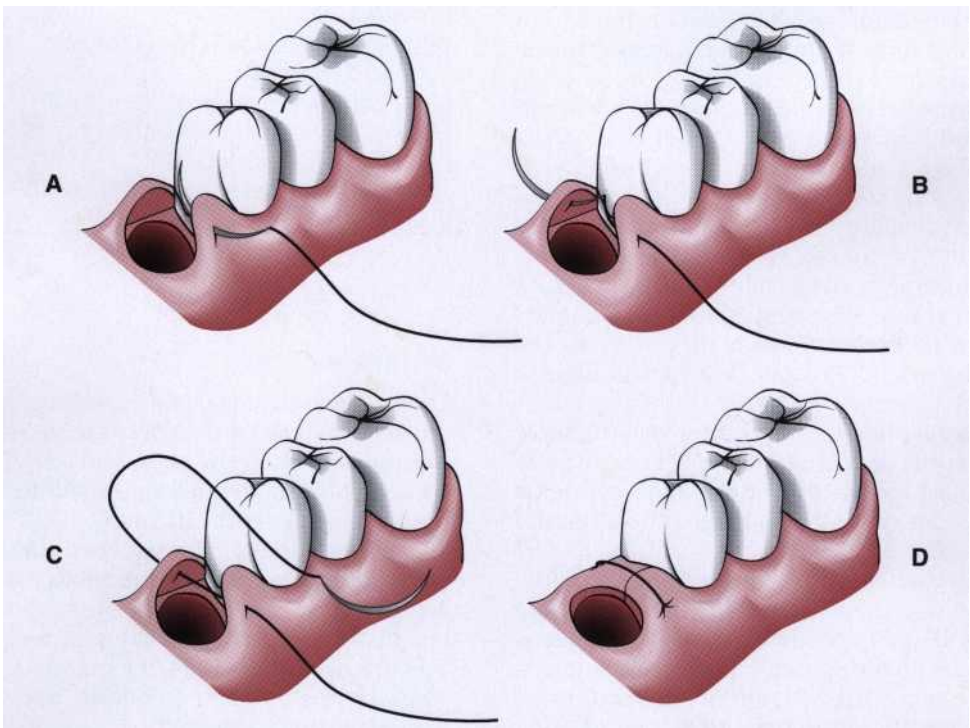

Fig. 60-15 A simple loop suture is used to approximate the buccal and lingual flaps. A, The needle penetrates the outer surface of the first flap. B, The undersurface of the opposite flap is engaged, and the suture is brought back to the initial side (C), where the knot is tied (D).

Types of Sutures

Horizontal Mattress Suture. This suture is often used for the interproximal areas of diastemata or for wide interdental spaces to properly adapt the interproximal papilla against the bone. Two sutures are often necessary. The horizontal mattress suture can be incorporated with continuous, independent sling sutures, as shown in Fig. 60-18.

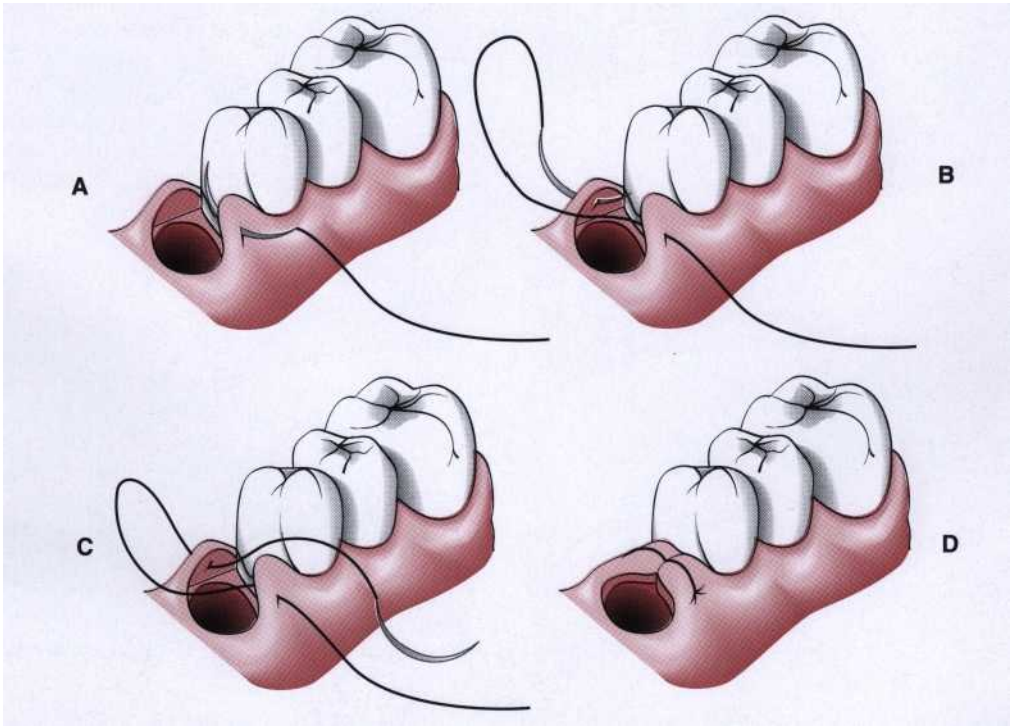

Fig. 60-16 An interrupted figure-eight suture is used to approximate the buccal and lingual flaps. The needle penetrates the outer surface of the first flap (A) and the outer surface of the opposite flap (B). The suture is brought back to the first flap (C), and the knot is tied (D).

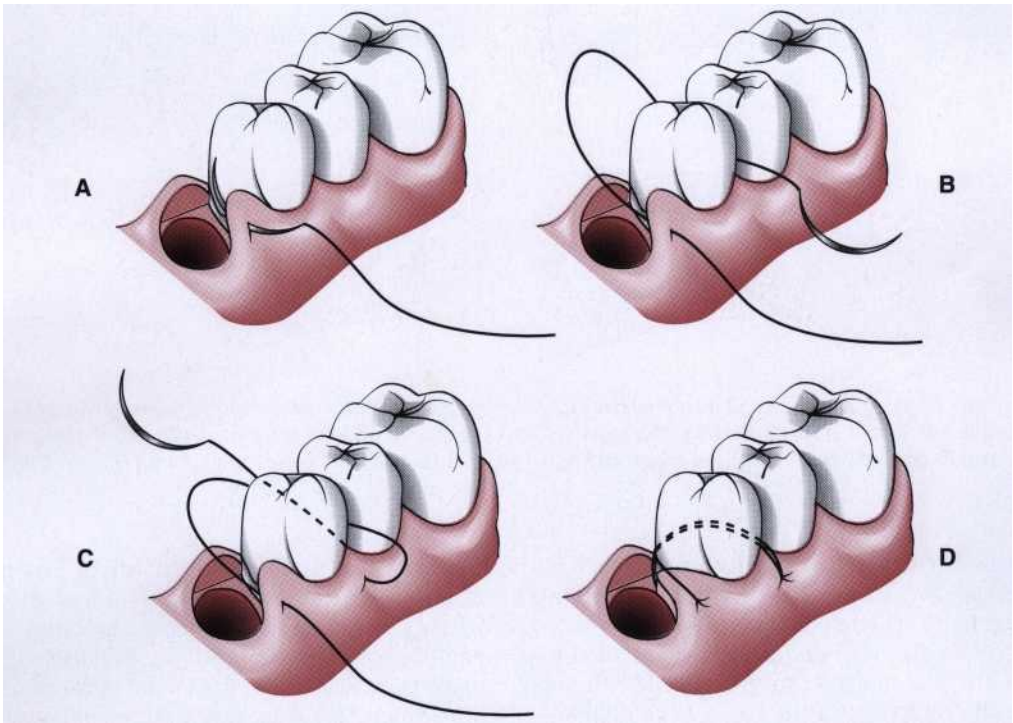

Fig. 60-17 A single, interrupted sling suture is used to adapt the flap around the tooth. A, The needle engages the outer surface of the flap and encircles the tooth (B). C, The outer surface of the same flap of the adjacent interdental area is engaged. D, the suture is returned to the initial site and the knot tied.

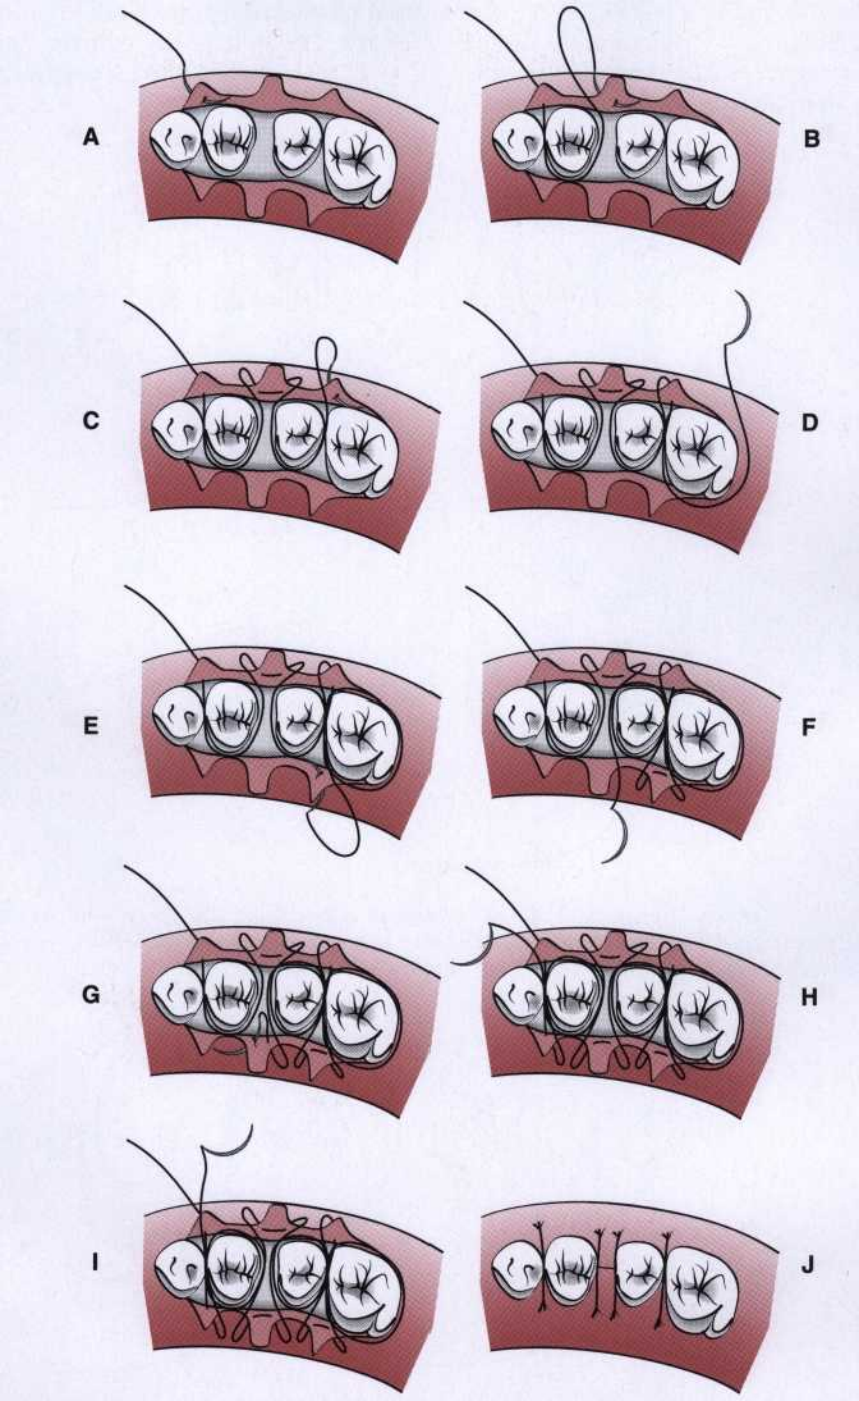

Fig. 60-18 A, Continuous, independent sling suture using a horizontal mattress suture around diastemata or wide interdental areas (B and C). This mattress suture is utilized on both the buccal (D) and the lingual (E and F) surfaces. Continuation of suture on lingual surfaces (G to I) and completed suture (1).

The penetration of the needle is performed in such a way that the mesial and distal edges of the papilla lie snugly against the bone. The needle enters the outer surface of the gingiva and crosses the undersurface of the gingiva horizontally. The mattress sutures should not be close together at the midpoint of the base of the papilla. The needle reappears on the outer surface at the other base of the papilla and continues around the tooth with the sling sutures.

Continuous Independent Sling Suture. This is used when there is both a facial and a lingual flap involving many teeth. The suture is initiated on the facial papilla closest to the midline, because this is the easiest place to position the final knot (Fig. 60-19). A continuous sling suture is laced for each papilla on the facial surface. When the last tooth is reached, the suture is anchored around it to prevent any pulling of the facial sutures when the lingual flap is sutured around the teeth

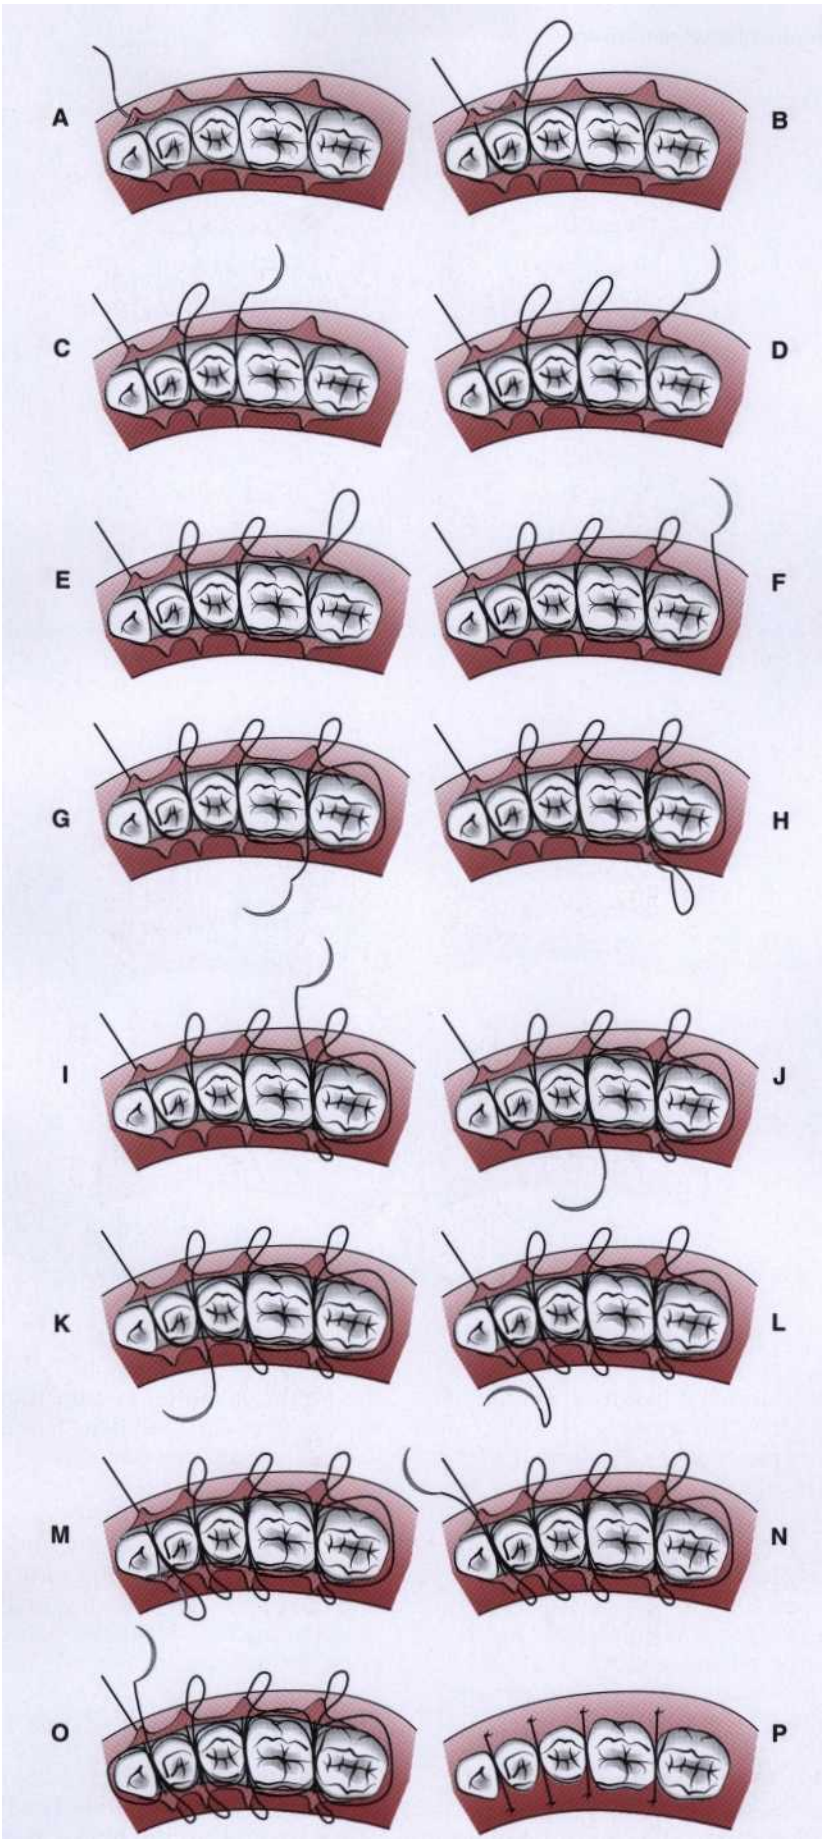

Fig. 60-19 The continuous, independent sling suture is used to adapt the buccal and lingual flaps without tying the buccal flap to the lingual flap. The teeth are used to suspend each flap against the bone. It is important to anchor the suture on the two teeth at the beginning and end of the flap so that the suture will not pull the buccal flap to the lingual flap.

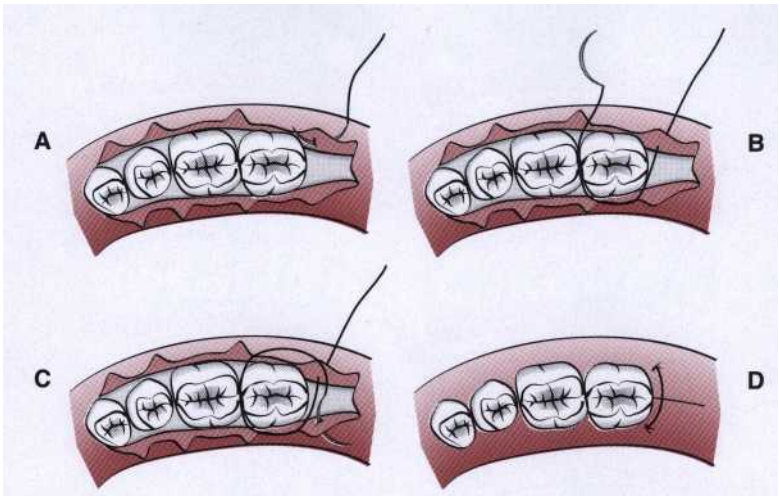

Fig. 60-20 A to D, Distal wedge suture. This suture is also used to close flaps that are mesial or distal to a lone-standing tooth.

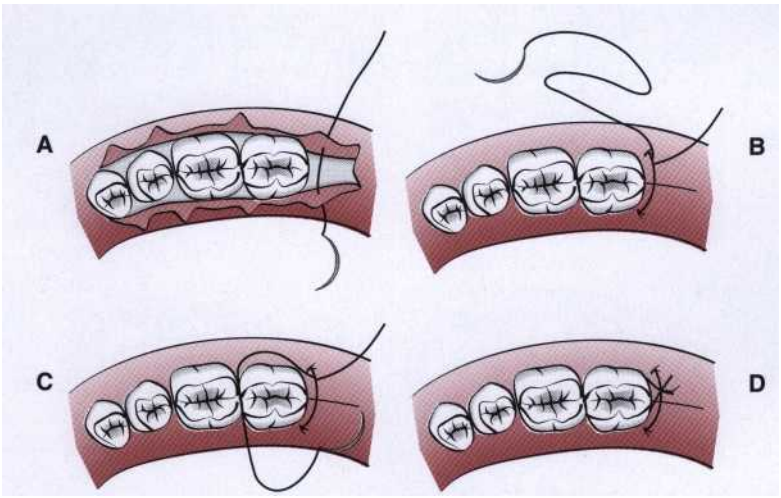

Fig. 60-21 The closed anchor suture, another technique to suture distal wedges.

in a similar fashion. The suture is again anchored around the last tooth before tying the final knot.

This type of suture does not produce a pull on the lingual flap when the latter is sutured. The two flaps are completely independent of each other owing to the anchoring around both the initial and the final tooth. The flaps are tied to the teeth and not to each other because of the sling sutures.

This type of suturing is especially appropriate for the maxillary arch because the palatal gingiva is attached and fibrous, whereas the facial tissue is thinner and mobile.

Anchor Suture. The closing of a flap mesial or distal to a tooth, as in the mesial or distal wedge procedures, is best accomplished by the anchor suture. This suture closes the facial and lingual flaps and adapts them tightly against the tooth. The needle is placed at the line angle area of the facial or lingual flap adjacent to the tooth, anchored around the tooth, passed beneath the opposite flap, and tied. The anchor suture can be repeated for each area that requires it (Fig. 60-20).

Closed Anchor Suture. Another technique to close a flap located in an edentulous area mesial or distal to a tooth consists of tying a direct suture that closes the proximal flap, carrying one of the threads around the tooth to anchor the tissue against the tooth, and then tying the two threads (Fig. 60-21).

Periosteal Suture. This type of suture is used to hold in place apically displaced partial thickness flaps. There are two types of periosteal sutures: the holding suture and the closing suture. The holding suture is a horizontal mattress suture placed at the base of the displaced flap to secure it into the new position. Closing sutures are used to secure the flap edges to the periosteum. Both types of periosteal sutures are shown in Fig. 60-22.

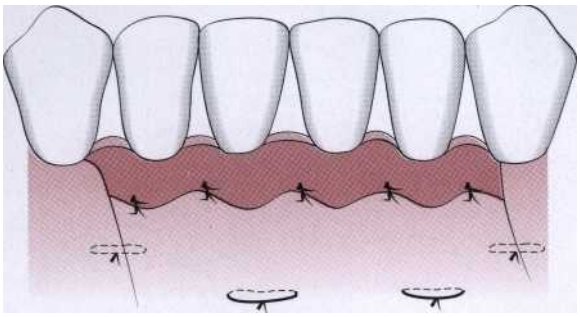

Fig. 60-22 Periosteal sutures for an apically displaced flap. Holding sutures, shown at the bottom, are done first, followed by the closing sutures, shown at the coronal edge of the flap.

HEALING AFTER FLAP SURGERY

Immediately after suturing (0 to 24 hours), a connection between the flap and the tooth or bone surface is established by a blood clot, which consists of a fibrin reticulum with many polymorphonuclear leukocytes, erythrocytes, debris of injured cells, and capillaries at the edge of the wound. A bacteria and an exudate or transudate also result from tissue injury.

One to 3 days after flap surgery, the space between the flap and the tooth or bone is thinner, and epithelial cells migrate over the border of the flap, usually contacting the tooth at this time. When the flap is closely adapted to the alveolar process, there is only a minimal inflammatory response .[3]

One week after surgery, an epithelial attachment to the root has been established by means of hemidesmosomes and a basal lamina. The blood clot is replaced by granulation tissue derived from the gingival connective tissue, the bone marrow, and the periodontal ligament.

Two weeks after surgery, collagen fibers begin to appear parallel to the tooth surface.' Union of the flap to the tooth is still weak, owing to the presence of immature collagen fibers, although the clinical aspect may be almost normal.

One month after surgery, a fully epithelialized gingival crevice with a well-defined epithelial attachment is present. There is a beginning functional arrangement of the supracrestal fibers.

Full-thickness flaps, which denude the bone, result in a superficial bone necrosis at 1 to 3 days; osteoclastic resorption follows and reaches a peak at 4 to 6 days, declining thereafter." This results in a loss of bone of about 1 mm[3,16]; the bone loss is greater if the bone is thin .[14,11]

Osteoplasty (thinning of the buccal bone) using diamond burs, included as part of the surgical technique, results in areas of bone necrosis with reduction in bone height, which is later remodeled by new bone formation. Therefore the final shape of the crest is determined more by osseous remodeling than by surgical reshaping. This may not be the case when osseous remodeling does not include excessive thinning of the radicular bone.' Bone repair reaches its peak at 3 to 4 weeks."

Loss of bone occurs in the initial healing stages both in radicular bone and in interdental bone areas. However, in interdental areas, which have cancellous bone, the subsequent repair stage results in total restitution without any loss of bone; whereas in radicular bone, particularly if thin and unsupported by cancellous bone, bone repair results in loss of marginal bone.

The Flap Technique for Pocket Therapy

Fermin A. Carranza and Henry H. Takei

CHAPTER

CHAPTER OUTLINE

THE MODIFIED WIDMAN FLAP
THE UNDISPLACED FLAP
The Palatal Flap
THE APICALLY DISPLACED FLAP
FLAPS FOR REGENERATIVE SURGERY
The Papilla Preservation Flap
Conventional Flap for Regenerative Surgery
DISTAL MOLAR SURGERY

Several techniques can be used for the treatment of periodontal pockets. The periodontal flap is one of the most commonly employed procedures, particu larly for moderate and deep pockets in posterior areas (see Chapter 54).

Flaps are used for pocket therapy to accomplish the following:

1. Increase accessibility to root deposits
2. Eliminate or reduce pocket depth by resection of the pocket wall
3. Expose the area to perform regenerative methods

To fulfill these purposes several flap techniques are available and in current use.

The modified Widman flap facilitates instrumentation but does not attempt to reduce pocket depth. Two flap techniques have as their main purpose the reduction or elimination of pocket depth: the now-displaced flap and the apically displaced flap. The decision of whether to perform one or the other depends on two important anatomical landmarks: pocket depth and the location of the mucogingival junction. These landmarks establish the presence and width of the attached gingiva, which is the basis for the decision.

The *modified Widman flap* has been described for exposing the root surfaces for meticulous instrumentation and for removal of the pocket lining'; it is not intended to eliminate or reduce pocket depth, except for the reduction that occurs in healing by tissue shrinkage.

The *undisplaced (unrepositioned) flap,* in addition to improving accessibility for instrumentation, removes the pocket wall, thereby reducing or eliminating the pocket. This is essentially an excisional procedure of the gingiva.

The *apically displaced flap* also improves accessibility and eliminates the pocket, but does the latter by apically positioning the soft tissue wall of the pocket.' Therefore it preserves and/or increases the width of the attached gingiva by transforming the previously unattached keratinized pocket wall into attached tissue. This increase in width of the band of attached gingiva is supposedly based on an apical shift of the mucogingival junction, which includes apical displacement of the muscle attachments. A study made before and 18 years after apically displaced flaps failed to show a permanent relocation of the mucogingival junction.' All three techniques use the basic incisions described in Chapter 60: the internal bevel incision, the crevicular incision, and the interdental incision. However, there are important variations in the way in which these incisions are performed for the different types of flaps.

The modified Widman flap does not intend to remove the pocket wall, but it does eliminate the pocket lining. Therefore the internal bevel incision starts close (no more than 1 to 2 mm apically) to the gingival margin and follows the normal scalloping of the gingival margin (Figs. 61-1 and 61-2).

For the apically displaced flap, the pocket wall also must be preserved to be positioned apically while its

lining is removed. The purpose of this surgical technique is to preserve the maximum amount of keratinized gingiva of the pocket wall to displace it apically and transform it into attached gingiva. For this reason, the internal bevel incision should be made as close to the tooth as possible (0.5 to 1.0 mm) (see Fig. 61-1).

There is no need to determine where the bottom of the pocket is in relation to the incision, as one would for the undisplaced flap; the flap is placed approximately at the tooth-bone junction by apically displacing the flap. Its final position is not determined by the placement of this first incision.

For an undisplaced flap, however, the internal bevel incision is initiated at or near a point just coronal to the projection of the bottom of the pocket on **the outer surface of the gingiva (see Fig. 61-1).** This incision can be accomplished only if there is sufficient attached gingiva remaining apical to the incision. Therefore the two anatomic landmarks, pocket depth and location of the mucogingival junction, must be considered to evaluate the amount of attached gingiva that remains.

Because the pocket wall is not displaced apically, the initial incision should also eliminate the pocket wall. If the incision is made too close to the tooth, it will not eliminate the pocket wall and may result in the recreation of a soft tissue pocket. If the tissue is thick it should also be thinned by the initial incision to cover the bone properly during flap closure. Proper placement of the flap during closure is essential to prevent either recurrence of pockets or bone exposure; placement is determined by where this first incision is placed. The internal bevel incision should be scalloped to preserve, as much as possible, the interdental papilla (see Fig. 61-2). This allows better coverage of the bone at both the radicular and the interdental areas.

If the surgeon contemplates osseous surgery, the first incision should be placed in such a way as to compensate for the removal of bone tissue so that the flap ends at the tooth-bone junction.

The *techniques used for regenerative purposes* are the papilla preservation flap and the flap using only crevicular or pocket incisions, to retain the maximum amount of gingival tissue, including the papilla, for graft or membrane coverage.

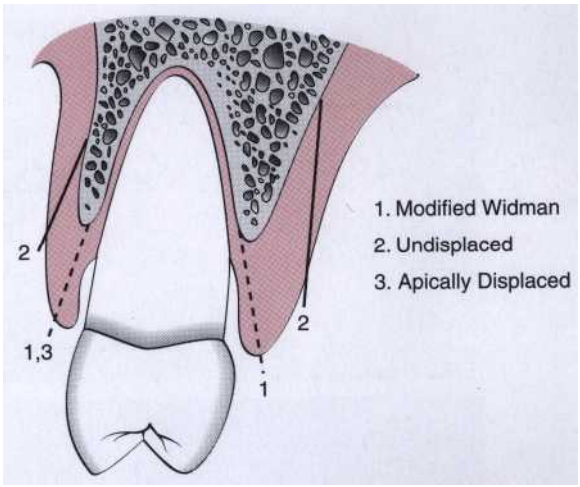

Fig. 61-1 Locations of the internal bevel incisions for the different types of flaps.

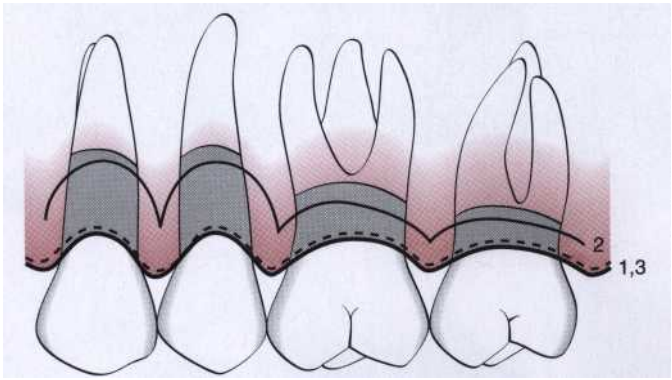

Fig. 61-2 Scallopings required for the different types of flaps.

THE MODIFIED WIDMAN FLAP

In 1965, Morris revived a technique described early in this century in the periodontal literature; he called it the *unrepositioned mucoperiosteal flap.*[4] Essentially the same procedure was presented in 1974 by Ramfjord and Nissle who called it the *modified Widman flap* (Fig. 61-3).[6] This technique offers the possibility of establishing an intimate postoperative adaptation of healthy collagenous connective tissue to tooth surfaces[5,6] and provides access for adequate instrumentation of the root surfaces and immediate closure of the area. The following is an outline of this technique:

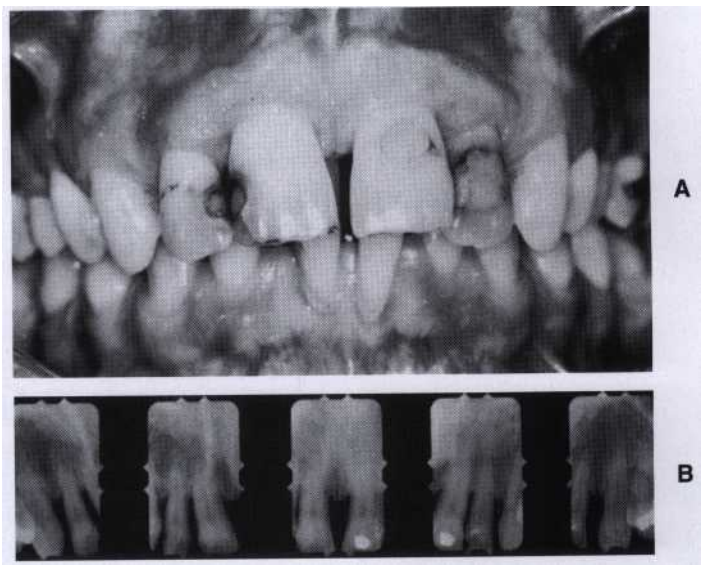

Fig. 61-3 The modified Widman flap technique. A, Facial view before surgery. Probing of pockets revealed interproximal depths ranging from 4 to 8 mm and facial and palatal depths of 2 to 5 mm. B, Radiographic survey of area. Note generalized horizontal bone loss.

Step 1: The initial incision is an internal bevel incision to the alveolar crest starting 0.5 to 1 mm away from the gingival margin (see Fig. 61-3, C). Scalloping

follows the gingival margin. Care should be taken to insert the blade in such a way that the papilla is left with a thickness similar to that of the remaining facial flap. Vertical relaxing incisions are usually not needed.

Step 2: The gingiva is reflected with a periosteal elevator (Fig. 61-3, D).

Step 3: A crevicular incision is made from the bottom of the pocket to the bone, circumscribing the triangular wedge of tissue containing the pocket lining (Fig. 61-3, E).

Step 4: After the flap is reflected, a third incision is made in the interdental spaces coronal to the bone with a curette or an interproximal knife, and the gingival collar is removed (Fig. 61-3, F and G).

Step 5: Tissue tags and granulation tissue are removed with a curette. The root surfaces are checked, and then scaled and planed if needed (Fig. 61-3, H). Residual periodontal fibers attached to the tooth surface should not be disturbed.

Step 6: Bone architecture is not corrected except if it prevents good tissue adaptation to the necks of the teeth. Every effort is made to adapt the facial and lingual interproximal tissue adjacent to each other in such a way that no interproximal bone remains exposed at the time of suturing (Fig. 61-3, 1). The flaps may be thinned to allow for close adaptation of the gingiva around the entire circumference of the tooth and to each other interproximally.

Step 7: Interrupted direct sutures are placed in each interdental space (Fig. 61-3, 1) and covered with tetracycline (Achromycin) ointment and with a periodontal surgical pack.

Ramfjord and colleagues performed an extensive longitudinal study comparing the Widman procedure, as modified by them, with the curettage technique and the pocket elimination methods that include bone contouring when needed.[6] The patients were assigned randomly to one of the techniques, and results were analyzed yearly up to 7 years posttherapy. They reported approximately similar results with the three methods tested. Pocket depth was initially similar for all methods but was maintained at shallower levels with the Widman flap (Fig. 61-4); the attachment level remained higher with the Widman flap.

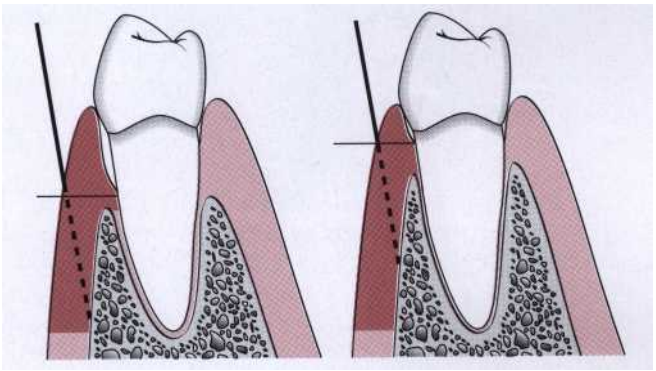

Fig. 61-5 Diagram showing the location of different areas where the internal bevel incision is made in an undisplaced flap. The incision is made at the level of the pocket to discard the tissue coronal to it if there is sufficient remaining attached gingiva.

THE UNDISPLACED FLAP

Currently, the undisplaced flap is perhaps the most commonly performed type of periodontal surgery. It differs from the modified Widman flap in that the soft tissue pocket wall is removed with the initial incision; thus it may be considered an internal bevel gingivectomy. The undisplaced flap and the gingivectomy are the two techniques that surgically remove the pocket wall. To perform this technique without creating a mucogingival problem it should be determined that enough attached gingiva will remain after removal of the pocket wall. The following is an outline of this technique:

Step 1: The pockets are measured with the periodontal probe, and a bleeding point is produced on the outer surface of the gingiva to mark the pocket bottom.

Step 2: The initial, internal bevel incision is made (Fig. 61-5) after the scalloping of the bleeding marks on the gingiva (Fig. 61-6). The incision is usually carried to a point apical to the alveolar crest, depending on the thickness of the tissue. The thicker the tissue, the more apical is the ending point of the incision (see Fig. 61-5). In addition, thinning of the flap should be done with the initial incision because at this time, it is easier to accomplish than later with a loose

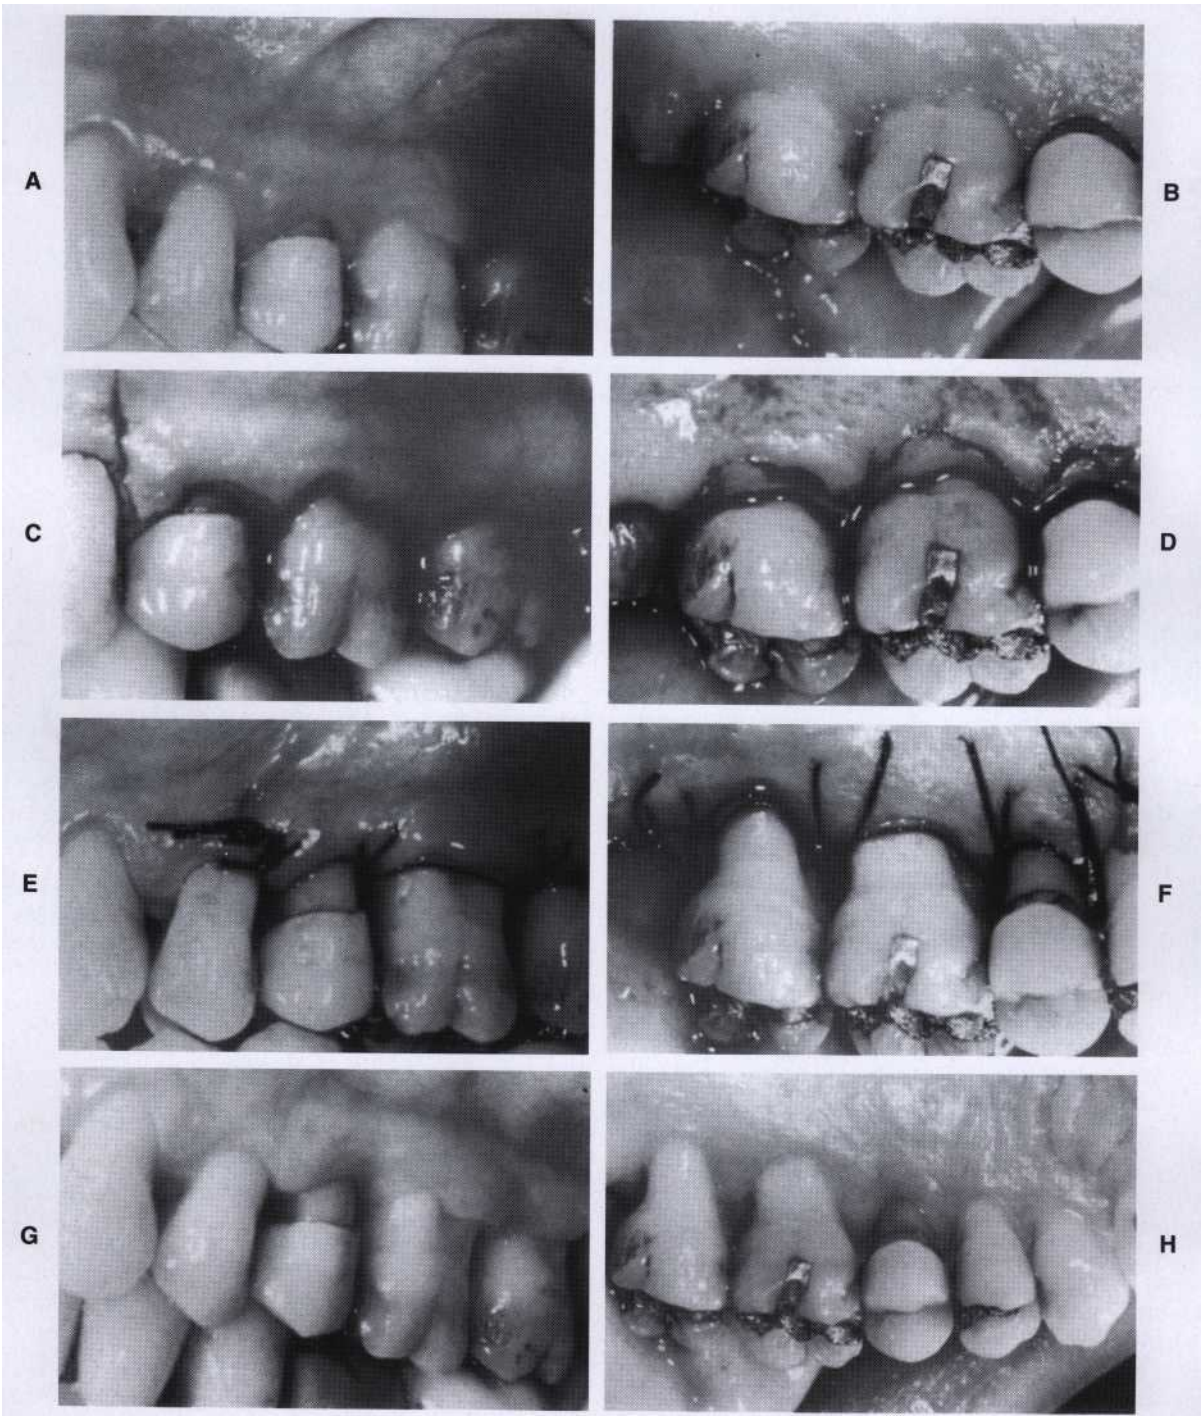

Fig. 61-6 The undisplaced. A and B, Preoperative facial and palatal views. C and D, Internal bevel incisions in the facial and palatal aspects. Note the deeper scalloping palatally for the replaced flap. E and F, After the necessary osseous surgery, the flaps have been sutured. reflected flap that is difficult to manage. (Use of this technique in palatal areas is considered in the following discussion.)

Step 3: The second or crevicular incision is made from the bottom of the pocket to the bone to detach the connective tissue from the bone.

Step 4: The flap is reflected with a periosteal elevator (blunt dissection) from the internal bevel incision. Usually there is no need for vertical incisions because the flap is not displaced apically.

Step 5: The interdental incision is made with an interdental knife, separating the connective tissue from the bone.

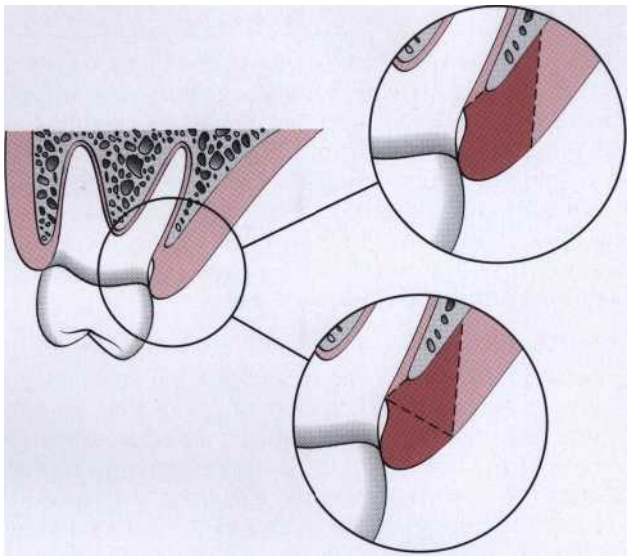

Fig. 61-7 Examples of two methods for eliminating a palatal pocket. One incision is an internal bevel incision made at the area of the apical extent of the pocket. The other procedure uses a gingivectomy incision, which is followed by an internal bevel incision.

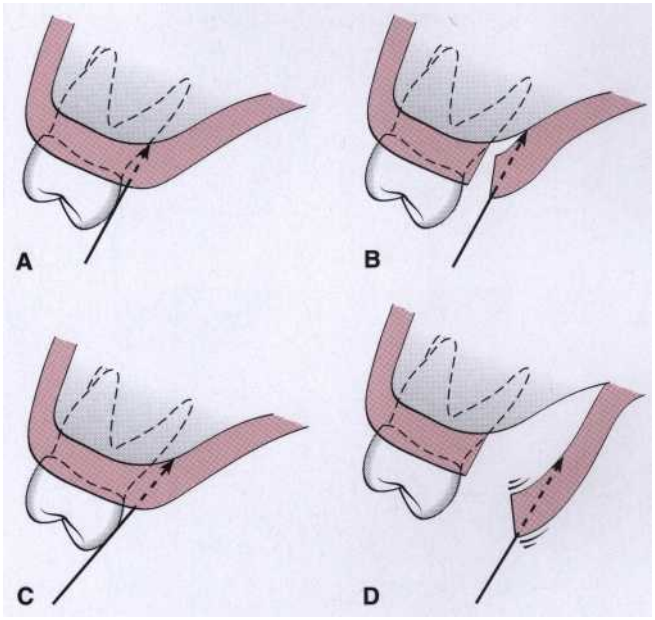

Fig. 61-8 Diagrams illustrating the angle of the internal bevel incision in the palate and the different ways to thin the flap. A, The usual angle and direction of the incision. B, The thinning of the flap after it has been slightly reflected with a second internal incision. C, The beveling and thinning of the flap with the initial incision if the position and contour of the tooth allow. D, The problem encountered in thinning the flap once it has been reflected. The flap is too loose and free for proper positioning and incision.

Step 6: The triangular wedge of tissue created by the three incisions is removed with a curette.

Step 7: The area is debrided, removing all tissue tags and granulation tissue using sharp curettes.

Step 8: After the necessary scaling and root planing, the flap edge should rest on the root-bone junction. If this is not the case, due to improper location of the initial incision or to the unexpected need for osseous surgery, the edge of the flap is rescalloped and trimmed to allow the flap edge to end at the root-bone junction.

Step 9: A continuous sling suture is used to secure the facial and the lingual or palatal flaps. This type of suture, using the tooth as an anchor, is advantageous to position and hold the flap edges at the root-bone junction. The area is covered with a periodontal pack.

The Palatal Flap

The surgical approach to the palatal area differs from that for other areas because of the character of the palatal tissue and the anatomy of the area. The palatal tissue is all attached, keratinized tissue and has none of the elastic properties associated with other gingival tissues. Therefore the palatal tissue cannot be apically displaced, nor can a partial (split) thickness flap be accomplished.

The initial incision for the palatal flap should be such that when the flap is sutured, it is precisely adapted at the root-bone junction. It cannot be moved apically or coronally to adapt to the root-bone junction, as can be done with the flaps in other areas. Therefore the location of the initial incision is important for the final placement of the flap.

The palatal tissue may be thin or thick, it may or may not have osseous defects, and the palatal vault may be high or low. These anatomic variations may require changes in the location, angle, and design of the incision.

The initial incision for a flap varies with the anatomic situation. As shown in Fig. 61-7, the initial incision may be the usual internal bevel incision, followed by crevicular and interdental incisions. If the tissue is thick, a horizontal gingivectomy incision may be made, followed by an internal bevel incision that starts at the edge of this incision and ends on the lateral surface of the underlying bone. The placement of the internal bevel incision must be done in such a way that the flap fits around the tooth without exposing the bone.

Before the flap is reflected to the final position for scaling and management of the osseous lesions, its thickness must be checked. Flaps should be thin to adapt to the underlying osseous tissue and provide a thin, knife-like gingival margin. Often flaps, particularly palatal flaps, are too thick; they may have a propensity to separate from the tooth and may delay and complicate healing. It is best to thin the flaps before their complete reflection, because a free, mobile flap is difficult to hold for thinning (Fig. 61-8). A sharp, thin papilla positioned properly around the interdental areas at the tooth-bone junction is essential to prevent recurrence of soft tissue pockets.

The purpose of the palatal flap should be considered before the incision is made. If the intent of the surgery is debridement, the internal bevel incision is planned so that the flap adapts at the root-bone junction when sutured. If osseous resection is necessary, the incision

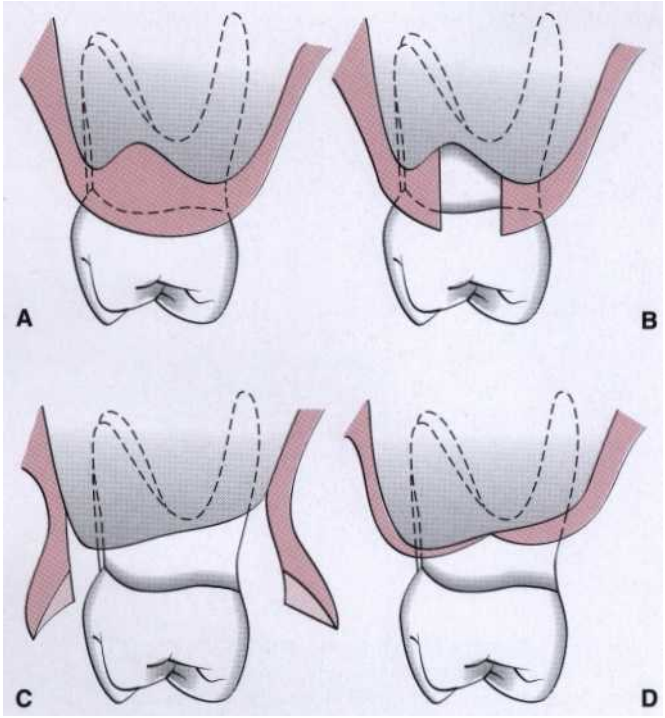

Fig. 61-9 A, A distal view of incisions made to eliminate a pocket distal to the maxillary second molar. B, Two parallel incisions and the removal of the intervening tissue. C, Thinning of the flap and contouring of the bone. D, Approximation of the buccal and palatal flaps.

should be planned to compensate for the lowered level of the bone when the flap is closed. Probing and sounding of the osseous level and the depth of the intrabony pocket should be used to determine the position of the incision.

The apical portion of the scalloping should be narrower than the line angle area because the palatal root tapers apically. A rounded scallop results in a palatal flap that does not fit snugly around the root. This procedure should be done before the complete reflection of the palatal flap, as a loose flap is difficult to grasp and stabilize for dissection.

It is sometimes necessary to thin the palatal flap after it has been reflected. This can be accomplished by holding the inner portion of the flap with a mosquito hemostat or Adson forceps as the inner connective tissue is carefully dissected away with a sharp #15 scalpel blade. Care must be taken not to perforate or overthin the flap. The edge of the flap should be thinner than the base; therefore the blade should be angled toward the lateral surface of the palatal bone. The dissected inner connective tissue is removed with a hemostat. As with any flap, the triangular papilla portion (Fig. 61-9) should be thin enough to fit snugly against the bone and into the interdental area.

The principles for the use of vertical releasing incisions are similar to those for using other incisions. Care must be exercised so that the length of the incision is minimal to avoid the numerous vessels located in the palate.

THE APICALLY DISPLACED FLAP

This technique with some variants can be used for one or both of the following purposes: pocket eradication or widening the zone of attached gingiva. Depending on the purpose, it can be a full thickness (mucoperiosteal) or a split thickness (mucosal) flap. The split thickness flap requires more precision and time, and a gingival tissue thick enough to split, but it can be more accurately positioned and sutured in an apical position using a periosteal suturing technique, as follows:

Step 1: An internal bevel incision is made (Fig. 61-10). To preserve as much of the keratinized and attached gingiva as possible, it should be no more than about 1 mm from the crest of the gingiva and directed to the crest of the bone (see Fig. 61-1). The incision is made after the existing scalloping, and there is no need to mark the bottom of the pocket in the external gingival surface because the incision is unrelated to pocket depth. It is also not necessary to accentuate the scallop interdentally, as the flap is displaced apically and not placed interdentally.

Step 2: Crevicular incisions are made, followed by initial elevation of the flap, and then interdental incisions are performed and the wedge of tissue that contains the pocket wall is removed.

Step 3: Vertical incisions are made extending *beyond the mucogingival junction,* if the objective is a full thickness flap it is elevated by blunt dissection with a periosteal elevator. If a split thickness flap is required, it is elevated using sharp dissection with a Bard-Parker knife to split it, leaving a layer of connective tissue, including the periosteum, on the bone.

Step 4: After removal of all granulation tissue, scaling and root planing, and osseous surgery if needed, the flap is displaced apically. It is important that the vertical incisions, and consequently, the flap elevation, reach past the mucogingival junction to provide adequate mobility to the flap for its apical displacement.

Step 5: If a full thickness flap was performed, a sling suture around the tooth prevents the flap from sliding to a position more apical than that desired, and the periodontal dressing can avoid its movement in a coronal direction. A partial thickness flap is sutured to the periosteum using a direct loop suture or a combination of loop and anchor suture. A dry foil is placed over the flap before covering it with the dressing to prevent the introduction of pack under the flap.

After 1 week, dressings and sutures are removed. The area is usually repacked for another week, after which the patient is instructed to use chlorhexidine mouth rinse or to apply chlorhexidine topically with cotton-tipped applicators for another 2 or 3 weeks.

FLAPS FOR REGENERATIVE SURGERY

In current regenerative therapy, either bone grafts, membranes, or a combination of these with or without other agents, are used for a successful outcome (see Chapter 63). The flap design should therefore be set up so that the maximum amount of gingival tissue and

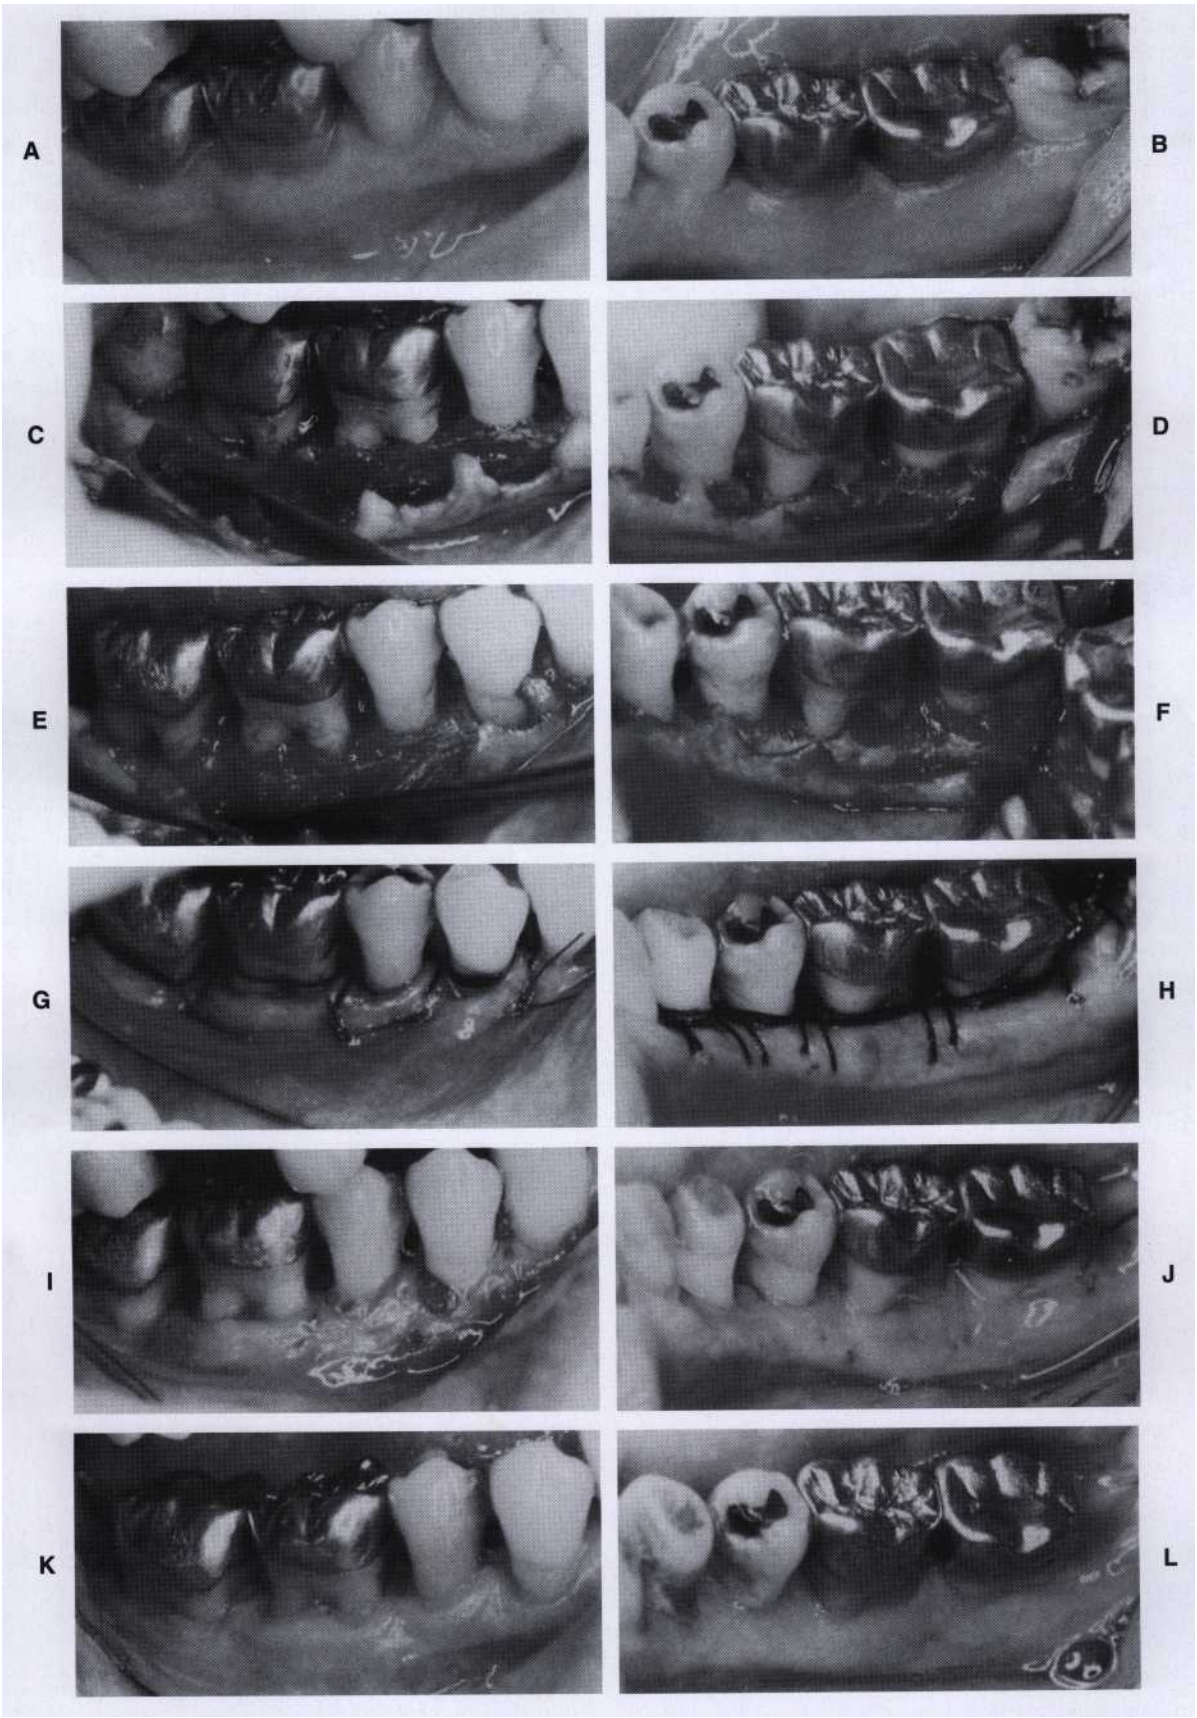

Fig. 61-10 Apically displaced flap. A and B, Facial and lingual preoperative views. C and D, Facial and lingual flaps elevated. E and F, After debridement of the areas. G and H, Sutures in place. 1 and 1, Healing after 1 week. K and L, Healing after 2 months. Note the preservation of attached gingiva displaced to a more apical position.

papilla are retained to cover the material(s) placed in the pocket.

Two flap designs are available for regenerative surgery: the papilla preservation flap and the conventional flap with only crevicular incisions. The flap design of choice is the papilla preservation flap, which retains the entire papilla covering the lesion. However, to use this flap, there must be adequate interdental space to allow the intact papilla to be reflected with the facial or lingual/palatal flap. When the interdental space is very narrow, making it impossible to perform a papilla preservation flap, a conventional flap with only crevicular incisions is made.

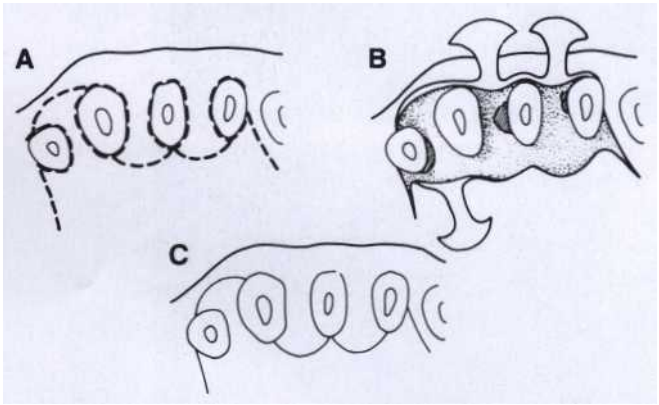

Fig. 61-11 Flap design for a papilla preservation flap. A, Incisions for this type of flap are depicted by interrupted lines. The preserved papilla can be incorporated into the facial or the lingual-palatal flap. B, The reflected flap exposes the underlying bone. Several osseous defects are seen. C, The flap returned to its original position covering the entire interdental spaces.

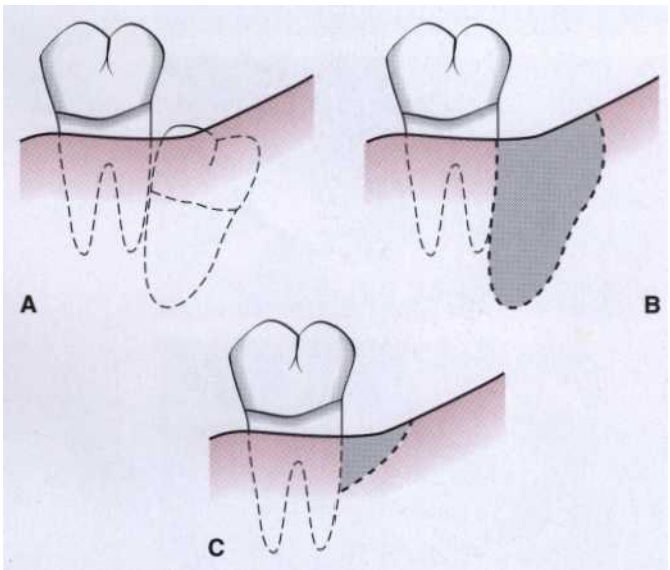

Fig. 61-12 A, The impaction of a third molar distal to a second molar with little or no interdental bone between the two teeth. B, Removal of the third molar creates a pocket with little or no bone distal to the second molar. This often leads to a vertical osseous defect distal to the second molar (C).

The Papilla Preservation Flap

The technique for employing a papilla preservation flap is as follows:

Step 1: A crevicular incision is made around each tooth with no incisions across the interdental papilla.

Step 2: The preserved papilla can be incorporated into the facial or lingual/palatal flap, although it is most commonly integrated into the facial flap. In these cases the lingual or palatal incision consists of a semilunar incision across the interdental papilla in its palatal or lingual aspect; this incision dips apically from the line angles of the tooth so that the papillary incision is at least 5 mm from the crest of the papilla.

Step 3: An Orban knife is then introduced into this incision to sever one-half to two-thirds of the base of the interdental papilla. The papilla is then dissected from the lingual or palatal aspect and elevated intact with the facial flap.

Step 4: The flap is reflected without thinning the tissue. These incisions are illustrated in Fig. 61-11 and Color Fig. 60-1.

Conventional Flap for Regenerative Surgery

The technique for employing a conventional flap for regenerative surgery is as follows:

Step 1: Using a #12 blade, incise the tissue at the bottom of the pocket and to the crest of the bone, splitting the papilla below the contact point. Every effort should be made to retain as much tissue as possible to subsequently protect the area.

Step 2: Reflect the flap maintaining it as thick as possible, not attempting to thin it as is done for resective surgery. The maintenance of a thick flap is necessary to prevent exposure of the graft or the membrane due to necrosis of the flap margins.

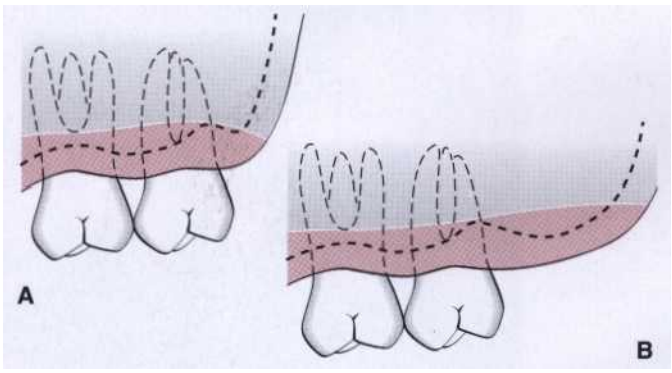

Fig. 61-13 A, Removal of a pocket distal to the maxillary second molar may be difficult if there is minimal attached gingiva. If the bone ascends acutely apically, the removal of this bone may make the procedure easier. B, A long distal tuberosity with abundant attached gingiva is an ideal anatomic situation for distal pocket eradication.

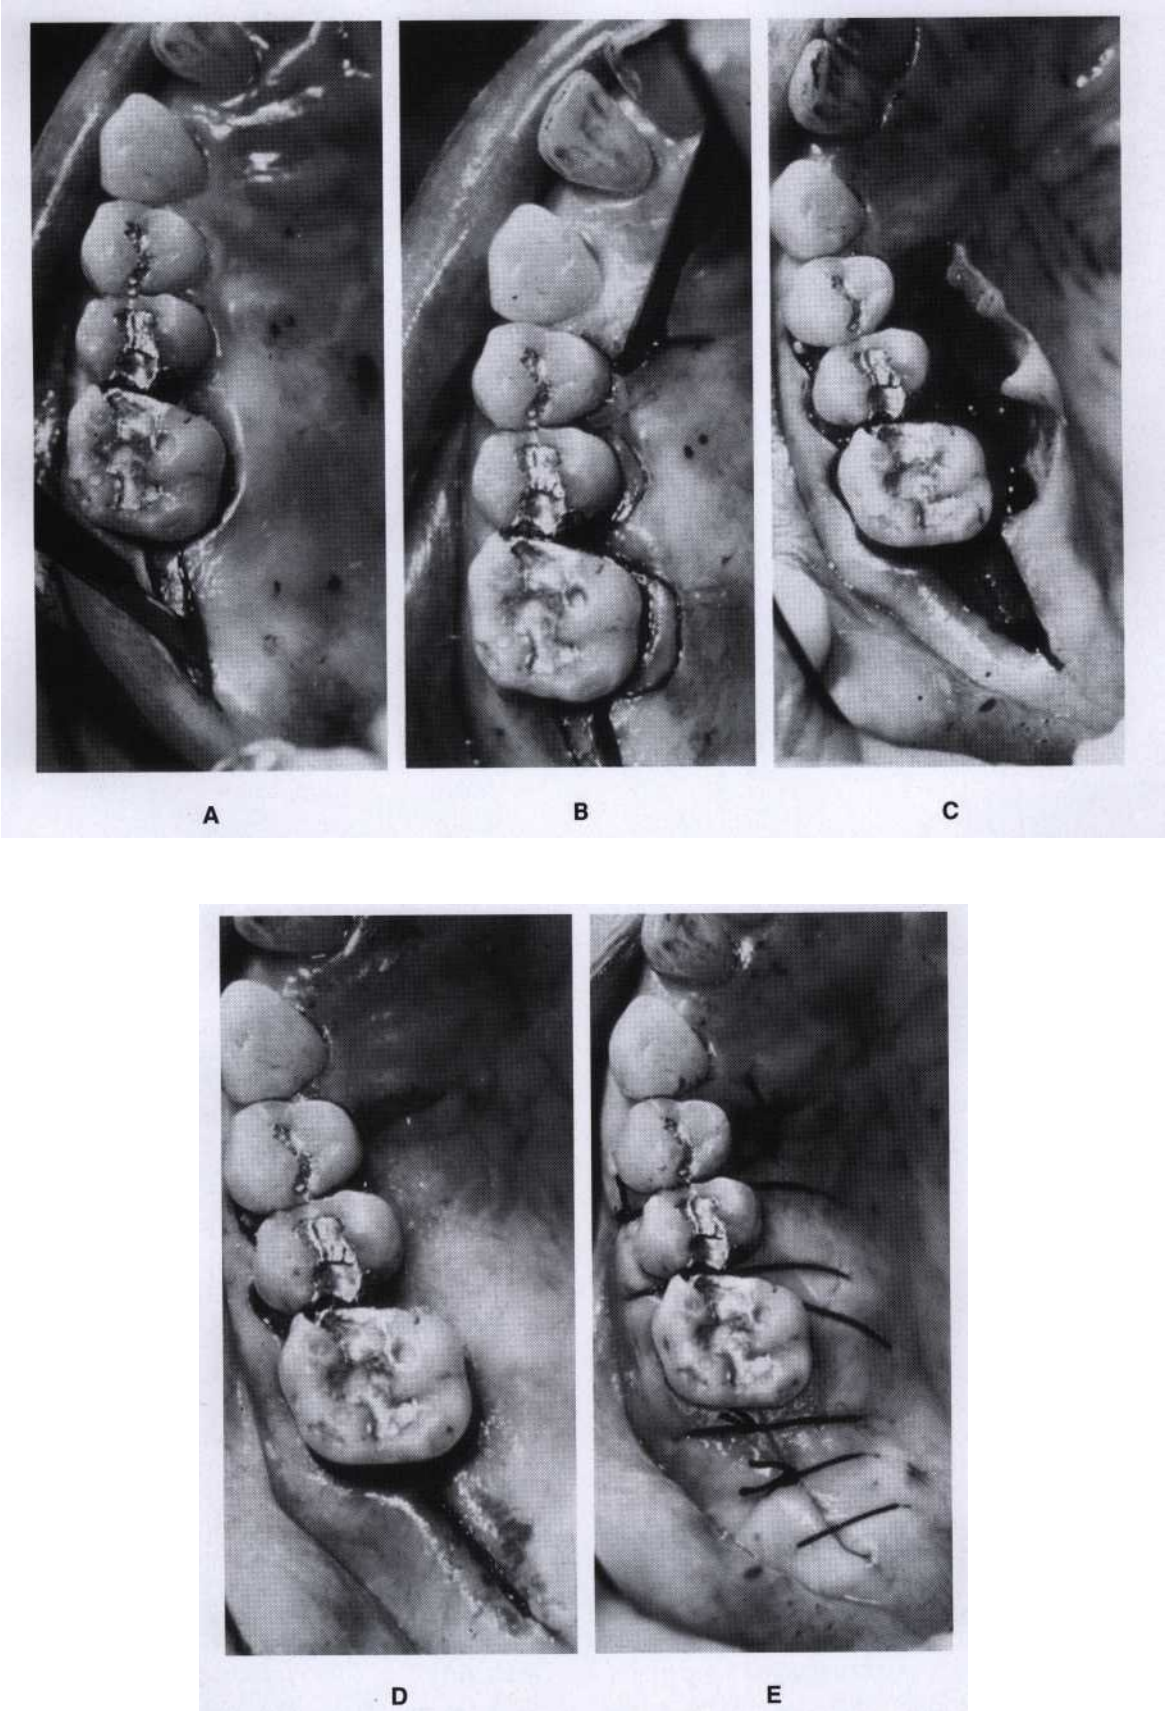

Fig. 61-14 A, A distal pocket eradication procedure with the incision distal to the molar. B, The scalloped incision around the remaining teeth. C, The flap reflected and thinned around the distal incision. D, The flap in position prior to suturing. It should be closely approximated. E, The flap sutured both distally and over the remaining surgical area.

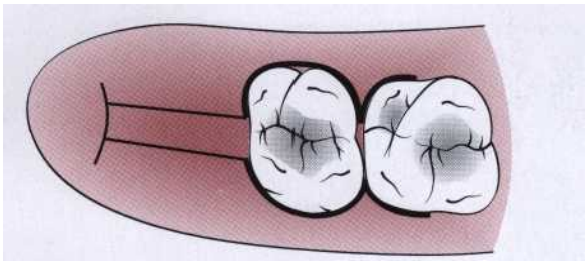

Fig. 61-15 A typical incision design for a surgical procedure distal to the maxillary second molar.

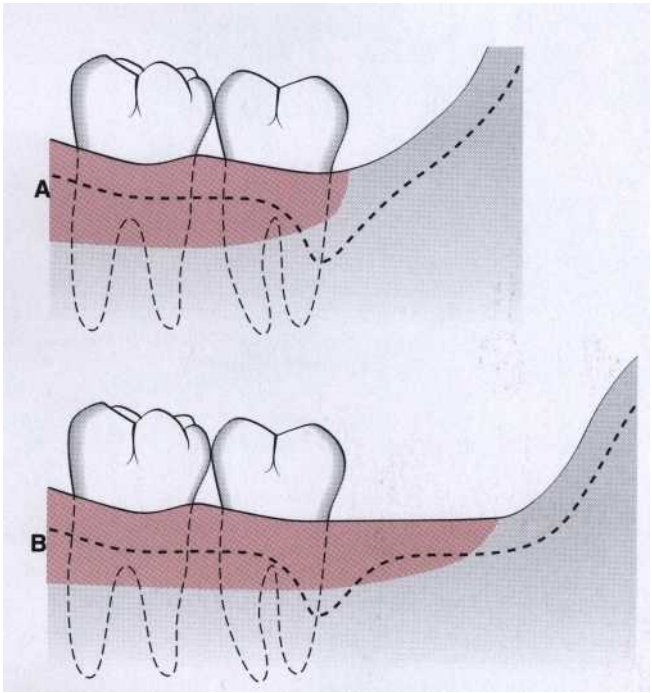

Fig. 61-16 A, Pocket eradication distal to a mandibular second molar with minimal attached gingiva and a close ascending ramus is anatomically difficult. B, For surgical procedures distal to a mandibular second molar, abundant attached gingiva and distal space are ideal.

DISTAL MOLAR SURGERY

Treatment of periodontal pockets on the distal surface of terminal molars is often complicated by the presence of bulbous fibrous tissue over the maxillary tuberosity or prominent retromolar pads in the mandible. Deep vertical defects are also commonly present in conjunction with the redundant fibrous tissue. Some of these osseous lesions may result from incomplete repair after the extraction of impacted third molars (Fig. 61-12).

The gingivectomy incision is the most direct approach in treating distal pockets that have adequate attached gingiva and no osseous lesions. However, the flap approach is less traumatic postsurgically, because it produces a primary closure wound rather than the open secondary wound left by a gingivectomy incision. In addition, it results in attached gingiva and provides access for examination and, if needed, correction of the osseous defect.

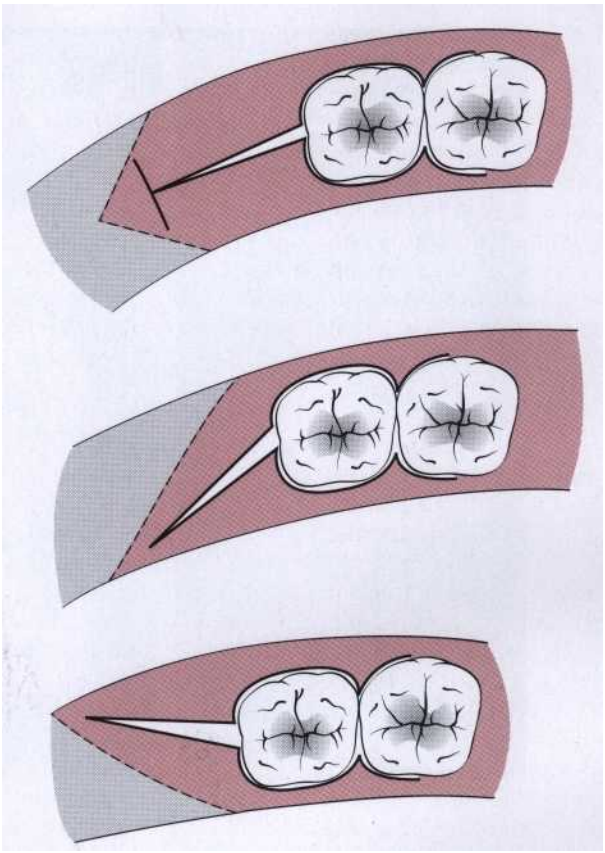

Fig. 61-17 Incision designs for surgical procedures distal to the mandibular second molar. The incision should follow the areas of greatest attached gingiva and underlying bone.

Operations for this purpose were described by Robinson[7] and Braden[1] and modified by several other investigators. Some representative procedures are discussed here.

Maxillary Molars. The treatment of distal pockets on the maxillary arch is usually more simple than the treatment of a similar lesion on the mandibular arch because the tuberosity presents a greater amount of fibrous attached gingiva than does the area of the retromolar pad. In addition, the anatomy of the tuberosity extending distally is more adaptable to pocket elimination than is that of the mandibular molar arch, where the tissue extends coronally. However, the lack of a broad area of attached gingiva and the abruptly ascending tuberosity sometimes complicates therapy (Fig. 61-13).

The following considerations determine the location of the incision for distal molar surgery: accessibility, amount of attached gingiva, pocket depth, and available distance from the distal aspect of the tooth to the end of the tuberosity or retromolar pad.

Technique. Two parallel incisions, beginning at the distal portion of the tooth and extending to the mucogingival junction distal to the tuberosity or retromolar pad, are made (Fig. 61-14). The faciolingual distance between these two incisions depends on the depth of the pocket and the amount of fibrous tissue involved. The

deeper the pocket, the greater the distance between the two parallel incisions. It should be noted that when the tissue between the two incisions is removed and the flaps are thinned, the two flap edges must approximate each other at a new apical position without overlapping.

When the depth of the pocket cannot be easily estimated, it is better to err on the conservative side, leaving overlapping flaps rather than too short flaps that result in exposure of bone. When the two flaps overlap after the surgery is completed, they should be placed one over the other and the overlapping portion of one of them is grabbed with a hemostat. Then a sharp knife or scissors is used to cut the excess.

A transversal incision is made at the distal end of the two parallel incisions so that a long, rectangular piece of tissue can be removed. These incisions are usually interconnected with the incisions for the remainder of the surgery in the quadrant involved. The parallel distal incisions should be confined to the attached gingiva because bleeding and flap management become problems when the incision is extended into the alveolar mucosa. If access is difficult, especially if the distance from the distal aspect of the tooth to the mucogingival junction is short, a vertical incision can be made at the end of the parallel incisions.

In treating the tuberosity area, the two distal incisions are usually made at the midline of the tuberosity (Fig. 61-15). In most cases, no attempt is made to undermine the underlying tissue at this time. These incisions are made straight down into the underlying bone where access is difficult. A #12B blade is generally used. It is easier to dissect out the underlying redundant tissue when the flap is partially reflected. When the distal flaps are placed back on the bone, the two flap margins should closely approximate each other.

Mandibular Molars. Incisions for the mandibular arch differ from those used for the tuberosity, owing to differences in the anatomy and histologic features of the areas. The retromolar pad area does not usually present as much fibrous attached gingiva. The keratinized gingiva, if present, may not be found directly distal to the molar. The greatest amount may be distolingual or distofacial and may not be over the bony crest. The ascending ramus of the mandible may also create a short horizontal area distal to the terminal molar (Fig. 61-16). The shorter this area, the more difficult it is to treat any deep distal lesion around the terminal molar.

The two incisions distal to the molar should follow the area with the greatest amount of attached gingiva (Fig. 61-17). Therefore the incisions could be directed distolingually or distofacially, depending on which area has more attached gingiva. Before the flap is completely reflected, it is thinned with a #15 blade. It is easier to thin the flap before it is completely free and mobile. After the reflection of the flap and the removal of the redundant fibrous tissue, any necessary osseous surgery is performed. The flaps are approximated similarly to those in the maxillary tuberosity area.

SUMMARY

The damage resulting from periodontal disease reveals itself in variable destruction of the tooth-supporting bone. Generally, bony deformities are not uniform. They are not indicative of the alveolar housing of the tooth before the disease process, nor do they reflect the overlying gingival architecture. Bone loss has been classified as either horizontal or vertical, but in fact, bone loss is most often a combination of horizontal and vertical loss. Horizontal bone loss generally results in a relative thickening of the marginal alveolar bone, since bone tapers as it approaches its most coronal margin.

The effects of this thickening and the development of vertical defects leave the alveolar bone with countless combinations of bony shapes. If these various topographic changes are to be altered to provide a more physiologic bone pattern, a method for osseous recontouring must be followed.

> Osseous surgery may be defined as the procedure by which changes in the alveolar bone can be accomplished to rid it of deformities induced by the periodontal disease process or other related factors, such as exostosis and tooth supraeruption.

Osseous surgery can be either additive or subtractive in nature. Additive osseous surgery includes procedures directed at restoring the alveolar bone to its original level, whereas subtractive osseous surgery is designed to restore the form of preexisting alveolar bone to the level existing at the time of surgery or slightly more apical to this level (Fig. 62-1).

Additive osseous surgery brings about the ideal result of periodontal therapy; it implies regeneration of lost bone and reestablishment of the periodontal ligament,

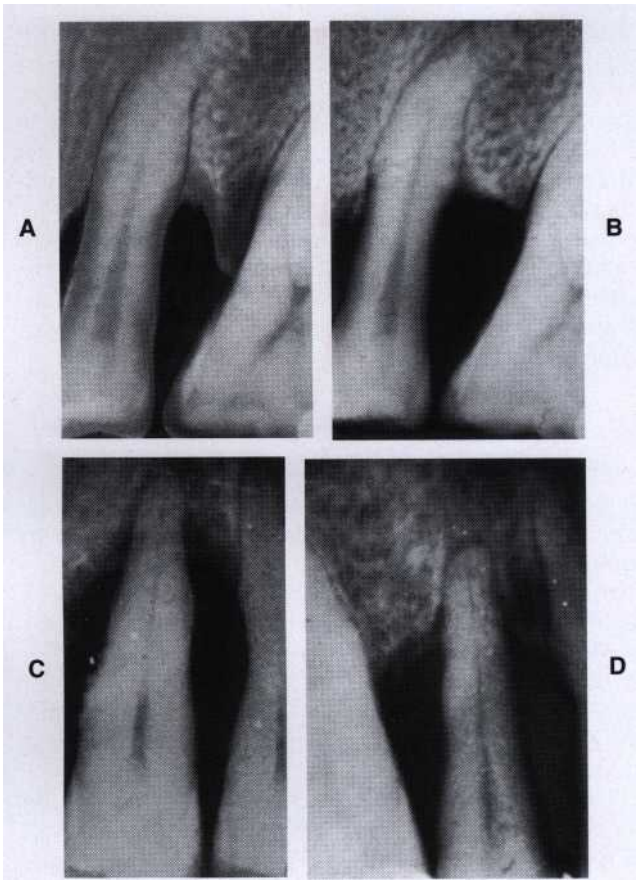

Fig. 62-1 Additive and subtractive osseous surgery. A, Before and B, immediately after subtractive osseous surgery; the osseous wall of the two adjoining infrabony pockets has been removed. C, Before and D, 1 year after additive osseous surgery; the area has been flapped and thoroughly instrumented, resulting in regeneration of the interdental and periapical bone. (Courtesy Drs. E. A. Albano and B. O. Barletta; Argentina.)

gingival fibers, and junctional epithelium at a more coronal level. This type of osseous surgery is discussed in Chapter 63.

Subtractive osseous surgery procedures provide an alternative to additive methods and should be resorted to when the latter are not feasible. They are discussed in this chapter.

SELECTION OF TREATMENT TECHNIQUE

The morphology of the osseous defect largely determines the treatment technique to be used. One-wall angular defects usually have to be recontoured surgically. Three-wall defects, particularly if they are narrow and deep, can be successfully treated with techniques that aim at new attachment and bone regeneration. Two-wall angular defects can be treated with either method, depending on their depth, width, and general configuration. Therefore except for one-wall defects, wide and shallow two-wall defects, along with interdental craters, osseous defects are treated with the objective of obtaining optimal repair by natural healing processes.

RATIONALE

Osseous resective surgery necessitates following a series of strict guidelines for proper contouring of alveolar bone and subsequent management of the overlying gingival soft tissues. The specifics of these techniques are discussed later in this chapter. They are quite technique sensitive. The techniques discussed here for osseous resective surgery have limited applicability in very deep intrabony or hemiseptal defects, which could be treated with a different surgical approach, are discussed in Chapter 63. Osseous surgery provides the purest and surest method for reducing pockets with bony discrepancies that are not overly vertical and also remains one of the principal periodontal modalities because of its long-term success and predictability.

Osseous resective surgery is the most predictable pocket reduction technique. [10,12,13] However, more than any other surgical technique, osseous resective surgery is performed at the expense of bony tissue and attachment level. Thus its value as a surgical approach is limited by the presence, quantity, and shape of the bony tissues and by the amount of attachment loss that is acceptable.

The major rationale for osseous resective surgery is centered on the tenet that discrepancies in level and shapes of the bone and gingiva predispose patients to the recurrence of pocket depth postsurgically.[6] Although this concept is not universally accepted [3,5] and despite the fact that the procedure induces loss of radicular bone in the healing phase, there are cases in which recontouring of bone is the only logical treatment choice. The goal of osseous resective therapy is to reshape the marginal bone to resemble that of the alveolar process undamaged by periodontal disease. The technique is performed in combination with apically positioned flaps, and the procedure eliminates periodontal pocket depth and improves tissue contour to provide a more easily maintainable environment. The relative merits of pocket reduction procedures are discussed in Chapters 33 and 54; this chapter discusses the osseous resective technique and how and where it may be accomplished.

It is proposed that the conversion of the periodontal pocket to a shallow gingival sulcus enhances the patient's ability to remove plaque and oral debris from the dentition. Likewise, the ability of dental professionals to maintain the periodontium in a state free of gingivitis and periodontitis is more predictable in the presence of shallow sulci. The more effective the periodontal maintenance therapy, the greater is the longitudinal stability of the surgical result. The efficacy of osseous surgery therefore is dependent on its ability to affect pocket depth and to promote periodontal maintenance. [11,23,24] The merits of resection vs. other treatment procedures are discussed in Chapter 54 of this text.

NORMAL ALVEOLAR BONE MORPHOLOGY

Knowledge of the morphology of the bony periodontium in a state of health is required to correctly perform

resective osseous surgery (Fig. 62-2). The characteristics of a normal bony form are as follows:

1. The interproximal bone is more coronal in position than the labial or lingual/palatal bone and pyramidal in form.
2. The form of the interdental bone is a function of the tooth form and the embrasure width. The more tapered the tooth, the more pyramidal is the bony form. The wider the embrasure, the more flattened is the interdental bone mesiodistally and buccolingually.
3. The position of the bony margin mimics the contours of the cementoenamel junction. The distance from the facial bony margin of the tooth to the interproximal bony crest is more flat in the posterior areas than the anterior. This "scalloping" of the bone on the facials and linguas/palatals is related to tooth and root form, as well as tooth position, within the alveolus. Teeth with prominent roots or that are displaced to the facial or lingual may also have fenestrations or dehiscences (Fig. 62-3). The molar teeth have less scalloping and a more flat profile than bicuspids and incisors. Although these general observations apply to all patients, the bony architecture may vary from patient to patient in the extent of contour, configuration, and thickness. These variations may be both normal and healthy.

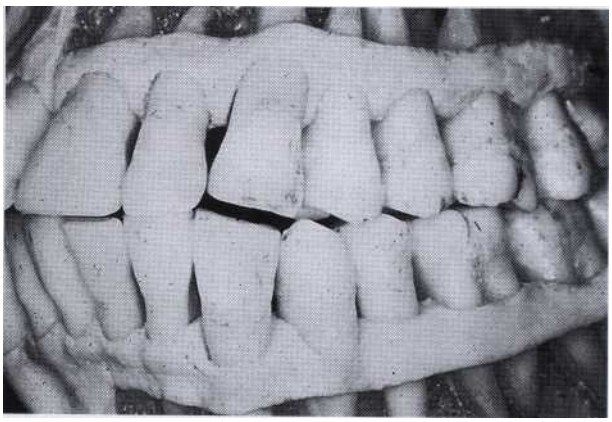

Fig. 62-2 Photograph of a healthy bony periodontium in a skull. Although a slight amount of attachment may have been lost, this skull demonstrates the characteristics of normal form.

TERMINOLOGY

Numerous terms have been developed to describe the topography of the alveolar housing, the procedure for its removal, and the resulting correction. These terms should be clearly defined.

Procedures used to correct osseous defects have been classified in two groups: osteoplasty and ostectomy. Osteoplasty refers to reshaping the bone without removing tooth-supporting bone. Ostectomy (or *osteoectomy*) includes the removal of tooth-supporting bone. One or both of these procedures may be necessary to produce the desired result.

Terms that describe the bone form after reshaping can refer to morphologic features or to the thoroughness of **the reshaping performed.** Examples of morphologically descriptive terms include *negative, positive, flat,* and *ideal.* These terms all relate to a preconceived standard of ideal osseous form.

Positive or negative architecture refer to the relative position of interdental bone to radicular bone (Fig. 62-4). The architecture is said to be positive if the radicu-

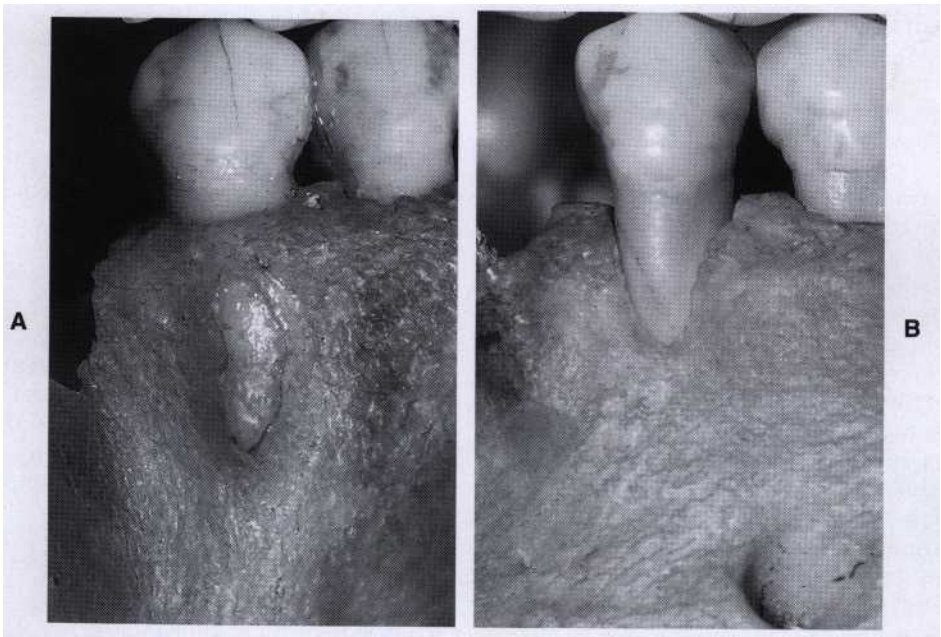

Fig. 62-3 The effects of tooth position on facial bony contours. A, Bony fenestration; B, bony dehiscence. These deformities can and should be detected by palpation, probing and sounding prior to flap surgery.

lar bone is apical to the interdental bone. The bone is said to have negative architecture if the interdental bone is more apical than the radicular bone. Flat architecture is the reduction of the interdental bone to the same height as the radicular bone.

Osseous form is considered to be *ideal* when the bone is consistently more coronal on the interproximal surfaces than on the facial and lingual surfaces. The ideal form of the marginal bone has similar interdental height, with gradual, curved slopes between interdental peaks (Fig. 62-5).

Terms that relate to the thoroughness of the osseous reshaping techniques include *definitive* and *compromise*. Definitive osseous reshaping implies that further osseous reshaping would not improve the overall result. Compromise osseous reshaping indicates a bone pattern that cannot be improved without significant osseous removal that would be detrimental to the overall result. References to compromise and definitive osseous architecture can be useful to the clinician, not as description of morphologic feature, but as terms that express the expected therapeutic result.

FACTORS IN THE SELECTION OF RESECTIVE OSSEOUS SURGERY

The relationship between the depth and configuration of the bony lesion(s) to root morphology and the adjacent teeth determines the extent that bone and attachment is removed during resection. Bony lesions have been classified according to their configuration and number of bony walls.' The technique of ostectomy is best applied to patients with early-to-moderate bone loss (2 to 3 mm) with moderate-length root trunks[19] that have bony defects with one or two walls. These shallow-to-moderate bony defects can be effectively managed by osteoplasty and osteoectomy. Patients with advanced attachment loss and deep intrabony defects are not candidates for resection to produce a positive contour. To simulate a normal architectural form, so much bone would have to be removed that the survival of the teeth could be compromised.

Two-walled defects/craters occur at the expense of the interseptal bone. As a result, they have buccal and lingual/palatal walls that extend from one tooth to the adjacent tooth. The interdental loss of bone exposes the proximal aspects of both adjacent teeth. The buccal-lingual interproximal contour that results is opposite to the contour of the cementoenamel junction of the teeth (Fig. 62-6, A and B). Two-walled defects (craters) are the most common bony defects found in patients with periodontitis.[15,21] If the facial and/or lingual plates of this bone are resected, the resultant interproximal contour would become more flattened or ovate (Fig. 62-6, C and D). However, confining resection only to ledges and the interproximal lesion results in a facial and lingual bone form in which the interproximal bone is located more apically than is the bone on the facial or lingual aspects of the tooth. This resulting anatomic form is *reversed* or *negative* architecture[18,19,23] (see Fig. 62-6, C and D).

Although the production of a reversed architecture minimizes the amount of ostectomy that is performed, it is not without consequences.' Peaks of bone commonly remain at the facial, lingual/palatal line angles of the teeth (so-called *widow's peaks*). During healing, the soft tissue tends to bridge the embrasure from the most coronal height of the bone on one tooth to the most coronal heights on the adjacent teeth. The result therefore is the tendency to replicate the attachment contour on the

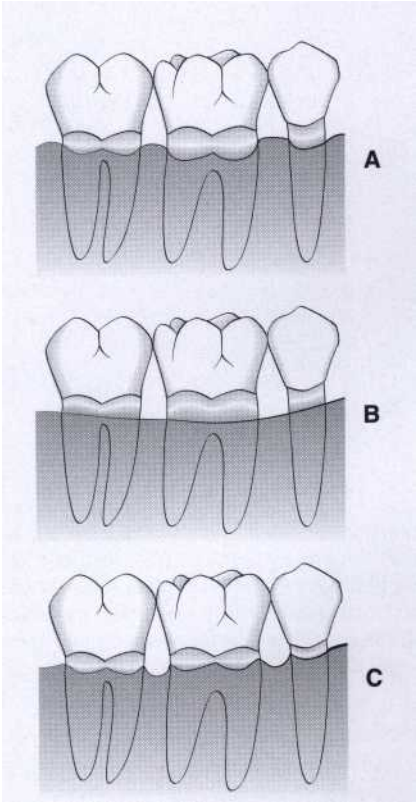

Fig. 62-4 Diagram of types of bony architecture. A, a positive bony architecture; B, a flat bony architecture; and C, a reversed or negative bony form.

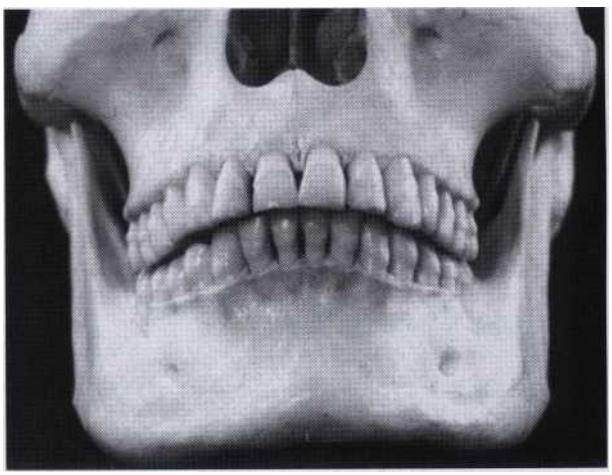

Fig. 62-5 Skull photograph of a healthy periodontium. Note the shape of the alveolar bone housing. This bone is considered to have ideal form. It is more coronal in the interproximal areas, with a gradual slope around and away from the tooth.

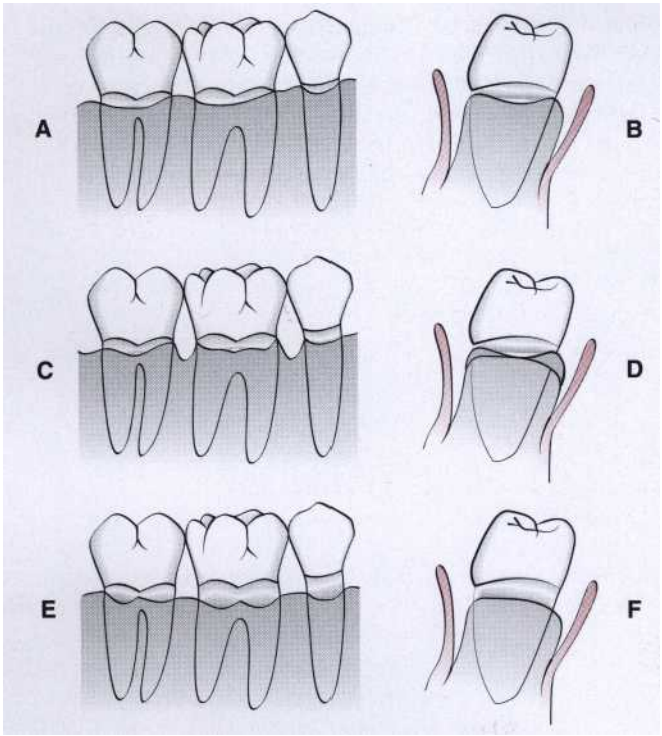

Fig. 62-6 Effect of correction of craters. A and B, Diagram of facial and interproximal bony contours after flap reflection. Note the loss of some interproximal bone and cratering. C and D, Line angles; this is only osteoplasty and has resulted in a reversed architecture. E and F, Ostectomy on the facial and lingual bone and the removal of the residual widow's peaks to produce a positive bony architecture.

tooth. The interproximal soft tissues invest these peaks of bone, which may subsequently resorb with a tendency to rebound without gain in attachment over time. A recurrence of interproximal pocket depth can occur.[23,25]

Ostectomy to a positive architecture requires the removal of the line angle inconsistencies (widow's peaks), as well as some of the facial, lingual and palatal and interproximal bone. The result is a loss of some attachment on the facial and lingual root surfaces but a topography that more closely resembles normal bone form before disease (Fig. 62-6, E and F). Proponents of osseous resection to create a positive contour believe that this architecture, devoid of sharp angles and spines, is conducive to the formation of a more uniform and reduced soft tissue dimension postoperatively.[18,22] The therapeutic result is less pocket depth and increased ease of periodontal maintenance by the patient, dental hygienist or dentist.

The amount of attachment lost from the use of ostectomy varies with the depth and configuration of the osseous defects that are treated. Osseous resection applied to two-wall intrabony defects (craters), the most common osseous defects, results in attachment loss at the proximal line angles and the facial and lingual aspects of the affected teeth without affecting the base of the pocket. The extent of attachment loss during resection to a positive architecture has been measured. When the technique is properly applied to appropriate patients, the mean reduction in attachment circumferentially around the tooth has been determined to be 0.6 mm at six probing sites.[23] Practically, this means that the technique is best applied to interproximal lesions 1- to 3-mm deep in patients with moderate to long root trunks.[18] Patients with deep, multiwalled defects are not candidates for resective osseous surgery. They are better treated with regenerative therapies or by combining osteoplasty to reduce bony ledges and to facilitate flap closure with new attachment/regeneration procedures.

EXAMINATION AND TREATMENT PLANNING WITH RESECTIVE SURGERY

The potential for the use of resective osseous surgery is usually identified during a comprehensive periodontal examination. Suitable patients display the signs and symptoms of periodontitis (see Chapter 30). The gingiva may be inflamed and deposits of plaque, calculus, and oral debris may be present. An increased flow of crevicular fluid may be detected, and bleeding on probing and exudation are commonly observed.

Periodontal probing and exploration are key aspects of the examination. Careful probing reveals the presence of (1) pocket depth greater than that of a normal gingival sulcus, (2) the location of the base of the pocket relative to the mucogingival junction and attachment level on adjacent teeth, (3) the number of bony walls, and (4) the presence of furcation defects. Transgingival probing, or *sounding,* under local anesthesia confirms the extent and configuration of the intrabony component of the pocket or offurcation defects.[6,11]

Routine dental radiographs do not identify the presence of periodontitis, nor do they accurately document the extent of bony defects. The number of bony walls and the presence or extent of bony lesions on the facial/buccal or lingual/palatal walls cannot be accurately determined by radiographs. Well-made radiographs provide useful information about the extent of interproximal bone loss, the presence of angular bone loss, caries, root trunk length, and root morphology. They also facilitate the identification of other dental pathoses that require treatment. In addition, a properly made radiographic survey serves as a means of evaluating the success of therapy and of documenting the longitudinal stability of the patient.[2°]

Treatment planning should provide solutions for active periodontal diseases and correction of deformities that result from periodontitis, and it should facilitate the performance of other dental procedures included in a comprehensive dental treatment plan. The extent of periodontal involvement can vary significantly from tooth to tooth in the same patient. The response to therapy from patient to patient may also vary, as may the treatment objectives for the patients. Therefore a treatment plan may encompass a number of steps and/or combinations of procedures in the same surgical area.

After oral hygiene instruction, scaling, and root planing, along with other disease control procedures, the response of the patient to these treatment procedures is evaluated by reexamination and recording the changes

that have occurred in the periodontium. Because the extent of periodontal involvement can vary significantly from tooth to tooth in the same patient, the local response to therapy is also variable. The resolution of inflammation and decrease in edema and swelling may have resulted in a return to normal depth and configuration of some pockets and additional therapy beyond periodic maintenance is not required.

The patient with moderate to advanced periodontitis and bony defects, although the overt signs of periodontitis may be reduced, may display a persistence of pocket depth bleeding on probing and suppuration. These signs may indicate the presence of residual plaque and calculus attributable to the difficulty of instrumentation in these deep pockets or an inability or unwillingness of the patient to perform adequate oral hygiene in these sites. Patients with inadequate oral hygiene are not good candidates for periodontal surgery. If the supragingival plaque control is good, and the residual pocket depths are 5 mm or more, such areas may be candidates for periodontal surgery. [14]

Resective osseous surgery is also used to facilitate certain restorative/prosthetic dental procedures. Dental caries can be exposed for restoration, fractured roots of abutment teeth can be exposed for removal, and bony exostoses and ridge deformities can be altered in contour to improve the performance of removable or fixed prostheses (Fig. 62-7, A to D). Severely decayed teeth or teeth with short anatomic crowns can be lengthened by resection or by a combination of orthodontic tooth extrusion and osseous resection. Such procedures allow the therapist to expose more tooth for restoration, prevent an invasion of the biologic width of attachment, and create a periodontal attachment of normal dimension. [8,16] Resection can also provide a means of producing optimal crown length for cosmetic purposes.

METHODS OF OSSEOUS RESECTIVE SURGERY

The reshaping process is fundamentally an attempt to gradualize the bone sufficiently to allow soft tissue structures to follow the contour of the bone. The soft tissue predictably attaches to the bone within certain specific dimensions. The length and quality of connective tissue and junctional epithelium that reforms in the surgical

site are dependent on numerous factors, including the health of the tissue, the condition of the root surface and the topography, as well as the proximity of the bone surrounding the tooth. Each of these factors must be controlled to the best of the clinician's ability to obtain the optimal result, making osseous resective surgery an extremely precise technique.

It is assumed in this chapter that the gingival tissue has been reflected by the apically positioned flap described in Chapter 60. Reshaping of the bone may necessitate selective changes in gingival height. These changes must be calculated and accounted for in the initial flap design. For this reason, it is important for the clinician to know about the underlying bone tissue before flap reflection. The clinician must gain as much indirect knowledge as possible from soft tissue palpation, radiographic assessment, and transgingival probing, or *sounding.*

Radiographic examination can reveal the existence of angular bone loss in the interdental spaces; these usually coincide with intrabony pockets. The radiograph does not show the number of bony walls of the defect, nor does it determine with any accuracy the presence of angular cone defects on facial or lingual surfaces. Clinical examination and probing determines the presence and depth of periodontal pockets on any surface of any tooth and can also give a general sense of the bony topography, but intrabony pockets can go undetected by probing. Both clinical and radiographic examinations can indicate the presence of intrabony pockets when (1) angular bone

loss, (2) irregular bone loss, or (3) pockets of irregular depth in adjacent areas of the same tooth or adjacent teeth are found.

The experienced clinician can use transgingival probing to predict many features of the underlying bony topography. The information thus obtained can change the treatment plan. For example, an area that had been selected for osseous resective surgery may be found to have a narrow defect that was unnoticed in the initial probing and radiographic assessment and is ideal for augmentation procedures. Such findings can and do change the flap design, osseous procedure, and results expected from the surgical intervention. Transgingival probing is extremely useful just before flap reflection. It is necessary to anesthetize the tissue locally before inserting the probe. The probe should be "walked" along the tissue-tooth interface so that the operator can feel the bony topography. The probe may also be passed horizontally through the tissue to provide three-dimensional information regarding bony contours (i.e., thickness, height, and shape of the underlying base). It must be remembered, however, that this information is still "blind," and although it is undoubtedly better than probing alone, it has significant limitations. Nevertheless, this step is recommended immediately before the surgical intervention.

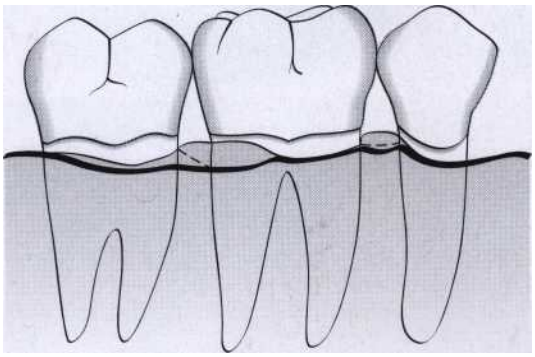

Fig. 62-10 Diagrammatic representation of bone irregularities in periodontal disease. The thick line is the proposed correction of the defect. Note the flattening of the interproximal bone between the molars and the protection of the furcal bone on the first molar. Facial crest height is reduced in both interproximal areas to the depth of the defect.

The situations that can be encountered after periodontal flap reflection vary greatly. When all soft tissue is removed around the teeth, there may be larger exotoses, ledges, troughs, craters, vertical defects, or combinations of any of these. For this reason, each osseous situa-

Minimal pocket depth results from such management.

tion presents uniquely challenging problems, especially if reshaping to the optimal level is contemplated.

THE OSSEOUS RESECTION TECHNIQUE

Instruments Used

A number of hand and rotary instruments have been used for osseous resective surgery. Some excellent clinicians use only hand instruments and rongeurs, whereas others prefer a combination of hand and rotary instruments. Rotary instruments are useful for the osteoplastic steps outlined previously, whereas hand instruments provide the most precise and safe results with ostectomy procedures. Nevertheless, care and precision are required each step of the way to prevent excessive bone removal or root damage, both of which are irreversible. Fig. 62-8 illustrates some of the instruments commonly used for osseous resective techniques.

Technique

To handle the multitude of clinical situations, the following sequential steps are suggested (Fig. 62-9, A to D):

1. Vertical grooving
2. Radicular blending
3. Flattening interproximal bone
4. Gradualizing marginal bone

Not all steps are necessary in every case, but the sequencing of the steps in the order given is necessary to expedite the reshaping procedure, as well as to minimize the removal of bone.

Vertical Grooving

Vertical grooving is designed to reduce the thickness of the alveolar housing and to provide relative prominence to the radicular aspects of the teeth (see Fig. 62-9, B) and Color Fig. 62-1). It also provides continuity from the interproximal surface onto the radicular surface. It is the first step of the resective process, because it can define the general thickness and subsequent form of the alveolar housing. This step is usually performed with rotary instruments such as round carbide burrs or diamonds. The advantages of vertical grooving are most apparent with thick, bony margins; shallow crater formations; or other areas that require maximal osteoplasty and minimal ostectomy. Vertical grooving is contraindicated in areas with close root proximity or thin alveolar housing.

Radicular Blending

Radicular blending, the second step of the osseous reshaping technique, is an extension of vertical grooving (see Fig. 62-9, C). Conceptually, it is an attempt to gradualize the bone over the entire radicular surface to provide the best results from vertical grooving. This provides a smooth, blended surface for good flap adaptation. The indications are the same as for vertical grooving (i.e., thick ledges of bone on the radicular surface, where selective surgical resection is desired). Naturally, this step is not necessary if vertical grooving is very minor or if the radicular bone is thin or fenestrated. Both vertical grooving and radicular blending are purely osteoplastic techniques that do not remove supporting bone. In most situations, they compose the bulk of osseous resective surgery. Classically, shallow crater formations, thick osseous ledges of bone on the radicular surfaces, and class I and early class II furcation involvements are treated almost entirely with these two steps.

Flattening Interproximal Bone

Flattening of the interdental bone requires the removal of very small amounts of supporting bone (Fig. 62-10). It is indicated when interproximal bone levels vary horizontally. By definition, most of the indications for this step are one-walled interproximal defects or so-called hemiseptal defects. The omission of flattening in such cases results in increased pocket depth on the most apical side of the bone loss. This step is typically not

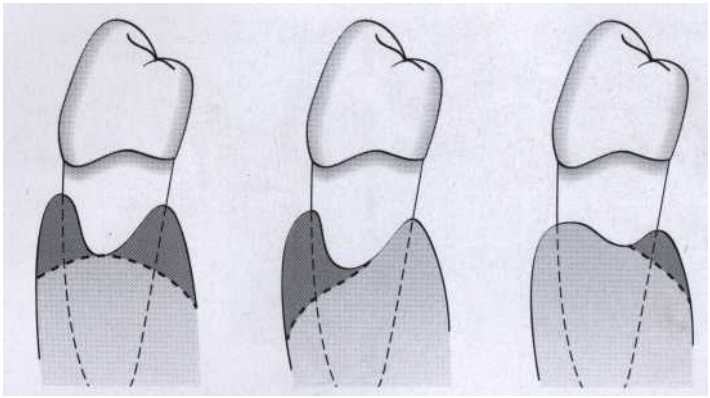

Fig. 62-13 Interproximal craters. The shaded areas illustrate different techniques for the management of such defects. The technique that reduces the least amount of supporting bone is preferable.

necessary in class crater formations or flat interproximal defects. It is best used in defects that have a coronally placed one-walled edge of a predominantly three-walled angular defect, and it can be helpful in obtaining good flap closure and improved healing in the three-walled defect. The limitation of this step, as with osseous resective surgical therapy in general, is in the treatment of advanced lesions. Large hemiseptal defects would require removal of inordinate amounts of bone to provide a flattened architecture, and the operation would be too costly in terms of bony support. Compromised osseous architecture is the only logical solution (Fig. 62-11).

Gradualizing Marginal Bone

The **final step in the osseous resective technique is also** an ostectomy process. Bone removal is minimal but necessary to provide a sound, regular base for the gingival tissue to follow. Failure to remove small bony discrepancies on the gingival line angles (often called widow's *peaks)* allows the tissue to rise to a higher level than the base of the bone loss in the interdental area (see Fig. 62-9, C and D). This may make the process of selective recession and subsequent pocket reduction incomplete. This step of the procedure also requires gradualization and blending of the radicular surface (see Fig. 62-10 and Color Fig. 62-1, C. The two ostectomy steps should be performed with great care so as not to produce nicks or grooves on the roots. When the radicular bone is thin, it is extremely easy to overdo this step, to the detriment of the entire surgical effort. For this reason, various hand instruments, such as chisels and curettes, are preferable to rotary instruments for gradualizing marginal bone.

FLAP PLACEMENT AND CLOSURE

Following the performance of resection, the flaps are positioned and sutured. Flaps may be replaced to their original position, to cover the new bony margin, or they may be apically positioned. Replacing the flap in areas that previously had deep pockets may result initially in greater postoperative pocket depth, although a selective recession may diminish the depth over time. Positioning the flap apically to expose marginal bone is one method

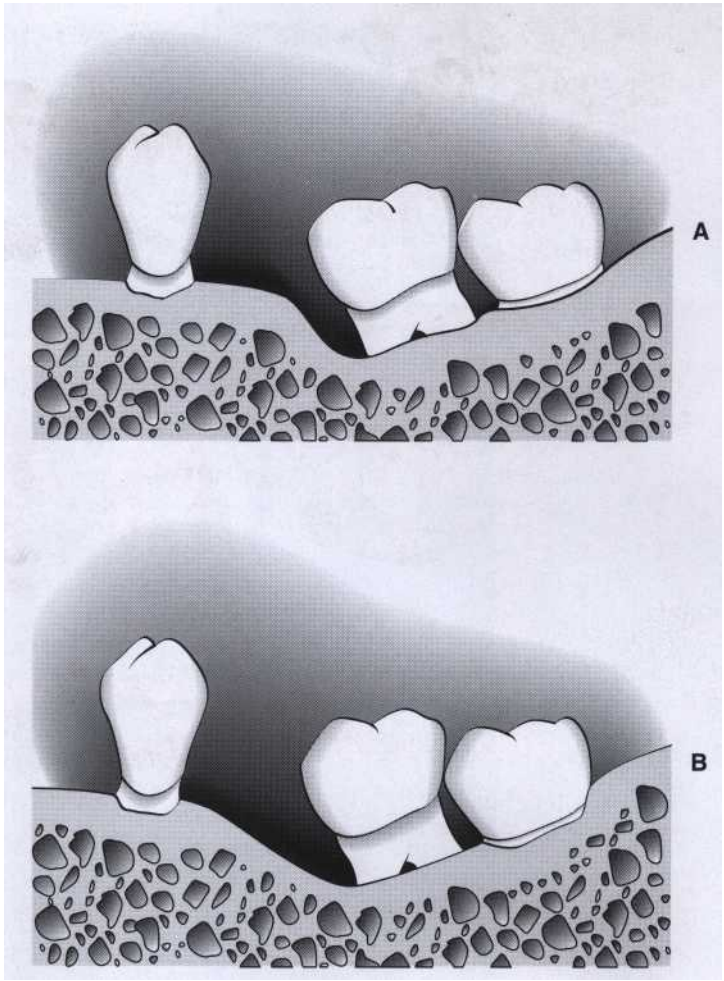

Fig. 62-14 Reduction of a one-wall angular defect. A, Angular bone defect mesial to the tilted molar. B, Defect reduced by "ramping" angular bone.

of altering the width of the gingiva (denudation). However, such flap placement results in more postsurgical resorption of bone and patient discomfort than if the newly created bony margin were covered by the flap. Positioning the flap to cover the new margin results in a minimum of postoperative complications and optimal postsurgical pocket depths' (Fig. 62-12, I and J).

Suturing may be accomplished using a variety of different suture materials and suture knots' (see Chapter 60). **The sutures should be placed with minimal tension to co**apt the **flaps, prevent their separation, and maintain the position of the** flaps. Sutures placed with excessive tension rapidly pull through the tissues.

POSTOPERATIVE MAINTENANCE

Sutures may be removed at varying periods. Nonresorbable sutures such as silk are usually removed after 1 week of healing, although some of **the newer synthetic materials may be left for periods of up to 3 weeks** or longer without adverse consequences. Resorbable sutures maintain wound approximation for varying periods or 1 to 3 weeks or more, depending on **the material of which they are made. At the suture removal appointment**

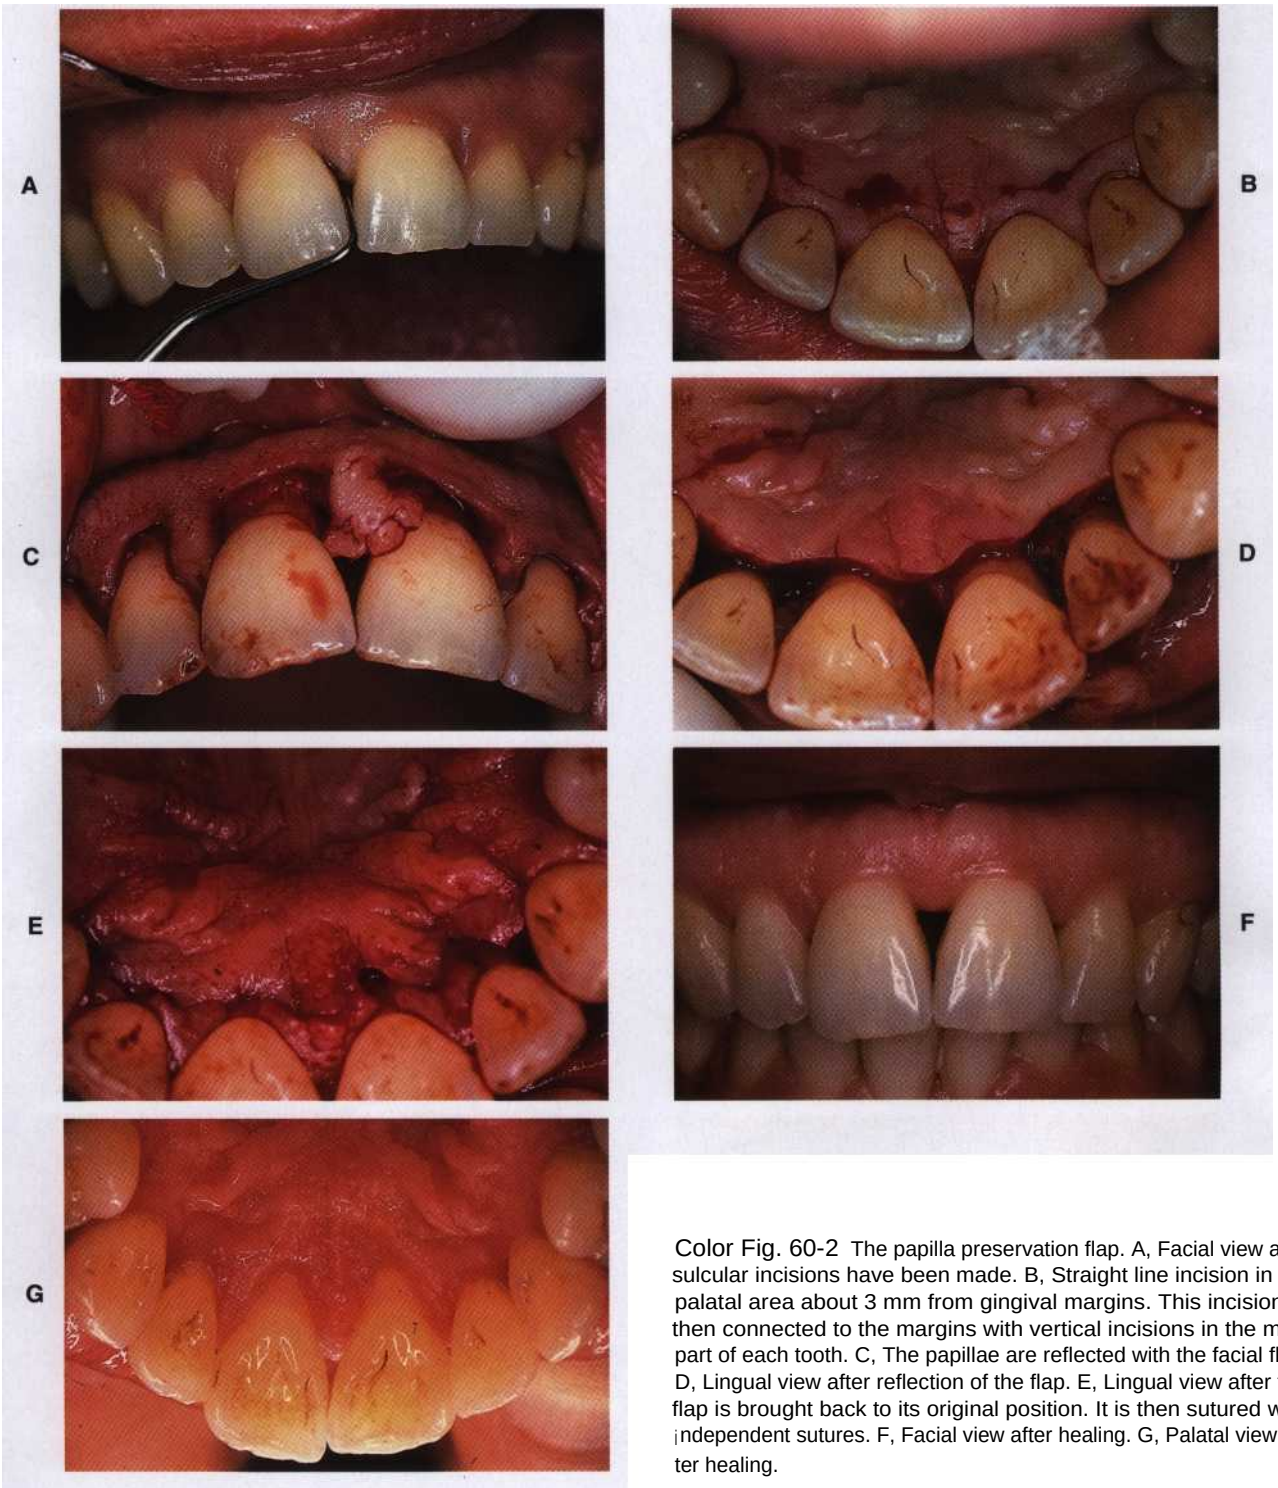
the periodontal dressing, if present, is removed, and the surgical site is gently cleansed of debris with a cotton pellet dampened with saline. Nonresorbable sutures are then cut and removed. If sutures of a resorbable material were used, then the area should be inspected carefully to insure that no suture fragments remain. Suture removal should be accomplished without dragging contaminated portions of the suture through the periodontal tissues. This may be accomplished by lightly compressing the soft tissue immediately adjacent to the suture. This exposes (extrudes) a portion of the suture that was previously under the gingival tissues and less likely to be contaminated by plaque. The suture is then cut at the gingival surface. Removal of the pressure from the site results in the cut surface being slightly submerged in the tissue. The sutures are then removed with cotton pliers by pulling the suture from its contaminated end.

After suture removal the surgical site is examined carefully, and any excessive granulation tissue is removed with a sharp curette. The patient is provided with postsurgical maintenance instructions and the instruments needed to maintain the surgical site in a plaque-free state. These instruments should not produce additional trauma to the healing tissues. Many therapists find the use of a plaque-suppressive agent such as chlorhexidine digluconate to be a valuable adjunct to postsurgical maintenance. A second postoperative visit is often performed at the second or third week, and the surgical site is lightly debrided for optimal results. A professional prophylaxis for complete plaque removal should be done every 2 weeks until healing is complete and the patient is maintaining appropriate levels of plaque control.



Healing should proceed uneventfully, with the attachment of the flap to the underlying bone being

completed by 14 to 21 days. Maturation and remodeling can continue for up to 6 months. It is usually advisable to wait a minimum period of 6 weeks after the completion of the last surgical area before beginning dental restorations. For those patients with a major cosmetic concern, it is wise to wait as long as possible to achieve a postoperative soft tissue position and sulcus that is stable.

SPECIFIC OSSEOUS RESHAPING SITUATIONS

The osseous corrective procedure that has been described is classically applied to shallow craters with heavy faciolingual ledges (Fig. 62-13). The correction of other osseous defects is also possible; however, careful case selection for definitive osseous surgery is very important.

Correction of one-walled hemiseptal defects requires that the bone be reduced to the level of the most apical portion of the defect. Therefore great care should be taken to select the adequate case. If one-walled defects occur next to an edentulous space, the edentulous ridge is reduced to the level of the osseous defect (Fig. 62-14).

Other situations that complicate osseous correction are exostoses (Fig. 62-15; see Color Fig. 62-1, D and E), malpositioned teeth, and supraerupted teeth. Each of these situations is best controlled by following the four steps previously outlined. In most situations, the unique feature of the bony profile is well managed by prudently applying the same principles. (Fig. 62-16; see Color Fig. 62-1). However, some situations require deviation from the definitive osseous reshaping technique; examples include dilacerated roots, root proximity, and furcations that would be compromised by osseous surgery.

In the absence of ledges or exostoses, the elimination of the bony lesion begins with reduction of the interdental walls of craters and the one-walled component of angular defects and wells (moats) and grooving into sites of early involvement." The walls of the crater may be reduced at the expense of the buccal, lingual, or both walls (Fig. 62-17). The reduction should be made to remove the least amount of alveolar bone required to produce a satisfactory form, prevent the therapeutic invasion of furcations, and blend the contours with the adjacent teeth. The selective reduction of bony defects by "ramping" the bone to the palatal or lingual to avoid involvement of the furcations has been advocated by Ochsenbein and Bohannan19 and Tibbetts, Ochsenbein, and Loughlin24 (Fig. 62-18).

One-walled or hemiseptal defects usually require the removal of some bone from the tooth with the greatest coronal bony height. This removal of bone may result in a significant reduction in attachment on relatively unaffected adjacent teeth to eliminate the defect (see Fig. 62-16, A and B). However, if a tooth in the surgical field has one-walled defects on both its mesial and distal surfaces and this is recognized during examination, the severely affected tooth may be extruded by orthodontics during disease control treatment to minimize or eliminate the need for resection of bone from the adjacent teeth.

In the presence of heavy ledges of bone, it is usually wise to do osteoplasty first to eliminate any exostoses or reduce the buccal/lingual bulk of the bone (Fig. 62-19). It is common to incorporate a degree of vertical grooving during the reduction of bony ledges, since it facilitates the process of blending the radicular bone into the interproximal areas at the next step.

SUMMARY

Though osseous surgical techniques cannot be applied to every single bony abnormality or topographic modification, clearly it has been demonstrated that properly used osseous surgery can eliminate and modify defects, as well as gradualize excessive bony ledges, irregular alveolar bone, early furcation involvement, excessive bony exostosis, and circumferential defects. When properly performed, osseous resective surgery achieves a physiologic architecture of marginal alveolar bone conducive to gingival flap adaptation with minimal probing depth. The advantages of this surgical modality include a predictable amount of pocket reduction that can enhance oral hygiene and periodic maintenance. It also preserves the width of the attached tissue, while removing granulatous tissue and providing access for debridement of the radicular surfaces. Additionally, recontouring of bony abnormalities, including hemiseptal defects, tori, and ledges, is permitted. Proper assessment for restorative procedures such as crown lengthening and assessment of restorative overhangs and tooth abnormalities such as enamel projections, enamel pearls, perforations, and fractures is also a substantial benefit of osseous resective surgery. All factors lead to the conclusion that osseous resective surgery can be an important technique in the armamentarium necessary to provide a maintainable periodontium for periodontal patients.

Non-Graft-Associated New Attachment
Graft Materials and Procedures
Combined Techniques
FACTORS INFLUENCING A SUCCESSFUL OUTCOME
SUMMARY

New attachment with periodontal regeneration is the ideal outcome of therapy because it results in obliteration of the pocket and reconstruction of the marginal periodontium (Color Fig. 63-1; Fig. 63-1). However, the techniques available are not totally dependable, and the following other results of therapy may be seen (Fig. 63-2):

1. Healing with a long junctional epithelium, which can occur even if filling in of bone has occurred.
2. Ankylosis of bone and tooth with resultant root resorption.
3. Recession.
4. Recurrence of the pocket.
5. Any combination of the above.

EVALUATION OF NEW ATTACHMENT AND BONE REGENERATION

It is sometimes difficult in clinical and experimental situations to determine whether new attachment has occurred and the extent to which it has occurred. Evidences of reconstruction of the marginal periodontium can be obtained by clinical, radiographic, surgical reentry, or histologic procedures.[28-99] All these methods have advantages and shortcomings that should be well understood and considered in individual cases and when critically evaluating the literature.

Clinical Methods

Clinical methods consist of comparison of pre- and posttreatment pocket probings and determinations of clinical gingival findings. The probe can be used to determine pocket depth, attachment level, and bone level (see Chapter 30) (Fig. 63-3). Clinical determinations of attachment level are more useful than strict pocket depths because the latter may change as a result of displacement of the gingival margin. Several studies have determined that the depth of penetration of a probe in a periodontal pocket varies according to the degree of inflammatory involvement of the tissues immediately beneath the bottom of the pocket (Fig. 63-4). Therefore even though the forces used may be standardized with pressure-sensitive probes, there is an inherent margin of error in this method that is difficult to overcome. Fowler and colleagues[54] have calculated this error to be 1.2 mm, but it is even greater when furcations are probed.'"

Bone probing performed under anesthesia is not subject to this error and has been found to be as accurate as bone height measurements made on surgical reentry.'°[144,186]

Measurements of the defect should be made before and after treatment from the same exact point within the defect and with the same angulation of the probe. This reproducibility of probe placement is difficult and

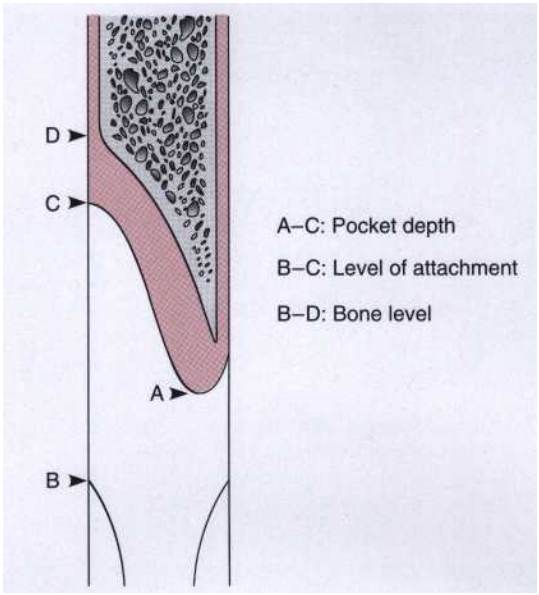

Fig. 63-3 Different types of probings in an interdental space.

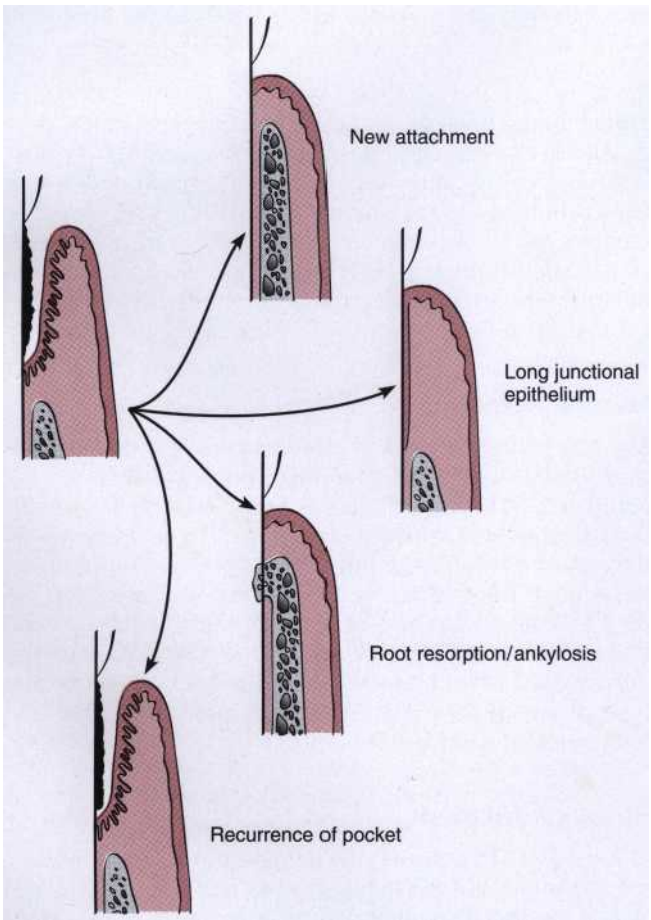

Fig. 63-2 Possible outcomes of therapy.

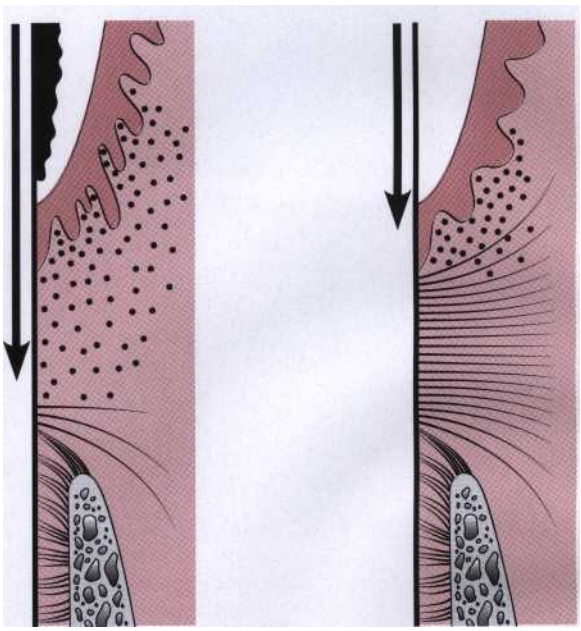

Fig. 63-4 *Left,* Arrow pointing downward depicts penetration of a probe in an untreated periodontal pocket. The probe tip goes past the junctional epithelium and the inflamed tissue and is stopped by the first intact, attached collagen fibers. *Right* After thorough scaling and root planing, the location of the bottom of the pocket has not changed, but the probe penetrates to only about one third the length of the junctional epithelium (see Chapter 30). *The reduction in probing depth may not reflect a change in attachment level.*

may be facilitated in part by using a grooved stent to guide the introduction of the probe (Fig. 63-5). Preoperative and postoperative comparability of probing measurements that do not use this standardized method may be open to question.

Radiographic Methods

Radiographic evaluation of bone regeneration also requires carefully standardized techniques for reproducible positioning of the film and the tube. [128,148] Even with standardized techniques (see Chapter 34), the radiograph

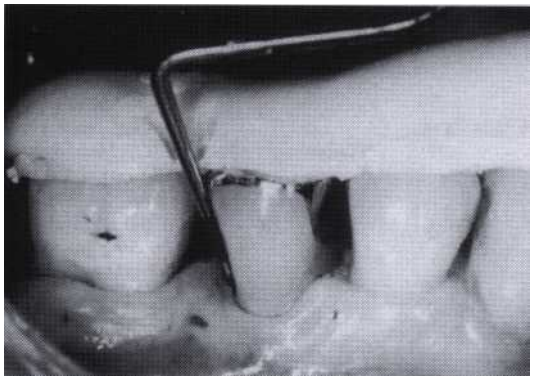

Fig. 63-5 Grooved acrylic stent used in clinical research to standardize the direction of introduction of the probe.

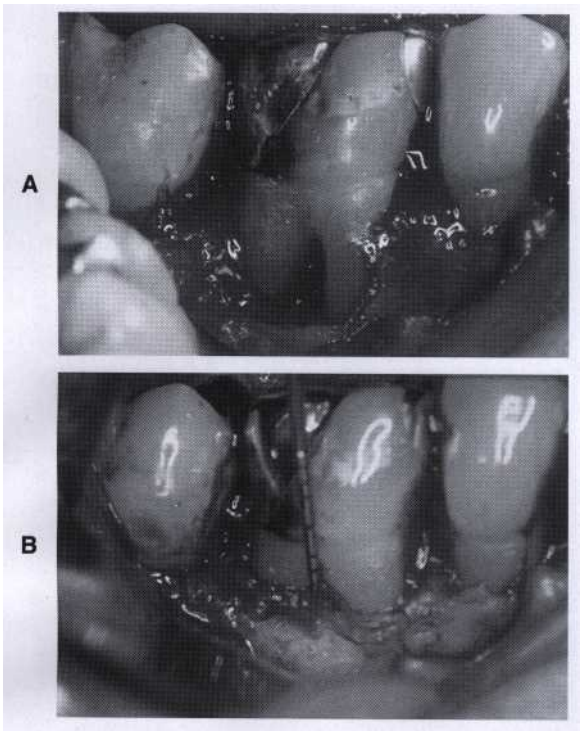

Fig. 63-6 Reentry evidence of bone apposition following regenerative therapy. A, Surgical exposure of facial bone dehiscence and furcation defects. Int j Periodont Restorative Dent 1993; 13:15.)

does not show the entire topography of the area before or after treatment. Furthermore, thin bone trabeculae may exist before treatment and go undetected radiographically because a certain minimal amount of mineralized tissue must be present to register on the radiograph. Several studies have demonstrated that radiographs, even those taken with standardized methods, are less reliable than clinical probing techniques .[91,178] A comparative study of pretreatment bone levels and posttherapy bone fill with 12-month reentry bone measurements showed that linear

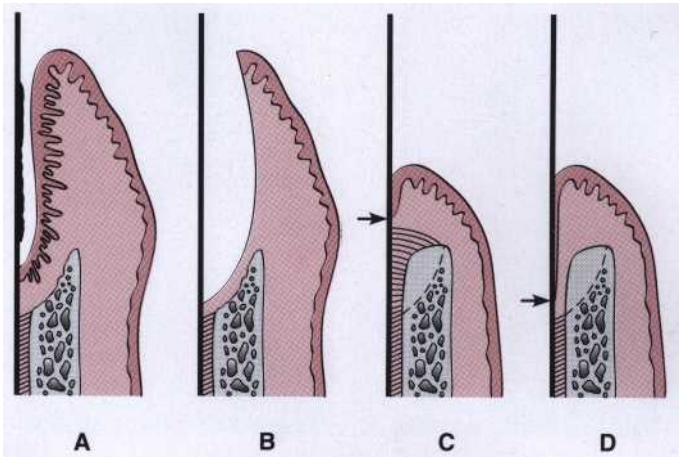

Fig. 63-7 A, Periodontal pocket preoperatively. B, Periodontal pocket immediately after scaling, root planing, and curettage. C, New attachment. Again, the arrow indicates the most apical part of the junctional epithelium. Note that the bone is new but the periodontal ligament is not.

radiographic analysis significantly underestimates pretreatment bone loss and posttreatment bone fill.'"

Studies with subtraction radiography have enhanced the usefulness of radiographic evaluation .[43,44,190] A comparative study between linear measurement, computer assisted densitometric analysis (CADIA) (see Chapter 34), and a method combining the two reported that the linear-CADIA method offers the highest level of accuracy. [179]

Surgical Reentry

The surgical reentry of a case after a period of healing can give a good view of the state of the bone crest that can be compared with the view taken during the initial surgical intervention and can also be subject to measurements (Fig. 63-6). Models from impressions of the bone taken at the time of the initial surgery and later at reentry can be used to assess the results of therapy. This method is very useful but has two shortcomings: it requires a frequently unnecessary second operation, and it does not show the type of attachment that exists (i.e., new attachment or long junctional epithelium (Fig. 63-7).[31]

Histologic Methods

The type of attachment can be determined only by histologic analysis of tissue blocks obtained from the healed area. Although this method can offer clear evidence of regeneration of the attachment apparatus, it is not without problems. The need to remove a tooth with its periodontium after successful treatment limits this method to volunteers who need the extraction for prosthetic or other reasons and agree to the procedure.

Animal studies can be used to clarify some aspects of the tissue response to different materials. However, species differences should always be remembered when extrapolations to humans are attempted. The compati-

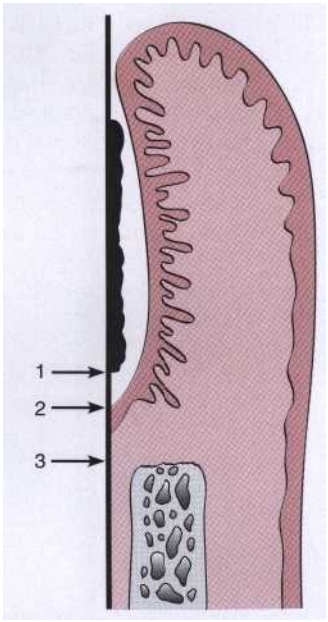

Fig. 63-8 For future histologic reference, notches can be placed clinically at the most apical part of the calculus (1) or at the level of the osseous crest (3). However, the real landmark that determines whether new attachment has taken place is the base of the pocket (2).

bility of a material with the tissues can be shown by implanting the substance into the long bones or calvaria of rats or other rodents, but this does not prove the regeneration of periodontal attachment.

Studies of the reconstruction of periodontal structures have been performed in dogs, monkeys, and pigs. Because it is difficult to find naturally occurring periodontal osseous defects that would be adequate for a study, experimentally induced bone defects must be used. Surgically produced bone defects can simulate the shape of osseous periodontal lesions but lack their chronicity and self-sustaining features. They are not exactly similar to naturally occurring disease. They can be allowed to become chronically infected, and then their similarity to chronic natural lesions improves, but they are never identical.[192] However, these studies are useful to establish healing sequences and mechanisms.

In addition, the exact location of the bottom of the pocket must be determined prior to the procedure because the surgical technique opens tissues beyond the bottom of the pocket, and healing below this point does not constitute new attachment. Notches on the root surface must be used to indicate this important point. Because the exact coronal point of the junctional epithelium is lost when surgically opening the area, a decision must be made as to whether to place the notch at the bottom of the calculus or on the crest of the alveolar bone (Figs. 63-8 and 63-9). The former is slightly coronal and the latter slightly apical to the real bottom of the pocket. The bottom of the calculus is a better landmark, but obviously the presence of calculus is required.

Numerous pitfalls are therefore inherent in histologic studies, and their accuracy and reliability should always be very carefully considered.

REGENERATIVE SURGICAL TECHNIQUES

Regenerative periodontics can be subdivided into two major areas: non-graft-associated new attachment and graft-associated new attachment. Many techniques combine both approaches.

All recommended techniques include careful and complete removal of all irritants. Although this can be done in some cases as a closed procedure, in the great majority of cases it should be done after exposure of the area with a flap. Flap design and incisions should follow the description given in Chapter 60 for regenerative flaps. Trauma from occlusion may impair posttreatment healing of the supporting periodontal tissues, reducing the likelihood of new attachment. Occlusal adjustment, if needed, is therefore indicated.

Systemic antibiotics are generally used after regenerative periodontal therapy, although definitive information on the advisabilitty of this measure is still lacking. Case reports have been presented showing extensive regeneration of the periodontal lesions after scaling, root planing, and curettage combined with systemic and local treatment with penicillin or tetracycline in combination with other forms of therapy.[25,120]

Non-Graft-Associated New Attachment

Periodontal reconstruction can be attained without the use of grafts in meticulously treated three-wall defects (intrabony defects) and in periodontal and endodontal abscesses.[21,66,79,122,138] New attachment is more likely to occur when the destructive process has occurred very rapidly (e.g., after treatment of pockets complicated by the formation of acute periodontal abscesses and after treatment of acute necrotizing ulcerative gingivitis).

The following section covers the rationale and technique for the removal of the junctional and pocket epithelium and the prevention of their migration into the healing area after therapy. It also covers the so-called bio-conditioning of the root surface and the use of growth factors and enamel matrix proteins to enhance or direct healing.

Removal of junctional and Pocket Epithelium.

Since the earliest attempts at periodontal new attachment, the presence of junctional and pocket epithelium has been perceived as a barrier to successful therapy because its presence interferes with the direct apposition of connective tissue and cementum, thus limiting the height to which periodontal fibers can become inserted to the cementum.[76,118,141,193] Several methods have been recommended to remove junctional and pocket epithelia. These include curettage, chemical agents, ultrasonic methods, and surgical techniques.

CURETTAGE. Results of removal of epithelium by means of curettage vary from complete removal to persistence of as much as 50%.[165] It therefore is not a reliable procedure. Ultrasonic methods and rotary abrasive stones have also been used, but their effects cannot be controlled because of the clinician's lack of tactile sense when using these methods

CHEMICAL AGENTS. Chemical agents have also been used to remove pocket epithelium, in most cases in

conjunction with curettage. The most commonly used drugs have been sodium sulfide, phenol camphor, antiformin, and sodium hypochlorite. However, the effect of these agents is not limited to the epithelium, and their depth of action cannot be controlled. They are mentioned here for their historical interest.

SURGICAL TECHNIQUES. Surgical techniques have been recommended to eliminate the pocket and junctional epithelia. The *excisional new attachment procedure* consists of an internal bevel incision performed with a surgical knife, followed by removal of the excised tissue.[194] No attempt is made to elevate a flap. After care-

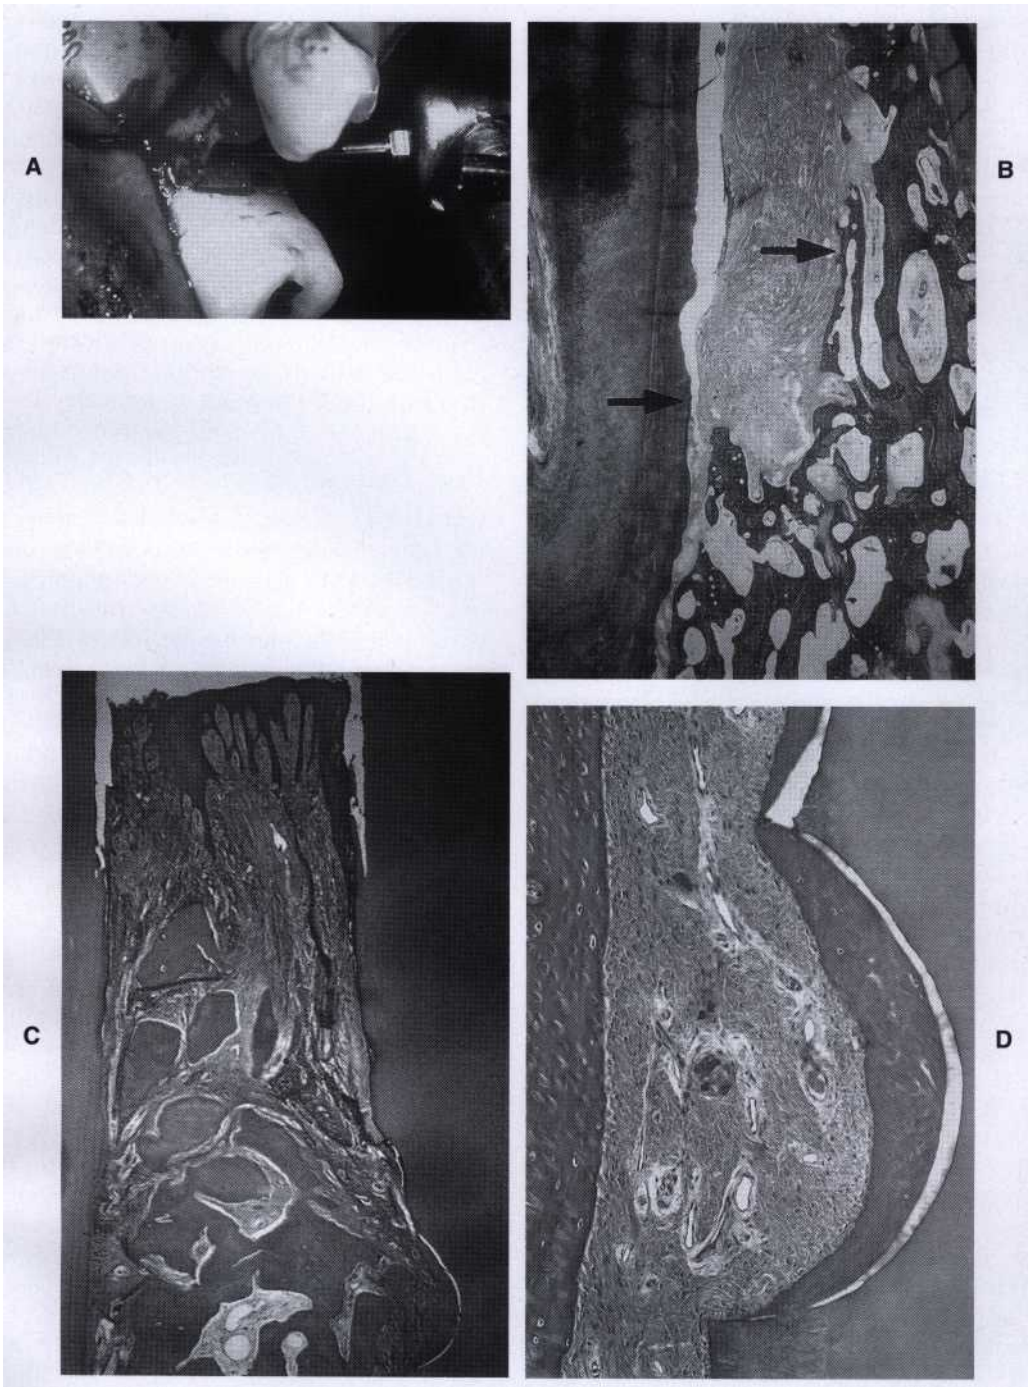

Fig. 63-9 A, Notch being placed through the apical extent of the calculus into the root surface as a histologic marker. B, Six-month postoperative histologic block section of control site depicting no regeneration coronal to the reference notch (arrow). C, Six-month postoperative histologic block section of experimental site using a demineralized freeze-dried bone allograft depicting regeneration coronal to the crestal bone notch (calculus notch 7 mm apical to crestal notch). D, High power of reference notch through calculus at base of defect with new cementum (artifactual split during histologic preparation), bone, and periodontal ligament. (Courtesy Dr. Gerald Bowers, University of Maryland.)

ful scaling and root planing, interproximal sutures are used to close the wound (see Chapter 57).

Glickman and Prichard have advocated performing a *gingivectomy to the crest of the alveolar bone and debriding the defect.*[65,137] Excellent results have been obtained with this technique in uncontrolled human studies .[8,138]

The *modified Widman flap,* as described by Ramfjord and Nissle, is similar to the excisional new attachment procedure but is followed by elevation of a flap for better exposure of the area.'" It eliminates the pocket epithelium with the internal bevel incision (see Chapter 61).

Another approach to delaying epithelial migration into the healing pocket area has been the use of *coronal displacement of the flap,* which increases the distance between the epithelium and the healing area. This technique is particularly suitable for the treatment of lower molar furcations and has been used mostly in conjunction with citric acid treatment of the roots .[61,10'] Periodontal regeneration after the use of this technique has been demonstrated histologically in humans.'"

Prevention of Epithelial Migration. Elimination of junctional and pocket epithelia may not be sufficient because the epithelium from the excised margin may rapidly proliferate to become interposed between the healing connective tissue and the cementum.

Several investigators have analyzed in animals and humans the effect of excluding the epithelium by amputating the crown of the tooth and covering the root with the flap *(root submergence).* [12,13,17] This experimental technique not only excludes the epithelium but also prevents microbial contamination of the wound during the reparative stages. Successful repair of osseous lesions in the submerged environment was reported, but obviously this method has little or no clinical application.

Another method proposed to prevent or retard the migration of the epithelium consists of total removal of the interdental papilla covering the defect and its replacement with a *free autogenous graft* obtained from the palate.[46] During healing, the epithelium necroses, and its migration is retarded.

GUIDED TISSUE REGENERATION. The method for the prevention of epithelial migration along the cemental wall of the pocket that has gained wide attention is the so-called *guided tissue regeneration (GTR).* This method derives from the classic studies of Nyman, Lindhe, Karring, and Gottlow and is based on the assumption that only the periodontal ligament cells have the potential for regeneration of the attachment apparatus of the tooth .[68,69,125,126] It consists of placing barriers of different types to cover the bone and periodontal ligament, thus temporarily separating them from the gingival epithelium (see Chapter 36). Excluding the epithelium and the gingival connective tissue from the root surface during the postsurgical healing phase not only prevents epithelial migration into the wound but also favors repopulation of the area by cells from the periodontal ligament and the bone.

Initial animal experiments using Millipore filters and Teflon membranes resulted in regeneration of cementum and alveolar bone and a functional periodontal ligament.[29,30,33,116] Clinical case reports showed that guided tissue regeneration results in a gain in attachment level, which is not necessarily associated with a buildup of alveolar bone.[9,10] Histologic studies in humans provided evidence of periodontal regeneration in most instances, even in cases of horizontal bone losses.[69,170,174]

The use of polytetrafluoroethylene membranes (Gore-Tex periodontal material, Gore-Tex, Flagstaff, AZ) has been tested in controlled clinical studies in lower molar furcations and has shown statistically significant decreases in pocket depths and improvement in attachment levels after 6 months; bone level measurements have been inconclusive .[94,136] A study on upper molar furcations did not result in significant gain in attachment or bone levels.'"

The initial membranes developed were nonresorbable and therefore required a second operation, albeit frequently very simple, to remove it. This second operation was done after the initial stages of healing, usually 3 to 6 weeks after the first intervention. This second operation was a significant obstacle in the utilization of the procedure, and therefore resorbable membranes were developed.[189]

The expanded polytetrafluoroethylene membrane (nonresorbable) can be obtained in different shapes and sizes to suit proximal spaces and facial/lingual surfaces of furcations (Fig. 63-10). The technique for its use is as follows (Figs. 63-11):

1. Raise a mucoperiosteal flap with vertical incisions, extending a minimum of two teeth anteriorly and one tooth distally to the tooth being treated.
2. Debride the osseous defect and thoroughly plane the roots.
3. Trim the membrane with sharp scissors to the approximate size of the area being treated. The apical border of the material should extend 3 to 4 mm apical to the margin of the defect and laterally 2 to 3 mm beyond the defect; the occlusal border of the membrane should be placed 2 mm apical to the cementoenamel junction.[10]
4. Suture the membrane tightly around the tooth with a sling suture.
5. Suture the flap back in its original position or slightly coronal to it, using independent sutures interdentally and in the vertical incisions. The flap should cover the membrane completely.
6. The use of periodontal dressings is optional, and the patient is placed on antibiotic therapy for 1 week.

After 4 to 6 weeks, the margin of the membrane becomes exposed. The membrane is removed with a gentle tug 5 weeks after the operation. If it cannot be removed

Burton Becker and William Becker, Tucson, Ariz.)

easily, the tissues are anesthetized and the material is surgically removed using a miniflap.

The results obtained with the guided tissue regeneration technique are enhanced when the technique is combined with grafts placed in the defects (see Combined Technique).', [16,92,103]

The Use of Biodegradable Membranes. The search for resorbable membranes included tests with rat collagen, bovine collagen, Cargile membrane derived from the cecum of an ox, polylactic acid, Vycril (polyglactin 910), synthetic skin (Biobrane), and freeze-dried dura mater. [14,11,24,32,52,53,60,100,101,131-133,189,196] Clinical studies with a mixture of copolymers derived from polylactic acid and acetyl tributylcitrate resorbable membranes (Guidor membrane, no longer on the market) and a poly-D,L-lactide-co-glycolide (Resolut membrane, also no longer on the market) have shown significant gains in clinical attachment and bone fill. [34,61,180]

Resorbable membranes marketed in the U.S. as of this writing include: OsseoQuest, Gore Co. (polyglycolic acid, polylactic acid and trimethylene carbonate; resorbs at 6 to 14 months); BioGuide, OsteoHealth Co. (bi-layer porcine-derived collagen); Atrisorb, Block Drug Co.

(polylactic acid gel); and BioMend, Calcitech Co. (bovine Achilles tendon collagen, resorbs in 4 to 18 weeks).

The potential of using autogenous periosteum as a membrane and also to stimulate periodontal regeneration has been explored in two controlled clinical studies, one of grade II furcation involvements in lower molars and another of interdental defects .90,93 The periosteum was obtained from the patient's palate by means of a window flap. Both studies reported that autogenous periosteal grafts can be used in guided tissue regeneration and result in significant gains in clinical attachment and osseous defect fill.

Clot Stabilization, Wound Protection, and Space Creation. Some investigators have attributed the successful results reported with graft materials, barrier membranes, and coronally displaced flaps to the fact that all protect the wound and create a space for undisturbed and stable maturation of the clot. 62,74,11 This hypothesis suggests that preservation of the root surface-fibrin clot interface prevents apical migration of the gingival epithelium and allows for connective tissue attachment during the early wound healing period .62,192

The importance of space creation for bone repair has long been recognized in orthopedic and maxillofacial surgery. Transference of this concept to periodontal therapy has been explored for regeneration techniques and root coverage and treatment of periimplant bone defects. The space is created by using a titanium-reinforced ePTFE membrane to prevent its collapse. For the study of regenerative techniques, these membranes were placed over experimentally created supraalveolar bone defects in dogs and considerable bone regeneration was reported. 164

Biomodification of the Root Surface. Changes in the tooth surface wall of periodontal pockets (e.g., degeneration of remnants of Sharpey's fibers, accumulation of bacteria and their products, and disintegration of the cementum and dentin) interfere with new attachment. However, these obstacles to new attachment can be eliminated by thorough root planing.

Several substances have been used in attempts to better condition the root surface for attachment of new connective tissue fibers. These include citric acid, fibronectin, and tetracycline.

CITRIC ACID. Studies by Urist showed that the implantation of demineralized dentin matrix into muscle tissue in animals induced mesenchymal cells to differentiate into osteoblasts and started an osteogenic process. 183-185 Following up on this concept, a series of studies applied citric acid to the roots to demineralize the surface, thus inducing cementogenesis and attachment of collagen fibers.

The following actions of citric acid have been reported:

1. Accelerated healing and new cementum formation occur after surgical detachment of the gingival tissues and demineralization of the root surface by means of citric acid. 143
2. Topically applied citric acid on periodontally diseased root surfaces has no effect on nonplaned roots, but after root planing, the acid produces a 4-mm-deep demineralized zone with exposed collagen fibers . 64
3. Root-planed, non-acid-treated roots are left with a surface smear layer of microcrystalline debris; citric acid application not only removes the smear layer, exposing the dentinal tubules, but also makes the tubules appear wider and with funnel-shaped orifices. 134
4. Citric acid has also been shown in vitro to eliminate endotoxins and bacteria from the diseased tooth surface .39,51
5. An early fibrin linkage to collagen fibers exposed by the citric acid treatment prevents the epithelium from migrating over treated roots."'

This technique has been extensively investigated in animals and humans. Studies in dogs have given encouraging results, especially for the treatment of furcation lesions, but the results in humans have been contradictory.3 7, 124,143,145,168

The recommended technique is as follows:

1. Raise a mucoperiosteal flap.
2. Thoroughly instrument the root surface, removing calculus and underlying cementum.
3. Apply cotton pledgets soaked in a saturated solution of citric acid (pH 1), and leave on for 2 to 5 minutes.
4. Remove pledgets, and irrigate root surface profusely with water.
5. Replace the flap and suture.

The use of citric acid has also been recommended in conjunction with coverage of denuded roots using free gingival grafts (see Chapter 66).

FIBRONECTIN. Fibronectin is the glycoprotein that fibroblasts require to attach to root surfaces. The addition of fibronectin to the root surface may promote new attachment . 21,50, "1 However, increasing fibronectin above plasma levels produces no obvious advantages. Adding fibronectin and citric acid to lesions treated with GTR in dogs did not improve the results. 22,166

The effect of a fibrin-fibronectin sealing system on healing of periodontal surgical wounds, particularly in reconstructive procedures, has been investigated. 130 This material is commercially available in Europe as Tissucol. It is a biologic mediator that enhances the tissue response in the early phases of wound healing, prevents separation of the flap, and favors hemostasis and connective tissue regeneration. Clinical trials have been promising, but further research is necessary. 35

TETRACYCLINE. In vitro treatment of the dentin surfaces with tetracycline increases binding of fibronectin, which in turn stimulates fibroblast attachment and growth while suppressing epithelial cell attachment and migration.1" It also removes an amorphous surface layer and exposes the dentin tubules. 191 In vivo studies, however, have not shown favorable results.191 A human study showed a trend for greater connective tissue attachment after tetracycline treatment of roots, tetracycline alone gave better results than when combined with fibronectin . 2

Polypeptide Growth Factors. Growth factors are polypeptide molecules released by cells in the inflamed area that regulate events in wound healing. They can be

considered hormones that are not released into the bloodstream but have only a local action. Growth substances regulate connective tissue cell migration and proliferation and synthesis of proteins and other components of the extracellular matrix. 98

These factors, primarily secreted by macrophages, endothelial cells, fibroblasts, and platelets, include platelet-derived growth factor (PDGF), insulin-like growth factor (IGF), basic fibroblastic growth factor (bFGF), and transforming growth factor (TGF)-a and -ß. Growth factors could be used to control events during periodontal wound healing (e.g., promoting proliferation of fibroblasts from the periodontal ligament and favoring bone formation) .187 Howell and co-workers reported that a single application in human periodontal defects of IGF-I resulted in significant improvement in bone fill above that obtained in controls, while another growth factor tested (PDGF-BB) was not effective .82

Enamel Matrix Proteins. Enamel matrix proteins, mainly amelogenin, are secreted by Hertwig's epithelial root sheath during tooth development and induce acellular cementum formation. Based on these observations, they are believed to favor periodontal regeneration. '2

One enamel matrix protein derivative obtained from developing porcine teeth has been approved by the Food and Drug Administration (FDA) and marketed under the trade name *Emdogain*. The material is a viscous gel obtained by mixing 1 ml of a vehicle solution with a powder and applied with a syringe into the site.

The technique, as described by Mellonig, is as follows, lo:

1. Raise a flap for regenerative purposes (see Chapter 60).
2. Remove all granulation tissue and tissue tags, exposing the underlying bone, and remove all root deposits by hand, ultrasonic scaling, or both.
3. Completely control bleeding within the defect.
4. Demineralize the root surface with citric acid pH 1, or preferably with 24% ethylenediaminetetracetic acid (EDTA Biora) pH 6.7 for 15 seconds. This removes the smear layer and facilitates adherence of the Emdogain.
5. Rinse the wound with saline and apply the gel to fully cover the exposed root surface. Avoid contamination with blood or saliva.
6. Close the wound with sutures. Perfect abutment of the flaps is necessary; if this cannot be obtained, correct the scalloping of the gingival margin or perform a slight osteoplasty. Although placement of the dressing is optional, it may protect the wound.

Systemic antibiotic coverage for 10 to 21 days is recommended (Doxycycline, 100 mg daily).

In a histologic study of 10 defects in 8 patients, Yukna and Mellonig report evidences of regeneration (new cementum, new bone, and new periodontal ligament) in 3 specimens, new attachment (connective tissue attachment/adhesion only) in 3 specimens, and a long junctional epithelium in 4 specimens.198 No evidence of root resorption or ankylosis was found.

Heijl et al have compared the use of enamel matrix derivatives with a placebo in 33 patients with 34 paired test and control sites, mostly one and two wall defects, followed for 3 years.'$ They found a statistically significant radiographic bone gain of 2.6 mm. Additional studies are needed to assess its potential use in various defects and possible enhancing effect in combined techniques.

Graft Materials and Procedures

Numerous therapeutic grafting modalities for restoring periodontal osseous defects have been investigated. Material to be grafted can be obtained from the same person (autografts), from a different person of the same species (allografts), or from a different species (xenografts).

Bone graft materials are generally evaluated based on their osteogenic, osteoinductive, or osteoconductive potential. *Ostegenesis* refers to the formation or development of new bone by cells contained in the graft; *osteoinduction is* a chemical process by which molecules contained in the graft (bone morphogenetic proteins or BMPs) convert the neighboring cells into osteoblasts, which in turn form bone; and *osteoconduction is* a physical effect by which the matrix of the graft forms a scaffold that favors outside cells to penetrate the graft and form new bone.

Periodontal defects as sites for transplantation differ from osseous cavities surrounded by bony walls. Saliva and bacteria may easily penetrate along the root surface, and epithelial cells may proliferate into the defect, resulting in contamination and possible exfoliation of the grafts. Therefore the principles established to govern transplantation of bone or other materials into closed osseous cavities are not fully applicable to transplantation of bone into periodontal defects.

The considerations that govern the selection of a material have been defined as follows'":

Biologic acceptability
Predictability
Clinical feasibility
Minimal operative hazards
Minimal postoperative sequelae
Patient acceptance

It is difficult to find a material with all these characteristics, and to date there is no ideal material or technique.

Graft materials have been developed and tried in many forms. To familiarize the reader with various types of graft material, as defined by either the technique or the material used, a brief discussion of each is provided.

All grafting techniques require presurgical scaling, occlusal adjustment as needed, and exposure of the defect with a full-thickness flap. The flap technique best suited for grafting purposes is the papilla preservation flap because it provides complete coverage of the interdental area after suturing. (See Chapter 60 for a description of the technique.) The use of antibiotics after the procedure is generally recommended.

Auto enous Bone Grafts

BONE FROM INTRAORAL SITES. In 1923, Hegedus attempted to use bone grafts for the reconstruction of bone defects produced by periodontal disease. The method was revived by Nabers and O'Leary in 1965, and numerous efforts have been made since that time to define its indications and technique. 121

Sources of bone include bone from healing extraction wounds, bone from edentulous ridges, bone trephined from within the jaw without damaging the roots, newly formed bone in wounds especially created for the purpose, and bone removed during osteoplasty and ostectomy.[27,71,78,80,147]

Osseous Coogulum. Robinson described a technique using a mixture of bone dust and blood that he termed osseous coagulum.[146] The technique uses small particles ground from cortical bone. The advantage of the particle size is that it provides additional surface area for the interaction of cellular and vascular elements.

Sources of the implant material include the lingual ridge on the mandible, exostoses, edentulous ridges, the bone distal to a terminal tooth, bone removed by osteoplasty or ostectomy, and the lingual surface of the mandible or maxilla at least 5 mm from the roots. Bone is removed with a carbide bur #6 or #8 at speeds between 5000 and 30,000 rpm, placed in a sterile dappen dish or amalgam cloth, and used to fill the defect (Fig. 63-12). The obvious advantage of this technique is the ease of obtaining bone from already exposed surgical sites, and its disadvantages are its relatively low predictability and inability to procure adequate material for large defects.[55] Although notable success has been reported by many individuals, studies documenting the efficacy of the technique are still inconclusive.[36,56,51,146]

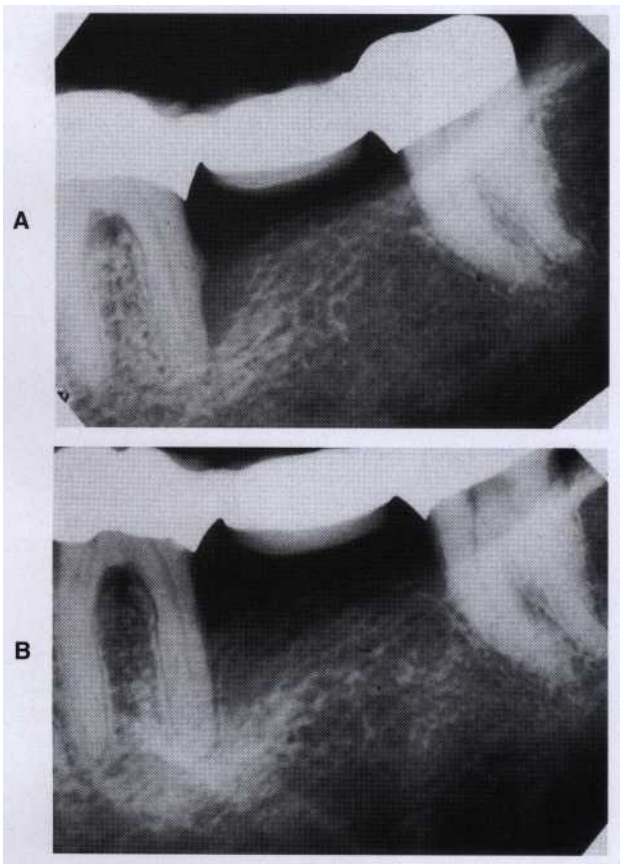

Fig. 63-12 Bone defect on the distal root of a first molar treated with osseous coagulum implants. A, Before treatment. B, One year after treatment. (Courtesy Dr. R. Earl Robinson.)

Bone Blend. Some disadvantages of osseous coagulum derive from the inability to use aspiration during accumulation of the coagulum; another problem is the unknown quantity and quality of the bone fragments in the collected material. To overcome these problems, the so-called bone blend technique has been proposed.[40]

The bone blend technique uses an autoclaved plastic capsule and pestle. Bone is removed from a predetermined site, triturated in the capsule to a workable, plastic-like mass, and packed into bony defects. Froum and co-workers have found osseous coagulum-bone blend procedures to be at least as effective as iliac autografts and open curettage.[56-58]

Intraoral Cancellous Bone Marrow Transplants. Cancellous bone can be obtained from the maxillary tuberosity; edentulous areas, and healing sockets. The maxillary tuberosity frequently contains a good amount of cancellous bone, particularly if the third molars are not present; also, foci of red marrow are occasionally observed. After a ridge incision is made distally from the last molar, bone is removed with a curved and cutting rongeur. Care should be taken not to extend the incision too far distally to avoid sectioning the tendons of the palatine muscle; also, the location of the maxillary sinus has to be analyzed on the radiograph to avoid cutting into it.

Edentulous ridges can be approached with a flap, and cancellous bone and marrow are removed with curettes. Healing sockets are allowed to heal for 8 to 12 weeks, and the apical portion is used as donor material. The particles are reduced to small pieces (Figs. 61-13 and 61-14).

Bone Swaging. This technique requires the existence of an edentulous area adjacent to the defect from which the bone is pushed into contact with the root surface without fracturing the bone at its base.[48,149] Bone swaging is technically difficult, and its usefulness is limited.

B, Mucoperiosteal flap elevated, showing osseous defect on the mesial surface of the first molar. The trephine is inserted into bone distal to the second molar. C, Bone separated by a trephine. D, Bone transplant; the cancellous portion is used and the cortical layer is removed. E, Radiograph showing an osseous defect on mandibular first molar. F, Six months after treatment, showing the osseous defect partially filled with the implant. The radiolucent area in the interdental bone is the donor site of the transplant.

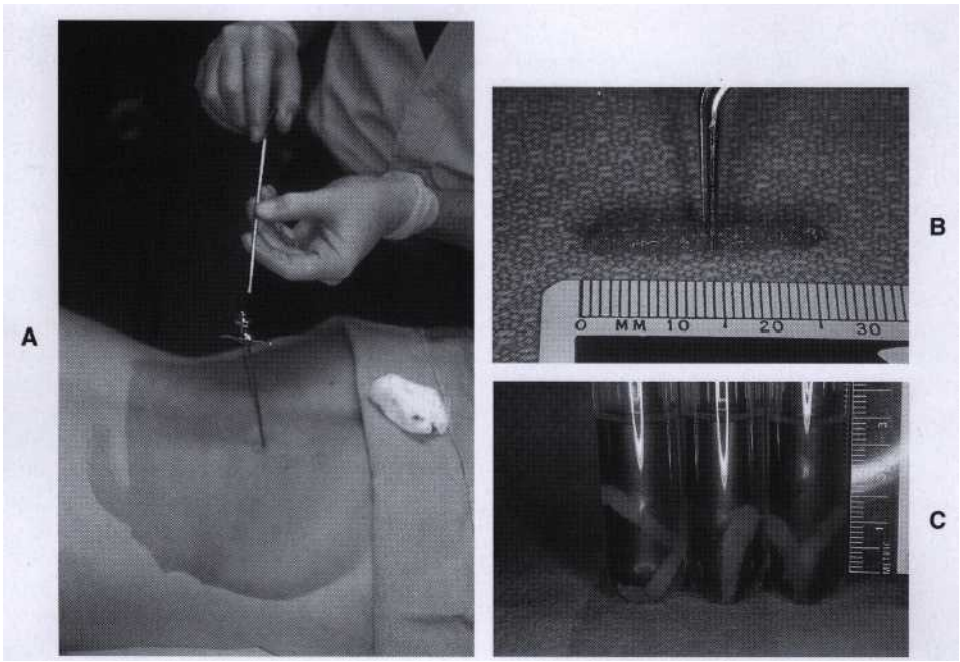

Fig. 63-15 A, Cancellous bone and marrow being procured from the posterior iliac crest with a Westerman-Jensen bone marrow biopsy needle. B, One of the cores obtained, approximately 3 x 25 mm in size. C, Five cores removed through the same 1/4-inch incision site through different cortical punctures and placed in a transfer storage media prior to direct placement of frozen storage if periodontal surgery is delayed/staged.

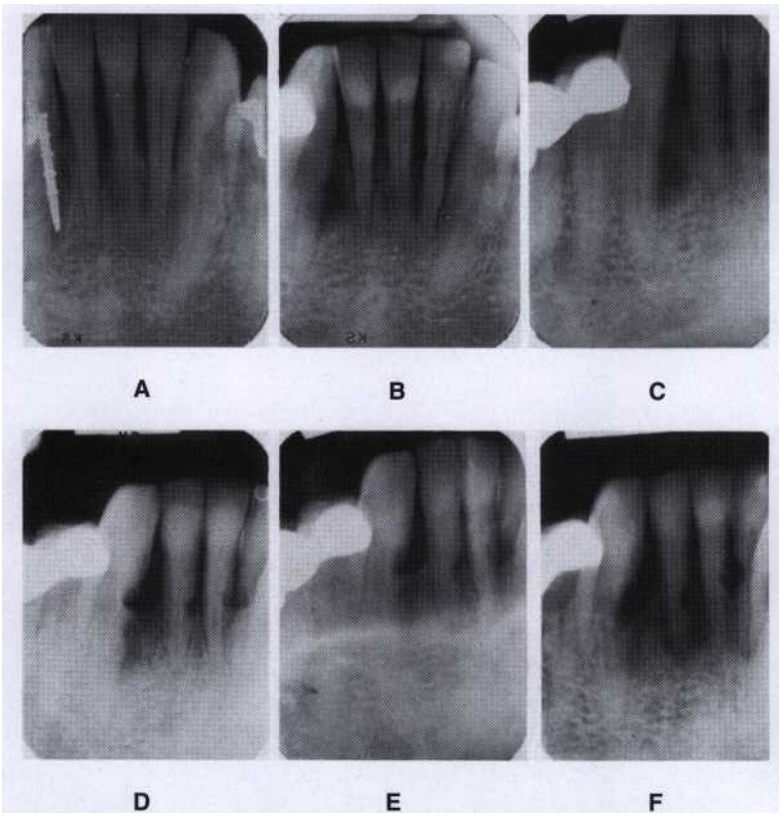

Fig. 63-16 A, November 1973. Radiograph of a patient immediately prior to the placement of a fresh iliac autograft. B, Two months later, bone repair is evident. Note the early radiolucent areas on the mesial aspect of the canine. C, After 7 months, "bone fill" is occurring, but obvious root resorption is present. D, April 1975. Root resorption is apparent on all grafted teeth. Note the obvious degree of fill of the original bone defects. E, February 1976. Further involvement. F, October 1977. Four years later, root resorption has progressed into the pulp of the lateral incisor, causing a periosteal-endosteal complication.

BONE FROM EXTRAORAL SITES

Iliac Autografts. The use of fresh or preserved iliac cancellous marrow bone has been extensively investigated. This material has been used by orthopedic surgeons for years. Data from human and animal studies support its use, and the technique has proved successful in bony defects with various numbers of walls, in furcations, and even supracrestally to some extent (Fig. 63-15).[11,20,38,41,42,154,155,151] However, owing to problems associated with its use, such as postoperative infection, exfoliation, sequestration; varying rates of healing; root resorption; and rapid recurrence of the defect (Fig. 63-16), in addition to increased patient expense and difficulty in procuring the donor material, the technique is no longer in use.[20,42,156,157]

Allografts. Obtaining donor material for autograft purposes necessitates inflicting surgical trauma on another part of the patient's body. Obviously, it would be to the patient's and therapist's advantage if a suitable substitute could be used for grafting purposes that would offer similar potential for repair and not require the additional surgical removal of donor material from the patient. However, both allografts and xenografts are foreign to the organism and therefore have the potential to provoke an immune response. Attempts have been made to suppress the antigenic potential of allografts and xenografts by radiation, freezing, and chemical treatment.[19]

Bone allografts are commercially available from tissue banks. They are obtained from cortical bone within 12 hours of the death of the donor, defatted, cut in pieces, washed in absolute alcohol, and deep frozen. The material may then be demineralized, and subsequently ground and sieved to a particle size of 250 to 750 mm and freeze dried. Finally, it is vacuum sealed in glass vials.

Numerous steps are also taken to eliminate viral infectivity. These include exclusion of donors from known high-risk groups and various tests on the cadaver tissues to exclude individuals with any type of infection or malignant disease. The material is then treated with chemical agents or strong acids to effectively inactivate the virus, if still present. The risk of human immunodeficiency virus (HIV) infection has been calculated as 1 in 1 million to 8 million and is therefore characterized as highly remote.

UNDECALCIFIED FREEZE-DRIED BONE ALLOGRAFT (FDBA). Several clinical studies by Mellonig, Bowers, and co-workers reported bone fill exceeding 50% in 67% of the defects grafted with FDBA and in 78% of the defects grafted with FDBA plus autogenous bone.[113,150,162] FDBA, however, is considered an osteoconductive material, whereas decalcified FDBA (DFDBA) is considered an

E, Three-year postoperative radiograph suggesting bone fill and stability, which correlates with probing attachment level improvement.

osteoinductive graft. Laboratory studies have found that DFDBA has a higher osteogenic potential than FDBA and is therefore preferred. [109,111,112]

DECALCIFIED FREEZE-DRIED BONE ALLOGRAFTS. Experiments by Urist and co-workers have established the osteogenic potential of DFDBA. [183,184] Demineralization in cold, diluted hydrochloric acid exposes the components of bone matrix, closely associated with collagen fibrils, that have been termed *bone morphogenetic protein* (Figs. 63-17 and 63-18). [185]

In 1975, Libin et al reported three patients with 4 to 10 mm of bone regeneration in periodontal osseous defects. [97] Subsequent clinical studies were made with cancellous DFDBA and cortical DFDBA. [129,139] The latter resulted in more desirable results (2.4 mm versus 1.38 mm of bone fill).

G, Two-year postoperative radiograph depicting favorable bone regeneration in the site.

Bowers and associates, in a histologic study in humans, showed new attachment and periodontal regeneration in defects grafted with DFDBA.[17] Mellonig and associates tested DFDBA against autogenous materials in the calvaria of guinea pigs and showed it to have similar osteogenic potential.'",'[12]

These studies provided strong evidence that DFDBA in periodontal defects results in significant probing depth reduction, attachment level gain, and osseous regeneration (Color Fig. 63-2); the combination of DFDBA and guided tissue regeneration has also proven very successful.[5,170] However, limitations of the use of DFDBA include the possible, albeit remote, potential of disease transfer from the cadaver.

A bone-inductive protein isolated from the extracellular matrix of human bones, termed *osteogenin,* has been tested in human periodontal defects and seems to enhance osseous regeneration.[18]

Xenografts. *Calf bone* (Boplant), treated by detergent extraction, sterilized, and freeze dried, has been used for the treatment of osseous defects.[7,160,161] *Kiel bone is* calf or ox bone denatured with 20% hydrogen peroxide, dried with acetone, and sterilized with ethylene oxide. *Anorganic bone is ox* bone from which the organic material has been extracted by means of ethylenediamine; it is then sterilized by autoclaving.[106,107] These materials have been tried and discarded for various reasons; they are mentioned here to provide a historical perspective.

Recently, however, Yukna and co-workers have used a natural, anorganic, microporous, bovine-derived hydroxyapatite bone matrix, in combination with a cell-binding polypeptide that is a synthetic clone of the 15 amino acid sequence of type I collagen.[199] The addition of the cell binding polypeptide was shown to enhance the bone regenerative results of the matrix alone in periodontal defects.[199]

Nonbone Graft Materials. In addition to bone graft materials, many nonbone graft materials have been tried for restoration of the periodontium (Fig. 63-19). Among them are sclera, dura, cartilage, cementum, dentin, plaster of Paris, plastic materials, ceramics, and coral-derived materials.[21,47,95,96,123,1S2] None offers a reliable substitute to bone graft materials; some of these materials are briefly presented here to offer a complete picture of the many attempts that have been made to solve the crucial problem of periodontal regeneration.

SCLERA. Sclera was originally used in periodontal procedures because it is a dense fibrous connective tissue with poor vascularity and minimal cellularity.[87-89] This affords a low incidence of antigenicity and other untoward reactions.[83] In addition, sclera may provide a barrier to apical migration of the junctional epithelium and serve to protect the blood clot during the initial healing period.

Although some studies show that sclera is well accepted by the host and is sometimes invaded by host cells and capillaries and replaced by dense connective tissue, it does not appear to induce osteogenesis or cementogenesis.[49,119,127,182] The available scientific research does not warrant the routine use of sclera in periodontal therapy.

CARTILAGE. Cartilage has been used for repair studies in monkeys and treatment of periodontal defects in humans. It can serve as a scaffolding; when so used, new attachment was obtained in 60 of 70 case studies.[1-53] However, cartilage has received only limited evaluation.

PLASTER OF PARIS. Plaster of Paris (calcium sulfate) is biocompatible and porous, thereby allowing fluid

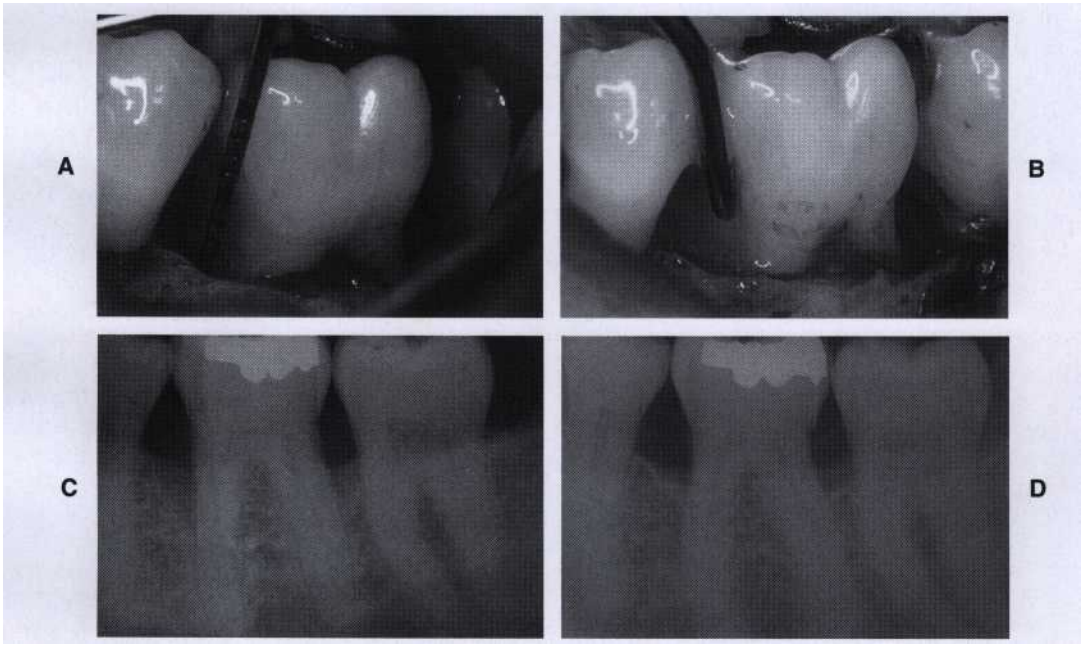

Fig. 63-19 A, Surgical exposure of the lower first molar, depicting a deep intrabony defect on the mesial and distal. B, Enamel matrix protein placement in site after root preparation. C, Preoperative radiograph. D, Two-year postoperative radiograph suggesting bone fill.

exchange, which prevents flap necrosis. Plaster of Paris resorbs completely in 1 to 2 weeks. One study in surgically created three-wall defects in dogs showed significant regeneration of bone and cementum.[86] It was found to be useful in one uncontrolled clinical study, but other investigators have reported that it does not induce bone formation.[1,163] One report suggested its use in combination with DFDBA and a Gore-Tex membrane.[167] Its usefulness in human cases, however, has not been proven.

PLASTIC MATERIALS. HTR polymer is a nonresorbable, microporous, biocompatible composite of polymethylmethacrylate and polyhydroxylethylmethacrylate.[195] A clinical 6-month study showed significant defect fill and improved attachment level.'" Histologically, this material is encapsulated by connective tissue fibers, with no evidence of new attachment.[173]

CALCIUM PHOSPHATE BIOMATERIALS. Several calcium phosphate biomaterials have been tested since the mid-1970s and are currently available for clinical use. Calcium phosphate biomaterials have excellent tissue compatibility and do not elicit any inflammation or foreign body response. These materials are *osteoconductive,* not osteoinductive, meaning that they will induce bone formation when placed next to viable bone but not when surrounded by non-bone-forming tissue such as skin.

Two types of calcium phosphate ceramics have been used:

1. Hydroxyapatite (HA) has a calcium-to-phosphate ratio of 1.67, similar to that found in bone material. HA is generally nonbioresorbable.
2. Tricalcium phosphate (TCP), with a calcium-to-phosphate ratio of 1.5, is mineralogically B-whitlockite. TCP is at least partially bioresorbable.

Case reports and uncontrolled human studies have shown that calcium phosphate bioceramic materials are perfectly tolerated and can result in clinical repair of periodontal lesions. Several controlled studies were conducted on the use of Periograf and Calcitite; clinical results were good, but histologically these materials appeared to be encapsulated by collagen.[59,105,140,197]

BIOACTIVE GLASS. Bioactive glass consists of sodium and calcium salts, phosphates, and silicon dioxide; for its dental applications it is used in the form of irregular particles measuring 90 to 170 b,m (PerioGlas, Block Drug Co., Jersey City, NJ) or 300 to 355 N,m (BioGran, Ortho Vita, Malvern, PA). When this material comes into contact with tissue fluids, the surface of the particles becomes coated with hydroxycarbonateapatite, incorporates organic ground proteins such as chondroitin sulfate and glycosaminoglycans, and attracts osteoblasts that rapidly form bone.'

This material may have potential, and clinical studies are needed to establish its real usefulness.

CORAL-DERIVED MATERIALS. Two different coralline materials have been used in clinical periodontics: natural coral and coral-derived porous hydroxyapatite. Both are biocompatible, but whereas natural coral is resorbed slowly (several months), porous hydroxyapatite is not resorbed or takes years to do so.

Clinical studies on these materials showed pocket reduction, attachment gain, and bone level gain.[81,84,115] The materials have also been studied in conjunction with membranes, with good results.[92,172] Both materials have demonstrated microscopic cementum and bone formation, but their slow resorbability or lack thereof has hindered clinical success in practice.[21,169]

Combined Techniques

The combination of barrier techniques with bone grafts and other methods has been suggested and procedures following these ideas proposed by several authors.[5,73,92,104,108,188] The following technique has been described by Schallhorn and McClain[103,159]:

1. Perform a regenerative type flap. If recession has occurred and/or coronal flap positioning is required for membrane coverage, periosteal separation is performed.
2. The defect is debrided of all granulation tissue and the root surface is planed to remove all remnants of plaque, accretions and other root surface alterations (grooves, notches, caries) employing ultrasonic/sonic, hand, and/or rotary instrumentation.
3. Odontoplasty and/or osteoplasty are performed if required for adequate access to the defect including intraradicular or furcation fundus concavities and/or reduction of enamel projections.
4. The bone graft (typically DFDBA) is prepared in a dappen dish, hydrating it with sterile saline or local anesthetic solution, and if there is no contraindication, is combined with tetracycline (125 mg/0.25 g of DFDBA). After mixing, the dappen dish is covered with a sterile, moistened gauze to prevent drying of the graft.
5. The appropriate membrane (usually ePTFE) is selected and trimmed to fit the desired position and placed on a sterile gauze. Care is taken to prevent contamination by contact with soft tissues or saliva.
6. The area is thoroughly cleansed and isolated, and the regenerative site root surface is treated with cotton pellets soaked in citric acid pH 1 for 3 minutes, taking care that the solution does not go beyond the root and bone surface. The pellets are removed and the site inspected for any residual cotton fibers prior to flushing the site with sterile water or saline.
7. If a sclerotic bone surface exists in the graft site, intramarrow penetration is performed with a 1/4 round bur.
8. The ligament surface is "scraped" with a periodontal probe to remove any eschar and stimulate bleeding.
9. The DFDBA is packed firmly in the defect using an overfill approach, covering the root trunk and combination or confluent vertical dehiscence or horizontal osseous defects.
10. The custom-fitted membrane is placed over the graft and secured as appropriate.
11. The area is rechecked to ensure that adequate graft material remains in the desired area, and the flap is positioned to cover the membrane and secured with nonabsorbable sutures.
12. A periodontal dressing is passively applied over the surgical area, with Surgicel covering the sutures.

Typical peri- and postoperative medication regimens include, if not contraindicated, 7 to 10 days of antibiotic coverage, which is subsequently extended with doxycycline, 100 mg daily for 2 to 7 weeks; steroid therapy such as methylprednisolone dosepak; and analgesic agents.

Sutures are removed if and when they become loose or no longer aid in tissue position or wound closure. The patient is seen for monitoring and local debridement as needed every 1 to 2 weeks. If a nonresorbable membrane has been used, it is removed 6 to 8 weeks after the operation.

Several studies and case reports have shown excellent results with the combined technique.[5,16,18,92,103,108,159,188]

FACTORS INFLUENCING A SUCCESSFUL OUTCOME

Factors adversely affecting outcomes were assessed in the 1996 evidence-based World Workshop in Periodontics.[6,139] These included the following:

- Inadequate plaque control
- Poor compliance with supportive periodontal therapy
- Smoking
- Other factors such as flap design, defect and root morphology, material employed, flap position, and postoperative management

Other factors possibly influencing outcomes but which lack conclusive evidence at this time include: age, systemic conditions, and use of membranes in patients requiring prophylactic medication.

Other reports have also attempted to delineate variables for case/site selection and management.[3,4] These included: therapist considerations (training and experience), patient factors (systemic conditions, stress level, smoking habits, plaque control, patient compliance, tissue response to presurgical therapy, and age), defect factors (bone height, access, tooth/defect anatomy, space maintenance of membranes employed, and tooth stability), surgical considerations (flap design/management, root preparation and possible biomodification, regenerative materials employed, infection control, etc.), postsurgical management, and supportive periodontal therapy after completion of active therapy.

SUMMARY

The subject of new attachment has received a great deal of attention because of its obvious importance in improving the results of therapy. On the basis of available information, reconstruction of human supporting periodontal tissues is possible in selected sites and patients with the use of autogenous bone grafts and/or freeze dried bone allografts and resorbable or nonresorbable barrier membranes.

The clinician should make an effort to differentiate between those techniques that have been studied in depth and with acceptable results and others that, although promising, are still experimental. Research papers must be critically evaluated for adequacy of controls, selection of cases, methods of evaluation, and long-range postoperative results.

PROGNOSIS FOR ROOT RESECTION/HEMISECTION

The progress of inflammatory periodontal disease, if unabated, ultimately results in attachment loss sufficient enough to affect the bifurcation or trifurcation of multirooted teeth. The furcation is an area of complex anatomic morphology[5,6,10] that may be difficult or impossible to be debrided by routine periodontal instrumentation.[28,33] Routine home care methods may not keep the furcation area free of plaque.[17,22] The presence of furcation involvement is one clinical finding that can lead to a diagnosis of advanced periodontitis and potentially to a less favorable prognosis for the affected tooth or teeth. Furcation involvement therefore presents both diagnostic and therapeutic dilemmas.

ETIOLOGIC FACTORS OF FURCATION PROBLEMS

The primary etiologic factor in the development of furcation defects is bacterial plaque and the inflammatory consequences that result from its long-term presence. The extent of attachment loss required to produce a furcation defect is variable and related to local anatomic factors such as root trunk length, root morphology,[11,27] and local developmental anomalies such as cervical enamel projections.[21,27] Local factors may affect the rate of plaque deposition or complicate the performance of oral hygiene procedures thereby contributing to the development of periodontitis and attachment loss. Studies indicate that prevalence and severity of furcation involvement increase with age.[26,21,33] Dental caries and pulpal death may also affect a tooth with furcation involvement or even the area of the furcation. All of these factors should be considered during the diagnosis, treatment planning and therapy of the patient with furcation defects.

DIAGNOSIS AND CLASSIFICATION OF FURCATION DEFECTS

A thorough clinical examination is the key to diagnosis and treatment planning. Careful probing is required to determine the presence and extent of furcation involve-

ment, the position of the attachment relative to the furca, and the extent and configuration of the furcation defect.[35] Transgingival sounding may further define the anatomy of the furcation defect.[28] The goal of this examination is to identify and classify the extent of furcation involvement and to identify factors that may have contributed to the development of the furcation defect or that could affect treatment outcome. Among these factors are 1) the morphology of the affected tooth, 2) the position of the tooth relative to adjacent teeth, 3) the local anatomy of the alveolar bone, 4) the configuration of any bony defects, and 5) the presence and extent of other dental diseases such as caries and pulpal necrosis.

The dimension of the furcation entrance is variable but usually quite small. Eighty-one percent of furcations have an orifice of 1 mm or less, and 58% are 0.75 mm or less.[5,6] These dimensions, along with the local anatomy[10,11,12] of the furcation area, should be kept in mind in the selections of instruments for probing. A probe of small cross section is required if one is to detect early furcation involvement.

CLASSIFICATION OF FURCATION INVOLVEMENT

The extent and configuration of the furcation defect are factors in both diagnosis and treatment planning. This has led to the development of a number of indices to record furcation involvement. These indices are based on the horizontal measurement of attachment loss in the furcation,[13-17] on a combination of horizontal and vertical measurements,[14] or a combination of these findings with the localized configuration of the bony deformity.' Glickman" graded furcation involvement into the following four classes (Fig. *64-1, A-D):*

Grade I: A Grade I furcation involvement is the incipient or early stage of furcation involvement (see Fig. *64-1, A).* The pocket is suprabony and primarily affects the soft tissues. Early bone loss may have occurred with an increase in probing depth, but radiographic changes are not usually found.

Grade II: Grade II furcation can affect one or more of the furcations of the same tooth. The furcation lesion is

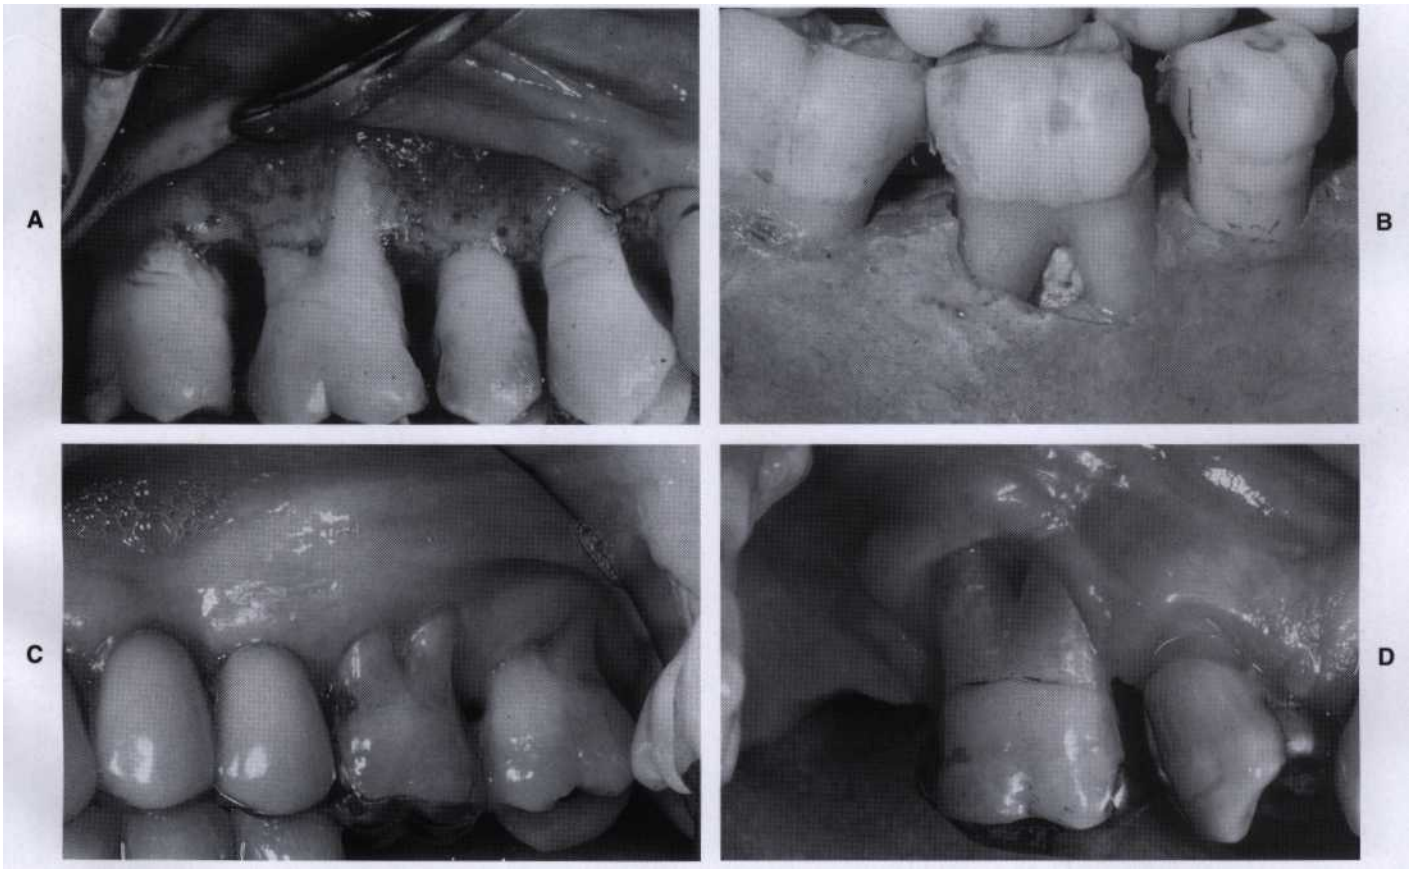

Fig. 64-1 Glickman's classification of furcation involvement. A, Grade I furcation involvement. Although the periodontal ligament is visible at the entrance to the furcation, no horizontal component of the furcation is evident on probing. B, Grade II furcation in a dried skull. Note both the horizontal and the vertical component of this cul-de-sac. C, Grade III furcations on maxillary molars. Probing confirms that the buccal furcation connects with the distal furcation of both of these molars, yet the furcation is filled with soft tissue. D, Grade IV furcation. The soft tissues have receded sufficiently to allow direct vision into the furcation of this maxillary molar.

essentially a cul-de-sac (see Fig. 64-1, B) with a definite horizontal component. If multiple defects are present, they do not communicate with each other, since a portion of the alveolar bone remains attached to the tooth. The extent of the horizontal probing of the furcation determines whether the defect is early or advanced. Vertical bone loss may be present and represents a therapeutic complication. Radiographs may or may not depict the furcation involvement. This is particularly true of maxillary molars because of the radiographic overlap of the roots. Although in some views the presence of furcation arrows indicate possible furcation involvement (see Chapter 31).

Grade III. In grade III furcations the bone is not attached to the dome of the furcation. In early grade III involvement the opening may be filled with soft tissue and may not be visible. Indeed one may not be able to pass a periodontal probe completely through the furcation because of interference with the bifurcational ridges or facial/lingual bony margins. However, if one adds the buccal and lingual probing dimensions and obtains a cumulative probing measurement that is equal to or greater than the buccal/lingual dimension of the tooth at the furcation orifice, it must be concluded that a grade III furcation exists (see Fig. 64-1, C. Properly exposed and angled radiographs of early class III furcations display the defect as a radiolucent area in the crotch of the tooth (see Chapter 32).

Grade IV: In grade IV furcations the interdental bone is destroyed and the soft tissues have receded apically so that the furcation opening is clinically visible. A tunnel therefore exists between the roots of such an affected tooth. The periodontal probe therefore passes readily from one aspect of the tooth to another (see Fig. 64-1, D).

Other classification indices: Hamp, Nyman, and Lindhe17 modified a three-stage classification system by attaching a millimeter measurement to separate the extent of horizontal involvement. Easley and Drennan,[9] and Tarnow and Fletcher" have described classification systems that consider both horizontal and vertical attachment loss in classifying the extent of furcation involvement. Consideration of defect configuration and the vertical component of the defect provides additional information that may be useful in planning therapy.

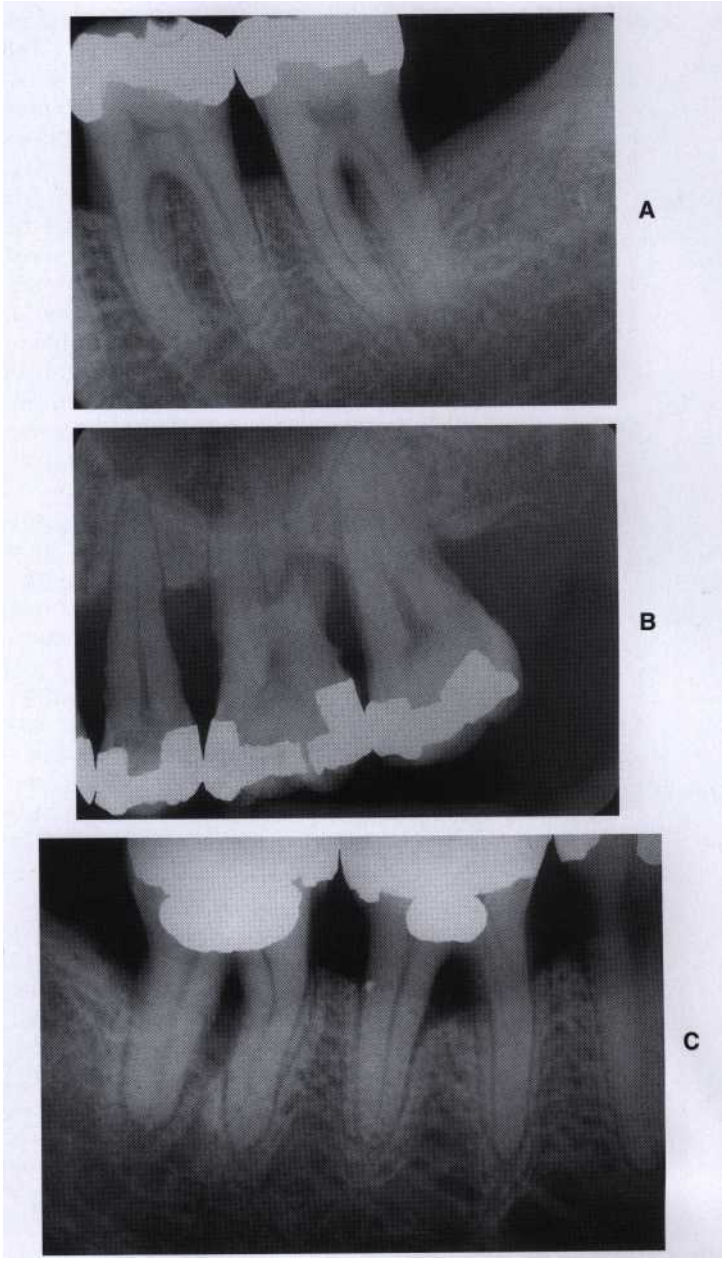

Fig. 64-2 Different degrees of furcation involvement in radiographs. A, Grade I furcation on the maxillary first molar and a Grade III furcation on the mandibular second molar. The root approximation on the second molar may be sufficient to impede accurate probing of this defect. B, Multiple furcation defects on a maxillary first molar. There is a class I buccal furcation involvement and grade II mesiopalatal and distopalatal furcations. Deep developmental grooves on the maxillary second molar simulate furcation involvement in this molar with fused roots. C, Grade III and IV furcations on mandibular molars.

LOCAL ANATOMIC FACTORS IN TREATMENT OF FURCATIONS

Clinical examination of the patient should allow the therapist to identify not only furcation defects but many of the local anatomic factors that may affect the result of therapy (prognosis). Well-made dental radiographs, while not allowing a definitive classification of furcation involvement, provide additional information vital for treatment planning (Fig. 64-2, A-C. Important local factors are described in the following section.

The Tooth

During treatment planning, the following anatomic features of the affected teeth should be considered:

Root trunk length: This is a key factor in both the development and treatment of furcation involvement. The distance from the cementoenamel junction to the entrance of the furcation can vary extensively. Teeth may have very short root trunks, moderate length trunks or roots than may be fused to a point near the apex (Fig. *64-3).* The combination of root trunk length with the number and configuration of the roots affects both the ease and success of therapy. The shorter the root trunk, the less attachment has to be lost before the furcation is involved. Once the furcation is exposed, teeth with short root trunks may be more accessible to maintenance procedures and the short root trunks may facilitate some surgical procedures. Alternatively teeth with unusually long root trunks or fused roots may not be appropriate candidates for treatment once the furcation has been affected.

Root length: Root length is directly related to the quantity of attachment supporting the tooth. Teeth with long roots trunks and short roots may have lost a majority of their support by the time that the furcation becomes affected.[12,19] Teeth with long roots and short to moderate root trunk length are more readily treated as sufficient attachment remains to meet functional demands.

Root form: The mesial root of most mandibular first and second molars and the mesiofacial root of the maxillary first molar are commonly curved to the distal in the apical third. In addition, the distal aspect of this root is usually heavily fluted. The curvature and fluting may increase the potential for root perforation during endodontics or complicate postplacement during restoration. 1.[24] These anatomic features may also result in an increased incidence of vertical root fracture. The size of the mesial radicular pulp may result in removal of the majority of the portion of the tooth during preparation.

Interradicular dimension: The degree of separation of the roots is also an important factor in treatment planning. Closely approximated or fused roots can preclude adequate instrumentation during scaling, root planing, and surgery. Teeth with widely separated roots present more treatment options and are more readily treated.

Anatomy of the furcation: The anatomy of the furcation is complex. The presence of bifurcational ridges, a concavity in the dome," and possible accessory canals [16] complicates not only scaling, root planing, and surgical therapy,[26] but also periodontal maintenance. Odontoplasty to reduce or eliminate these ridges may be required during surgical therapy for an optimum result.

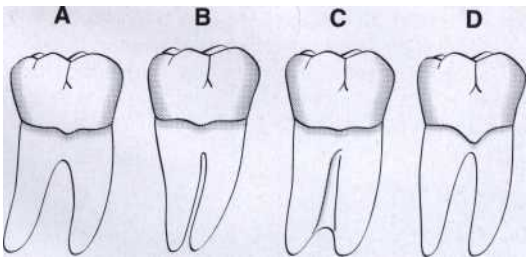

Fig. 64-3 Different anatomic features that may be important in prognosis and treatment of furcation involvement. A, Widely separated roots. B, Roots are separated but close. C, Fused roots separated only in their apical portion. D, Presence of enamel projection that may be conducive to early furcation involvement.

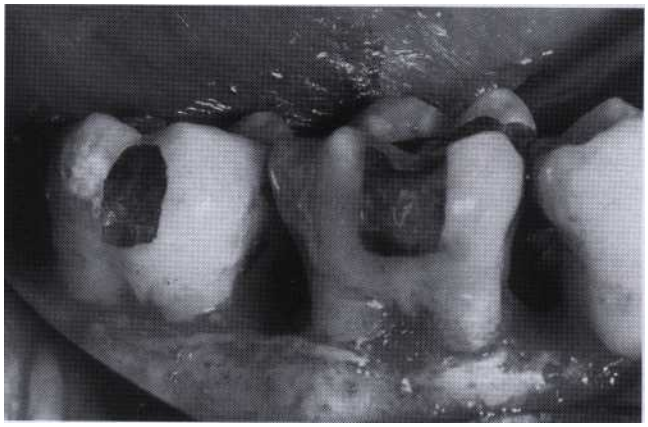

Fig. 64-4 Furcation involvement by grade III cervical enamel projections.

BOX 64-1

Classification of Cervical Enamel Projections

Grade I: The enamel projection extends from the cementoenamel junction of the tooth toward the furcation entrance.
Grade II: The enamel projection approaches the entrance to the furcation. It does not enter the furcation, therefore there is no horizontal component.
Grade III: The enamel project actually extends horizontally into the furcation.

Masters DH, Hoskins SW: Projection of cervical enamel into molar furcations. J Periodontol 1964; 35:49.

Cervical enamel projections: Cervical enamel projections (CEPS) are reported to occur on *8.6%* to *28.6%* of molars.[25.21,32] The prevalence is highest for mandibular and maxillary second molars. The extent of CEPs was classified by Masters and Hoskins[27] in *1964 (Box 64-1).* An example of a grade III CEP is shown in Fig. *64-4.* These projections can affect plaque removal, complicate scaling and root planing, and may be a local factor in the development of gingivitis and periodontitis. They should be removed to facilitate maintenance.

THE ANATOMY OF THE BONY LESIONS

Pattern of Attachment Loss

The form of the bony lesions associated with the furcation can vary significantly. Horizontal bone loss can expose the furcation as thin facial/lingual plates of bone that may be totally lost during resorption. Alternatively, areas with thickened bony ledges may persist and predispose to the development of furcations with deep vertical components. The pattern of bone loss on other surfaces of the affected tooth and adjacent teeth must also be

considered during treatment planning. The **treatment** response in deep multiwalled bony defects is different from that in areas of horizontal bone loss. Complex multiwalled defects with deep interradicular vertical components may be candidates for regenerative therapies. Alternatively, molars with advanced attachment loss on only one **root may be treated by resective procedures.**

OTHER DENTAL FINDINGS

The dental and periodontal condition of the adjacent teeth must be considered during treatment planning for furcation involvement. The combination of furcation involvement and root approximation with an adjacent **tooth represents the same problem that** exists in furcations without adequate root separation. Such a finding may dictate the removal of the most severely affected tooth or the removal of a root or roots (Fig. 64-5).

The presence of an adequate band of gingiva and a moderate to deep vestibule will facilitate the performance of a surgical procedure should it be indicated.

Fig. 64-5 Advanced bone loss, furcation involvement, and root approximation. Note the buccal furcation, which communicates with the distal furcation of a maxillary first molar that also displays advanced attachment loss on the distal root and approximation with the mesial of the maxillary second molar. The patient with such teeth may benefit from root resection of the distobuccal root of the first molar or extraction of the molar.

TREATMENT OF FURCATION DEFECTS

The objectives of furcation therapy are to 1) facilitate maintenance, 2) prevent further attachment loss, and 3) obliterate the furcation defects as a periodontal maintenance problem. The selection of therapeutic mode varies with the class of furcation involvement, the extent and configuration of bone loss, and other anatomic factors.

Therapy for Early Furcation Defects: Class I

Incipient or early furcation defects (class I) are amenable to conservative periodontal therapy. As the pocket is suprabony and has not entered the furcation, oral hygiene, scaling, and root planing are effective." Any thick overhanging margins of restorations, facial grooves, or cervical enamel projections should be eliminated by odontoplasty, recontouring, or replacement. The resolution of inflammation and subsequent repair of the periodontal ligament and bone is usually sufficient to restore periodontal health.

Therapy for Furcation Involvement: Class II

Once a horizontal component to **the furcation has developed (class II), therapy becomes more complicated.** Shallow horizontal involvement without significant vertical bone loss usually responds favorably to localized flap operation with odontoplasty and osteoplasty. Isolated deep class II furcations may respond to flap procedures with osteoplasty and odontoplasty (Fig. 64-6, A and B). This

G, Three-month postoperative view of the lingual aspect of this resection.

reduces the dome of the furcation and alters gingival contours to facilitate the patient's plaque removal.

Therapy for Advanced Furcation Defects: Class II-IV

The development of a significant horizontal component to one or more furcations of a multirooted tooth (late class II, class III or IV") and/or the development of a deep vertical component to the furca poses additional problems. Nonsurgical treatment is commonly ineffective as the ability to instrument the tooth surfaces adequately is compromised .[30-36] Periodontal surgery, endodontics, and restoration of the tooth may be required to retain the tooth.

SURGICAL THERAPY FOR FURCATION INVOLVEMENT

Root Resection

Root resection may be indicated in multirooted teeth with grade II to IV furcation involvements. Root resection may be performed on vital'$ or endodontically treated teeth. It is preferable, however, to have endodontic therapy completed before resection of a root(s).[14] If this is not possible, then the pulp should be removed, the patency of the canals determined, and the pulp chamber medicated before resection. It is distressing to perform a vital root resection and to subsequently have an untoward event occur such as perforation, fracture of the root, or an inability to instrument the canal.

The indications and contraindications for root resection were well summarized by Bassaraba.[1] In general, teeth planned for root resection should include the following:

1. Teeth that are of critical importance to the overall dental treatment plan .[4] Examples are teeth serving as abutments of fixed or removable restorations for which the loss of the tooth would result in the loss of the prosthesis and entail major prosthetic retreatment.
2. Teeth that have sufficient attachment remaining for function. Molars with advanced bone loss in the interproximal and interradicular zones, unless the lesions have three bony walls, are not candidates for root amputation.
3. Teeth for which there is no more predictable or cost-effective method of therapy. Examples are teeth with furcation defects that have been treated successfully with endodontics but now present with a vertical root fracture, advanced bone loss or caries on bone root.
4. Teeth in patients with good oral hygiene and low activity for caries are suitable candidates. Patients unable or unwilling to perform good oral hygiene and preventive measures are not suitable candidates for root resection or hemisection. Root-resected teeth require endodontic treatment[14] and commonly require cast restorations.

These therapies can represent a sizeable financial investment on the part of the patient in an effort to save the tooth. Alternative therapies and their impact on the overall treatment plan should always be considered and presented to the patient.

Root Resection: Which Root to Remove and Why? A tooth with an isolated furcation defect in an otherwise intact dental segment may present few diagnostic problems. However, the existence of multiple furcation defects of varying severity when combined with generalized advanced periodontitis can be a treatment planning challenge. Careful diagnosis usually allows the therapist to determine the feasibility of root resection and the identification of which root to remove before surgery (Fig. 64-7, A-G).

The following is a guide to determining which root should be removed in these cases:

1. Remove the root(s) that will elliminate the furcation and allow the production of a maintainable architecture on the remaining roots.
2. Remove the root with the greatest amount of bone and attachment loss. It is obvious that sufficient periodontal attachment must remain after surgery for the tooth to withstand the functional demands placed on it. Teeth with uniform advanced horizontal bone loss are not candidates for root resection.
3. Remove the root that best contributes to the elimination of periodontal problems on adjacent teeth. For example, a maxillary first molar, with a class III buccal-to-distal furcation is adjacent to a maxillary second molar with a two-walled intrabony defect between the molars and an early class II furcation on the mesial furcation of the second molar. There may or may not be local anatomic factors affecting the teeth. The removal of the distobuccal root of the first molar allows the elimination of the furcation and management of the two-walled intrabony lesion and also facilitates access for instrumentation and maintenance of the second molar (Fig. 64-8).
4. Remove the root with the greatest number of anatomic problems such as severe curvature, developmental grooves, root flutings, or accessory and multiple root canals.
5. Remove the root that least complicates future periodontal maintenance.

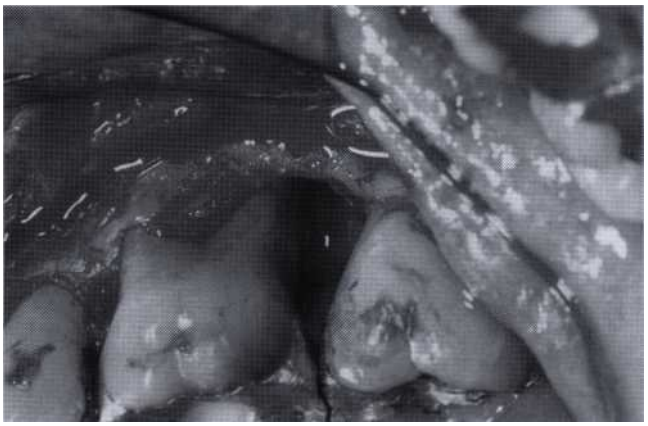

Fig. 64-8 Advanced bone loss on one root with furcation involvement. The majority of the attachment has been lost on the distal surface of this maxillary first molar. A buccal grade I and a deep grade II distal furcation defect is present. A shallow two-walled defect, correctable by osteoplasty and osteoectomy, is present at the mesial of the second molar. Treatment options are root amputation or extraction.

HEMISECTION

Hemisection is the splitting of a two-rooted tooth into two separate portions. This process has been called bicus*pidization* or *separation* as it changes the molar into two separate roots. It is most likely to be performed on mandibular molars with buccal and lingual class II or III furcation involvements. As with root resection, molars with advanced bone loss in the interproximal and interradicular zones are not good candidates for hemisection. After sectioning of the teeth, one or both roots can be retained. This decision is based on the extent and pattern of bony loss, root trunk and root length, ability to eliminate the osseous defect, and endodontic and restorative considerations. The anatomy of the mesial roots of mandibular molars often leads to their extraction and the retention of the distal root to facilitate both endodontics and restorative dentistry.

The interradicular dimension between the two roots of a tooth to be hemisected is also important. Narrow interradicular zones can complicate the surgical procedure. The retention of both molar roots can complicate the restoration of the tooth, since it may be virtually impossible to finish margins or to provide an adequate embrasure between the two roots for effective oral hygiene and maintenance (Fig. 64-9). Therefore orthodontic separation of the roots is commonly required to allow restoration with adequate embrasure form (Fig. 64-10, A-D). The result can be the need for multiple procedures and extensive interdisciplinary therapy. In such patients the availability of other treatment alternatives such as guided tissue/guided bone regeneration or replacement by osseointegrated dental implants should be considered.

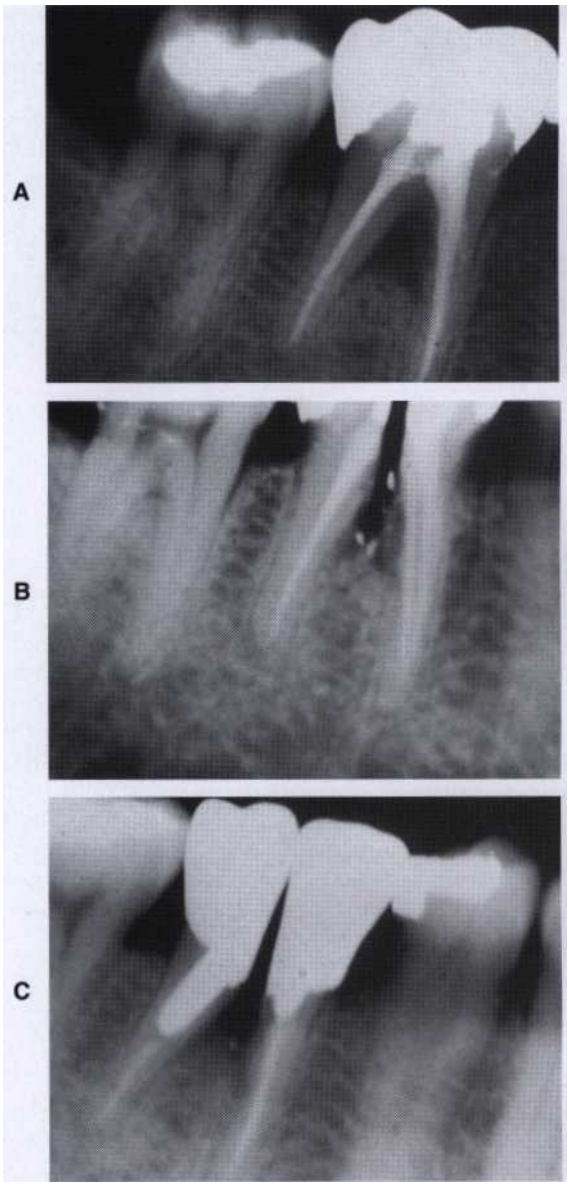

Fig. 64-9 Hemisection.

THE ROOT RESECTION/HEMISECTION PROCEDURE

The most commonly performed root resection is the distobuccal root of the maxillary first molar.3 This resection is diagramed in Fig. 64-11, *A-F.* After appropriate local anesthesia, a full-thickness mucoperiosteal flap is elevated. Root resection or hemisection of teeth with advanced attachment loss usually requires opening both facial and lingual/palatal flaps. Chapter 60 of this text describes the process of flap elevation. It is uncommon to be able to resect a root without elevation of a flap. The flap should provide adequate access for visualization and instrumentation and to minimize trauma during the operation.

After debridement the resection of the root begins with the exposure of the furcation on the root to be removed (see Fig. 64-11, A). The removal of a small amount of facial or palatal bone may be required to provide access for elevation and facilitate root removal (see Fig. 64-11, B). A cut is then directed from just apical to the contact point of the tooth, through the tooth, to the facial

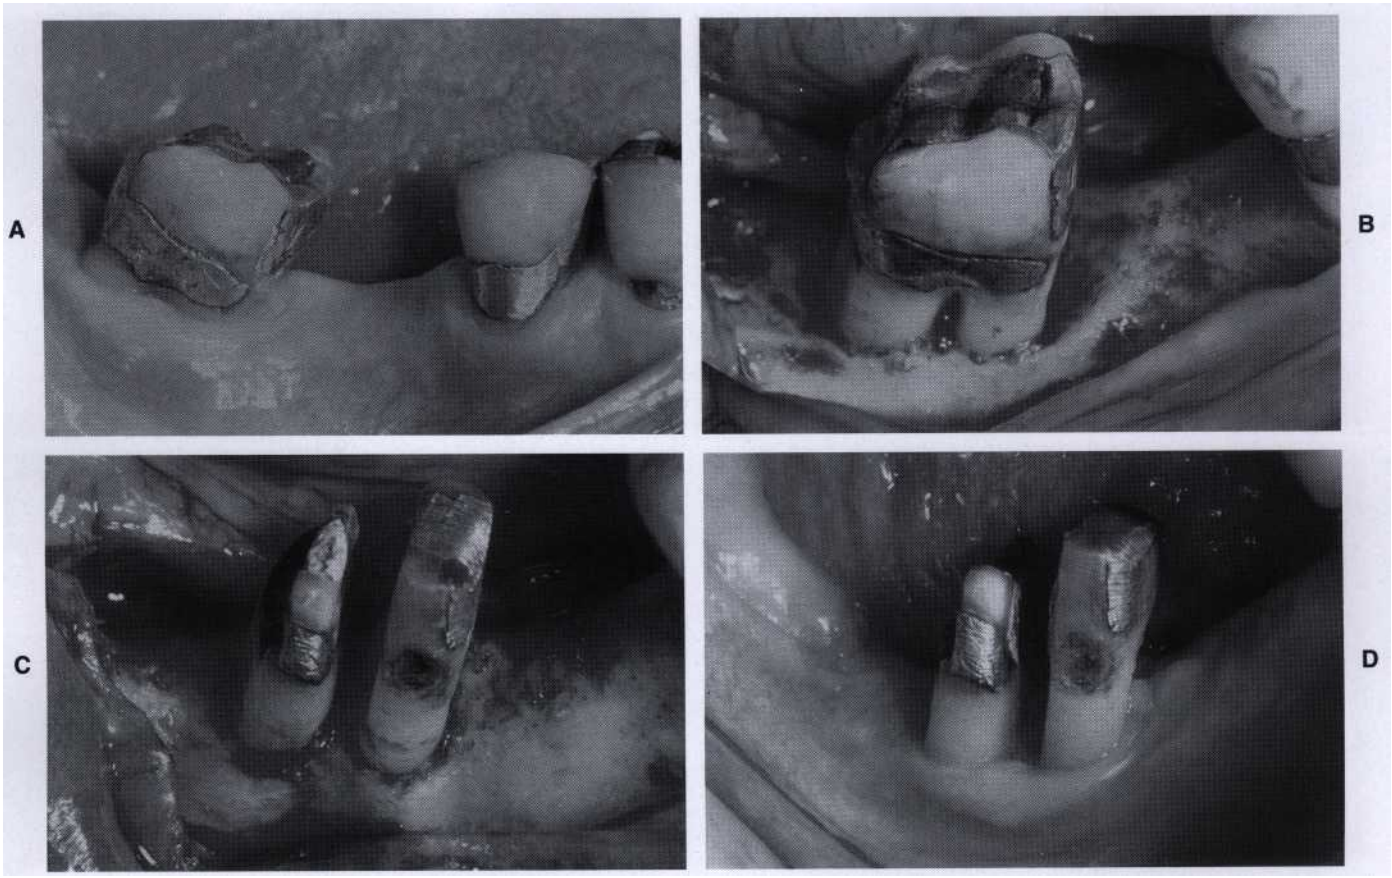

Fig. 64-10 Hemisection and interradicular dimension. A, Buccal preoperative view of a mandibular right second molar with a deep grade II buccal furcation and root approximation. B, Buccal view of bony lesions with flaps. Note the mesial and distal one-wall bony defects. The lingual furcation was similarly affected. C, The molar has been hemisected and partially prepared for temporary crowns. Observe the minimal dimension between the two roots. D, Buccal view 3 weeks postoperative. As the embrasure space is minimal, these roots will be separated with orthodontics to facilitate restoration. (Courtesy Dr. Louis Cuccia; Roseville, Calif.)

and distal orifices of the furcation, (see Fig. 64-11, C. This cut is made with a high-speed surgical length fissure or cross-cut fissure carbine bur. The placement of a curved periodontal probe into or through the furcation aids in orienting the angle of the resection. For hemisection a vertically oriented cut is made faciolingually through the buccal and lingual developmental grooves of the tooth, through the pulp chamber, and through the furcation. If the sectioning cut passes through a metallic restoration, the metallic portion of the cut should be made before flap elevation. This prevents the contamination of the surgical field with metallic particles.

If a vital root resection is to be performed a more horizontal cut through the root is advisable (see Fig. 64-11, D). An oblique cut exposes a large surface area of the radicular pulp and/or dental pulp chamber. This can lead to postoperative pain and can complicate the performance of endodontics. A horizontal cut, although it may complicate root removal, has less postoperative complications. This root stump can be removed by odontoplasty after the completion of endodontic therapy or at the time of tooth preparation.

After sectioning, the root is elevated from its socket (see Fig. 64-11, E). Care should be taken not to traumatize bone on the remaining roots or to damage an adjacent tooth. Removal of the root provides visibility to the furcation aspects of the remaining roots and simplifies the debridement of the furcation with hand, rotary, or ultrasonic instruments. If necessary, odontoplasty is performed to remove portions of the developmental ridges and prepare a furcation that is free of any deformity that would enhance plaque retention or adversely affect plaque removal (see Fig. 64-11, F).

Patients with advanced periodontitis commonly have root resection performed in conjunction with other surgical procedures. An example of combining root resection and periodontal osseous surgery is shown in Fig. 64-12, A-I. The bony lesions that may be present on adjacent teeth are then treated using resective or regenerative therapies. After resection the flap(s) are then approximated to cover any grafted tissues or to slightly cover the bony margins around the tooth. Sutures are then placed to maintain the position of the flaps. The area may or may not be covered with a surgical dressing.

The removal of a root alters the distribution of occlusal forces on the remaining roots. Therefore it is wise

to evaluate the occlusion of teeth from which roots have been resected and if necessary to adjust the occlusion. Centric holds should be maintained, but eccentric forces should be eliminated from the area over the root that was removed. Patients with advanced attachment loss may benefit from temporary stabilization of the resected tooth to prevent movement (Fig. *64-13, A-1).*

REGENERATION

The periodontal literature has well-documented therapeutic efforts designed to induce new attachment and/or regeneration on molars with furcation defects. Many surgical procedures using a variety of grafting materials have been tested on teeth with different classes of furcation involvement. Some investigators have reported clinical success with these techniques,[23] whereas others have suggested that the use of these materials in class II, III, or IV furcations offers little advantage compared with surgical controls.[3-8,29]

Furcation defects with deep two-walled or significant three-walled components may however be candidates for regeneration procedures. These vertical bony deformities respond favorably to a variety of other surgical procedures such as debridement with or without membranes and bone grafts. Therapies designed to induce new attachment or reattachment are addressed in Chapter *63.*

EXTRACTION

loss may be the most appropriate therapy for some patients. This is particularly true for individuals who cannot or will not perform adequate plaque control, have a high level of caries activity, will not commit to a suitable maintenance program, or have socioeconomic factors that may preclude more complex therapies. Some patients are reluctant to accept periodontal surgery or even allow the removal of a tooth with advanced furcation involvement even though the long-term prognosis is poor. The patient may elect to forego therapy, opt to treat the area with scaling and root planing or site-specific antibacterial therapies, and delay removal of the tooth until the tooth becomes symptomatic. Although additional attachment loss may occur, it is not uncommon for such teeth to last a significant number of years .[20,31]

The advent of osseointegrated dental implants as an alternative abutment source has had a major impact on the retention of teeth with advanced furcation problems. The high level of predictability of osseointegration may motivate the therapist and patient to consider removal of teeth with a guarded or poor prognosis and to seek an implant-supported prosthetic treatment plan.

PROGNOSIS FOR ROOT RESECTION/H EM [SECTION

For many years the presence of significant furcation involvement was deemed to give a tooth a hopeless long-term prognosis. Clinical research, however, has indicated that furcation problems are not as severe a complication as originally suspected if one can prevent the development of caries in the furcation. Relatively simple periodontal therapy is sufficient to maintain these teeth in function for long periods.[20,31] Other investigators have defined the reasons for clinical failure of root-resected or hemisected teeth.[2,24] Their data indicate that recurrent periodontal disease is not a major cause of the failure of these teeth. Investigations of root-resected or hemisected teeth have provided evidence that such teeth can function successfully for long periods .2, The keys to long-term success appear to be thorough diagnosis, selection of patients with good oral hygiene, and careful surgical and restorative management.

The simultaneous existence of pulpal problems and inflammatory periodontal disease can complicate diagnosis and treatment planning and affect the sequence of care to be performed. This is particularly true for the patient with advanced periodontitis, tooth loss and pulpal disease.

ETIOLOGIC FACTORS OF PULPAL DISEASE

The major causes of pulpal inflammation are 1) instrumentation during periodontal, restorative or prosthetic dentistry; 2) the progression of dental caries; and 3) direct, local trauma such as tooth fracture. The extent of inflammation of the pulp and the signs and symptoms that result vary with the severity of the insult and the ability of the host to ameliorate the inflammation that results.

Of these, dental caries is the most common cause of pulpal disease. Bacteria are present in carious enamel and dentin. Although the numbers of bacteria may diminish in the deepest layers of the dentin, the ability of microorganisms and their by-products to penetrate through the dentinal tubules and to provoke pulpal inflammation is well documented. Direct exposure of the pulp by caries[21] or sealing infected pulps may alter the process of infection if the pulp is unable to eliminate the bacteria.[6,20] The dynamics of the pulpal reaction is dictated by the virulence of the bacteria, the host response, the effectiveness of pulpal circulation, and the degree of vascular and lymphatic drainage.[42]

Pulpal infection is a polymicrobial process. Although a correlation between causation and any species of bacteria is not currently possible,[2] studies based on culturing suggest that a mean of five bacterial strains may be cultured from infected root canals.[2] The organisms cultured are predominately gram-negative anaerobes.[2,3,10,13,38] As the infective process proceeds the proportion of strict anaerobic-to-facultative organisms and the total number of bacteria increases. The most common organisms associated with pulpitis are listed in Table 65-1.

CLASSIFICATION OF PULPAL DISEASE

The correlation between the histology of pulpal disease and the patient's symptoms is poor. Therefore pulpal disease is generally classified based on clinical signs and symptoms rather than on histologic changes. Such a classification is illustrated in Box 65-1.

Minor injury such as periodontal root planing or the conservative preparation of a tooth for a restoration may lead to pulpal symptoms. A transient hypersensitivity to thermal stimuli is the most common symptom noted. The application of a thermal stimulus results in a brief, painful response that varies in intensity from mild to severe. The response rapidly disappears after removal of the stimulus. Although permanent pulpal damage may not occur, a transient inflammatory response can lead to the deposition of reparative dentin if odontoblasts are destroyed. The reversibility of inflammation and symptoms, without permanent pulpal damage, has led to a classification of this condition as reversible pulpitis.

If the pulp is so affected that the inflammatory lesion cannot be resolved, even though the source of the trauma is eliminated, a progressive degeneration of the pulp results. This progression has been described as being an *irreversible pulpitis.* Irreversible pulpitis may be void of symptoms or it may be associated with intermittent or continuous episodes of spontaneous pain. The application of heat to a tooth with irreversible pulpitis can lead to an immediate painful response that can persist for a prolonged period. Cold may also provoke such a response, although occasionally, the application of cold may provide relief from the pain. A reduced responsiveness of teeth with irreversible pulpitis to thermal stimuli has been claimed, but Mumford found similar pain thresholds in both inflamed and noninflamed pulps.

Irreversible pulpitis ultimately leads to loss of pulpal vitality (necrosis). Necrosis usually results from the same factors that induced the irreversible pulpitis and may lead to an alteration in the patient's symptoms. Not all nonvital teeth display signs and symptoms of pulpal disease and necrotic pulps are commonly asymptomatic. When symptoms do occur, they may be manifested as episodes of spontaneous pain. Testing the pulp with heat may be inconclusive, and a response to cold stimuli is rare.

BOX 65-1

Classification of Pulpal Disease

- Reversible pulpitis
- Irreversible pulpitis
- Hyperplastic pulpitis
- Pulpal necrosis

EFFECTS OF PULPAL DISEASE ON THE PERIODONTIUM

Pulpal tissue may be significantly inflamed and yet exert little or no effect on the periodontium. As long as the pulp remains vital it is unlikely that significant changes will occur in the periodontium. Necrosis of the pulp, however, can result in bone resorption and the production of radiolucency at the apex of the tooth, in the furcation or at points along the root[25,34,41,43] (Fig. 65-1). Dental radiographs usually document the presence of apical or lateral lesions.

The lesion that results may be an acute apical lesion or abscess, a more chronic periradicular lesion (cyst or granuloma); or a lesion associated with a lateral or accessory canal. The lesion may remain small, or it can expand sufficiently to destroy a substantial amount of the attachment of the tooth and/or to communicate with a lesion of periodontitis. A classification of periradicular lesions is found in Box 65-2.

The histopathologic structure of the periapical inflammatory lesion is usually a highly vascularized granulation tissue infiltrated to varying degrees by inflammatory cells. Neutrophils may be present near the apical foramen, whereas plasma cells, macrophages, lymphocytes and fibroblasts are increased in the periphery of the lesion.[5,28,39,44] This cellular infiltrate may vary with the nature and intensity of the irritants to the tissues.

Similar lesions may develop adjacent to accessory or lateral canals. These canals form when the epithelial root sheath breaks down before root formation or anasto-

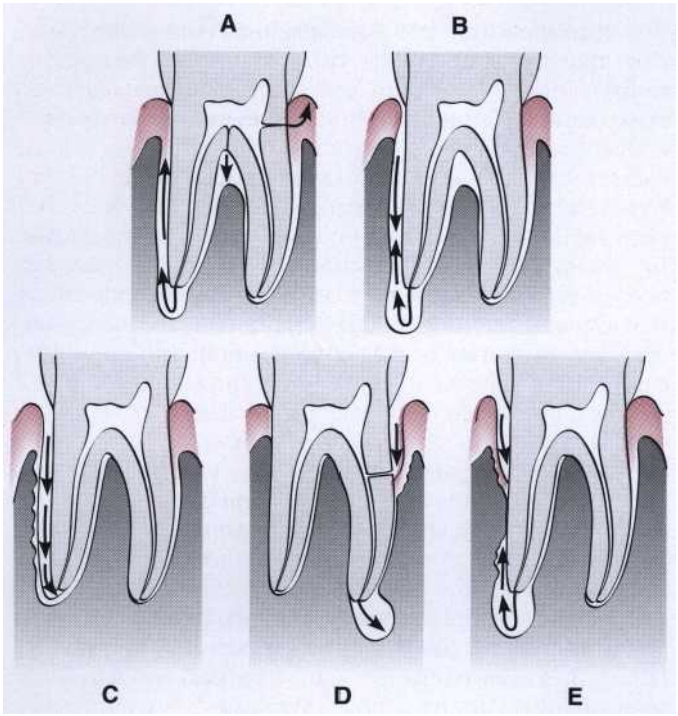

Fig. 65-1 Diagrammatic representation of different types of endoperiodontal problems. A, An originally endodontic problem with fistulization from the apex and along the root to the gingiva. Pulpal infection can also spread through accessory canals to the gingiva or to the furcatioh. B, A long-standing periapical lesion draining through the periodontal ligament can become secondarily complicated, leading to a *retrograde periodontitis. C,* A periodontal pocket can deepen to the apex and secondarily involve the pulp. D, A periodontal pocket can infect the pulp through a lateral canal, and this, in turn, can result in a periapical lesion. E, Two independent lesions, periapical and marginal, can coexist and eventually fuse with each other. (Redrawn and modified from Simon JHS, Glick DH, Frank AL: The relationship of endodontic-periodontic lesions. J Periodontol 1972; 43:202.)

moses between the dental papilla and the dental sac persist. Although many of the anastomoses are blocked or reduced by the formation of dentin or the depositing of cementum, some of the communications between the pulp and periodontium may remain patent in the adult dentition. Lateral canals are usually not visible on x-rays and are most commonly identified only when the root and lateral canal has been filled with a radiopaque material during endodontic therapy

The incidence of accessory and/or lateral canals has been quoted as ranging from *2%* to *27%,* but the true incidence is unknown .[9,12,43] The majority of these canals occur in the apical portion of the root, with decreased numbers in the furcation area. They are more common in posterior teeth and in the apical portion of the root. [9,22,33] The prevalence of lateral canals in the middle and cervical areas of the root and the prevalence of endodontic-derived lesions in the marginal periodontium via lateral or accessory canals are low. The clinical significance of accessory or lateral canals in spreading infection from the necrotic pulp to the periodontium is therefore unclear. Necrotic pulps apparently exert no effect through the dentinal tubules on the cementum.'

EFFECT OF PERIODONTITIS ON THE DENTAL PULP

Although the effects of pulpal disease on the periodontium are well documented, a clear-cut relationship between periodontitis and pulpal involvement is less evident. One may postulate that bacterial and the inflammatory products of periodontitis could gain access to the pulp via accessory canals, apical foramina, or dentinal tubules. This process, the reverse of the effects of a necrotic pulp on the periodontal ligament, has been referred to as *retrograde pulpitis.* [31,35]

However, although inflammatory changes have been reported adjacent to accessory canals exposed by periodontitis, periodontitis rarely produces significant changes in the dental pulp. Neither irreversible pulpitis or pulpal necrosis has been consistently found in histologic studies of teeth extracted because of severe periodontal disease .[8,20,40] It has been suggested that the presence of an intact layer of cementum may protect the pulp from injurious elements produced by plaque microbiota.[1] Severe breakdown of the pulp apparently does not occur until periodontitis has reached a terminal state-that is, when bacterial plaque has involved the main apical foramina.20 The pulp has a good capacity for defense as long as the blood supply via the apical foramina is intact. Therefore retrograde periodontitis, if it occurs, is exceedingly rare. [14,15,40]

DIFFERENTIATION OF PERIODONTAL AND PULPAL LESIONS

The Signs and Symptoms of Periodontitis

The signs and symptoms of periodontitis are described in Chapters *26* to *28* of this text. Periodontitis is a chronic inflammatory lesion, which begins in the marginal gingiva and extends apically causing attachment loss and periodontal pocket formation In general the progression rate of attachment loss is slow, unless an acute incident such as a periodontal abscess occurs.

Teeth with chronic periodontal lesions are commonly free of acute symptoms. The patient may indeed be unaware of the condition, with the exception of bleeding on brushing and flossing, or bad breath, until sufficient attachment is lost, resulting in increased tooth mobility. The pocket may be tender to probing and extensive deposits may be present on the root(s) of the tooth/teeth. Probing is usually accompanied by bleeding and in

deeper pockets with suppuration. However, significant discomfort is not elicited by percussion or thermal stimuli. Increased tooth mobility may occur if sufficient attachment has been lost. Dental radiographs usually disclose the extent of attachment loss, which should correlate with clinical probing data.

The Signs and Symptoms of Pulpal Disease

The pulp has the ability to respond to stimulation through enamel or dentin, or directly to the pulp. Higher nerve centers interpret these sensations as pain. There is some evidence that the pulp may also sense temperature and touch,[27] although the ability to discriminate between hot and cold may be affected by age." The character of the pain may vary with its source. Pulpal sensation initiation by the stimulation of dentin is usually fast, sharp, and severe and is mediated by A-delta myelinated fibers. Sensation from the core of the pulp is initiated by smaller unmyelinated C fibers. This pain has been described as being slower, duller, and more diffuse.[27]

The only symptom a patient with reversible pulpitis may report is a sensitivity to hot or cold fluids. The period of discomfort is usually brief. Teeth in which the inflammation is confined to the pulp chamber respond normally to percussion and palpation. Thermal stimuli or percussion applied to teeth with irreversible pulpitis can provoke severe pain. This pain may be intense and is commonly described as bright or throbbing. When provoked, a significant period and/or the use of medications may be required before the pain is ameliorated. The progression of inflammation alters the response of the tooth to pulp testing. If the inflammatory process extends to involve the periodontal ligament, then the affected tooth can become tender to pressure, biting, or light tapping with an instrument. Necrosis of the pulp can result in bony resorption. Thus pulp death may result in radiolucency at the apex of the tooth, in the furcation,[15,41] or at points along the root (see Fig. 65-1). The ability of inflammatory periodontal disease to affect the pulp is much less certain .[8,40] Dental radiographs usually document the presence of apical or lateral lesions. However, it should be remembered that some inflamed and/or necrotic pulps are asymptomatic and the patient is unaware of their existence.

DIFFERENTIATION BETWEEN PULPAL AND PERIODONTAL ABSCESSES

Periodontal abscesses (see Chapter 22) are not usually severely painful lesions. They occur in the pocket or sulcus at the level of the connective tissue attachment, so there is little or no elevation of the periosteum to cause significant pain. The patient becomes aware of a sore or tender area in the gingiva and may notice swelling of the tissues to form a lump. This area may be sensitive to touch, mastication, or toothbrushing and/or flossing. Any stimulus to the site can indeed be painful. The formation of a fistula is less common than with apical periodontitis. If a fistula does form, it may be found in both the gingiva and mucosa. The path of the sinus tract can be determined by carefully placing a fine gutta percha point into the fistula and then making a radiograph. The point communicates with and stops within the periodontal pocket. Careful probing confirms the presence of the pocket, and dilation of the sulcus commonly results in drainage.

Acute apical abscesses commonly communicate directly with the external soft tissue surface by a sinus tract and a stoma through the oral mucosa or gingiva (Fig. 65-2). Before the completion of the tract, the patient commonly experiences acutely painful symptoms as a result of the involvement of the periodontal ligament. The tract may exit through the periodontium and dissect along the root to empty into the gingival sulcus and the interfurcal area. It then goes through the periodontal ligament of an adjacent tooth or into an existing periodontal pocket (see Fig. 65-1). When the latter occurs, the resulting defect is a true *combined lesion.",'*[1,35]

Acute apical abscesses can extend to involve the adjacent periodontium. The sinus tract that forms usually extends from the apex of the tooth to the buccal [word missing]; hence, the mandible and maxillary curvature results in thin plates of bone at these sites. Although palatal or lingual tracts do occur, they occur at a much lower frequency than buccal tracts. During formation of a sinus tract, the patient may experience extreme pain because of involvement of the periodontal ligament and the elevation of the periosteum. Perforation of the plate is accompanied by swelling, pus formation, and collection under the periosteum. The swelling that results can lead to substantial alterations in the appearance of the face, as substantial volumes of pus may be confined in the lesion. Ultimately, drainage is established via a stoma. As long as the sinus remains open and drainage occurs, the symptoms and signs may be diminished. The acute inflammatory response may then take on the characteristics of a chronic lesion.

The endodontic sinus tract is usually a narrow, constricted lesion directed from the apex of the tooth laterally. In the absence of inflammatory periodontal disease, a tract emptying into the sulcus exerts little effect on the

Fig. 65-2 Gutta percha point inserted into a stoma located near the junction of the gingiva and oral mucosa on a mandibular first molar. This molar tested nonvital.

remainder of the sulcus. Prichard stated that the "pulpal lesion does not change its character and become marginal periodontitis when it reaches the bony crest or gingival margin, and the pulp does not immediately or inevitably become infected when bone resorption from marginal periodontitis reaches the apex."[31] Both endodontic and periodontal lesions may, however, result in attachment loss that affects the furcation"[31] and/or the apex of the tooth.

THERAPEUTIC MANAGEMENT OF PULPAL AND PERIODONTAL DISEASE

Patients with pulpal disease may have a healthy periodontium, gingivitis, or varying amounts of attachment loss (periodontitis) on the affected or adjacent teeth. A host of other dental problems may also exist. Therefore, appropriate treatment varies with the presence, nature, and extent of involvement of the diseases.

ENDODONTIC LESION PRIMARY

Patients with pulpal disease present only diagnostic and treatment decisions relative to the endodontic lesion. Debridement of the pulp chamber and canal, as well as the completion of appropriate endodontic therapy, are sufficient to result in healing of the lesion (Fig. 65-3, *A and B*). Pulpal abscesses and apical lesions generally resolve with conventional therapy, although apical surgery may be required in certain instances. Periodontal treatment is not required in the absence of any periodontal involvement.

Occasionally, an abscess of pulpal origin, through an apical or lateral canal, may establish drainage through the periodontal ligament and erupt into the furcation or the gingival sulcus.[12,15,31,34] The signs and symptoms of this process are identical to the initial signs and symptoms of abscesses establishing a path in a more horizontal direction, with the exception that a fistula is not evident. Therefore it becomes necessary to separate the signs and symptoms of pulpal disease from those associated with a periodontal abscess. The patient's history, periodontal probing, radiographs, and pulpal testing are therefore consistent with pulpal disease. Root canal treatment resolves any tract or stoma that is present.

INDEPENDENT PERIODONTAL AND ENDODONTIC LESIONS

Patients with pulpal disease may also present with inflammatory periodontal disease. Gingivitis or early periodontitis, other than tenderness, bleeding on brushing, or probing, commonly results in little discomfort. Pulpal disease, however, is associated with more noxious signs and symptoms. The progress of periodontitis is slow, with the exception of acute disease such as periodontal abscesses or necrotizing ulcerative gingivitis. Therefore the prompt management of the pulpal lesion is the primary concern. Pulpal extirpation and filling of the canals is the proper course of therapy, since extirpation of the pulp usually leads to the elimination of the patient's acute symptoms. Although residual sensitivity to percussion or movement of the tooth may persist for a period, therapy for gingivitis or early periodontitis may

Fig. 65-3 Radiographs of suspected combined lesion (pero-endo lesion) on a maxillary cuspid and lateral incisor. A, Notice the advanced bone loss on the distal of the lateral incisor and the possible extension of the apical lesion to involve the maxillary canine. B, Posttreatment response. This canine was treated by a root canal procedure only. The lesion was of pulpal origin, and repair occurred following pulp extirpation and treatment.

be delayed until the acute symptoms of pulpal disease are alleviated.

A different scenario may result if a patient with chronic periodontitis experiences a loss of pulpal vitality. Such a patient may simultaneously have the clinical signs and symptoms of both periodontitis and apical periodontitis. The extent to which each can affect the tooth is both independent and variable. The involvement of the apical periodontium by a pulpal lesion may obscure the symptoms of periodontitis. Therefore the ability to determine the independence of the two lesions on any tooth or area is a key consideration in the sequence of therapy. Most commonly the lesions are independent and do not communicate (Fig. 65-4, A -D).

Rarely a patient may present with abscesses of both pulpal and periodontal origin (Fig. 65-5, A-C). As the apical lesion tends to be the most painful lesion, endodontic therapy is normally initiated before or at the same appointment at which the periodontal abscess is drained. Again, the patient's history and thorough probing allows a determination of **the extent** of each problem and the independence of the two defects. Endodontic therapy results in the resolution of the endodontic lesion. It will, however, have little or no effect on the periodontal pocket (see Fig. 65-5, C), and appropriate periodontal therapy will be required for a successful result.[16,17,31]

COMBINED LESIONS (PERIO-ENDO

The true combined lesion results from the development and extension of an endodontic lesion into an existing periodontal lesion (pocket).[14,31] Such lesions may present with the characteristics of both diseases, which may complicate diagnosis and treatment sequencing (Fig. 65-6, A and B). A thorough history and careful clinical and radiographic examinations are required to identify and accurately assess the contribution of each lesion to the patient's dental problems and to derive a treatment sequence that is likely to produce an optimal therapeutic result. Usually the developing periapical lesion extends coronally to connect with a preexisting, chronic, wide-based periodontal pocket. On rare occasions a developing periodontal lesion, associated with a developmental groove, may extend apically to connect with an apical or

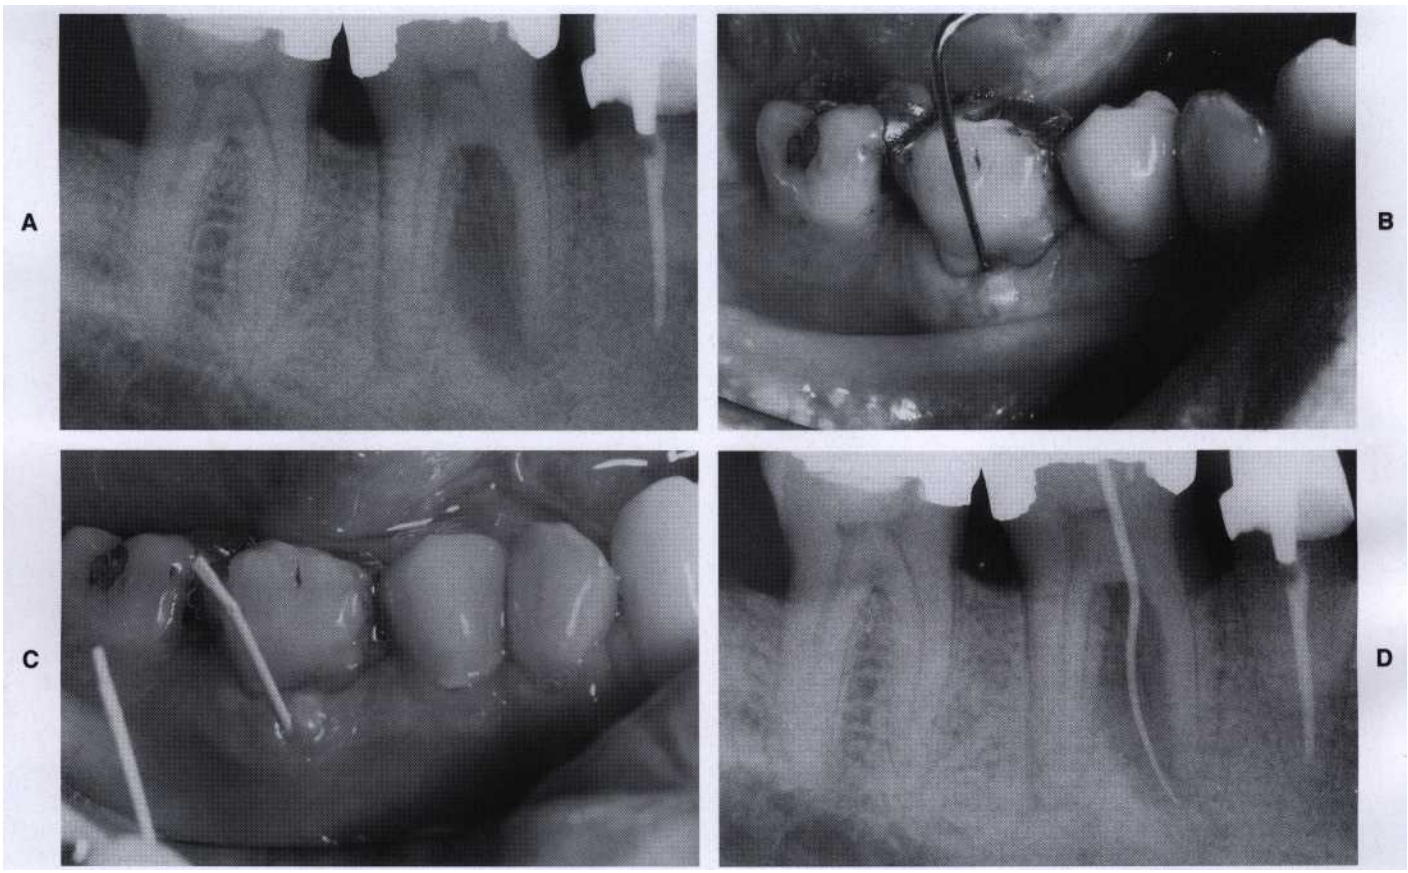

Fig. 65-4 Independent periodontal and endodontic lesions. A, Radiograph of the mandibular left molars. Note the radiographic appearance of bone loss on the first and second molars, a possible cervical enamel projection on the first molar, and a large interradicular area of reduced bone density. B, Periodontal probe inserted in buccal furcation of no. 19. Note the adjacent stoma. Observe that the sulcus depth is 3 mm at this site. C, Gutta percha point inserted into the facial stoma. D, Note the gutta percha point enters the furcation defect and extends to the apex of the mesial root of the molar. Although the molar displays signs consistent with periodontitis, the interradicular defect is purely of endodontic origin.

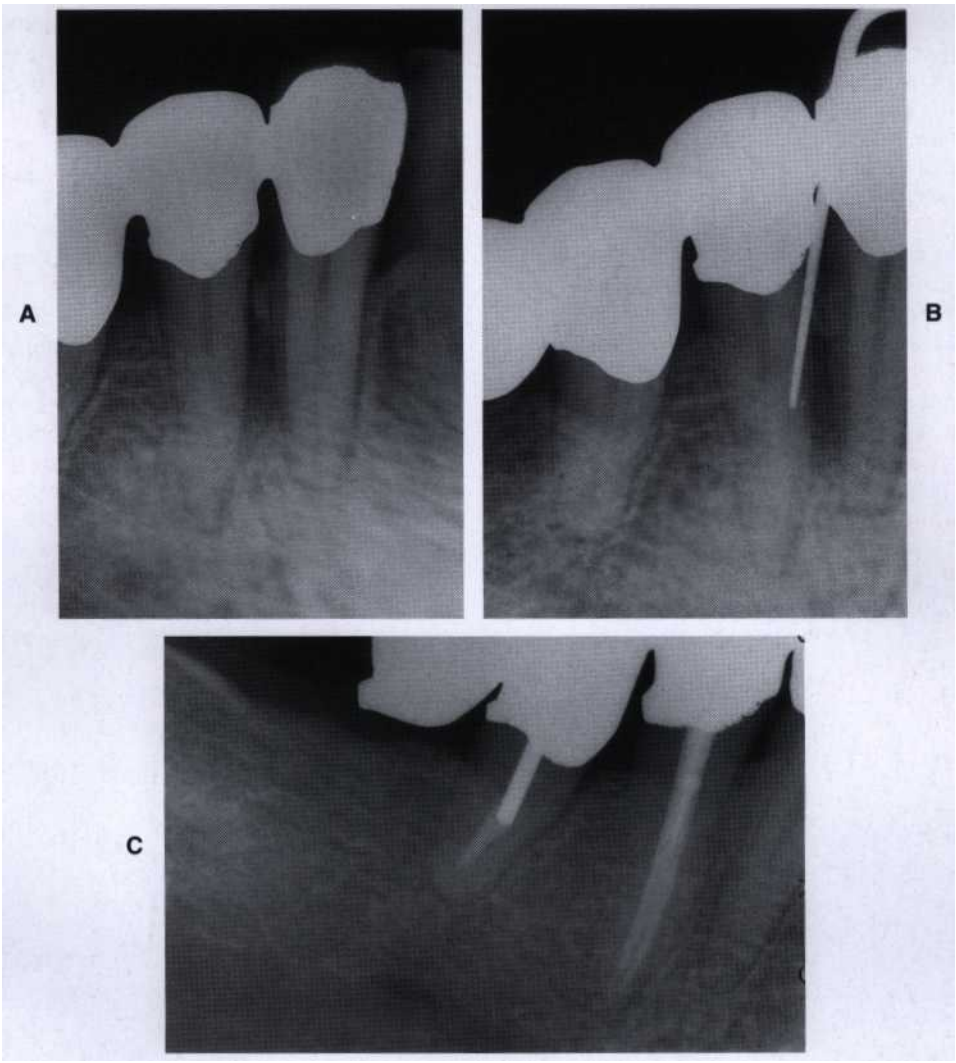

Fig. 65-5 Independent period ontal-endodontic abscesses. A, Radiograph of a mandibular left cuspid-bicuspid area. The patient presented with a large abscess involving all three teeth. Note the signs of marginal bone loss on the teeth, along with the area of decreased bone density-at the mesial of the mandibular left first bicuspid and the apparent calcification of the pulp canals. B, Radiograph with periodontal probe inserted into the mesio-lingual sulcus. There was, however, no communication with the mesial radiolucent area. C, Radiograph taken 6 months postendodontic treatment. Note the resolution of the mesial radiolucent area. The periodontal abscess was debrided, but the residual bony deformities remain.

lateral endodontic lesion. It also has been suggested that if periodontitis progresses to involve a lateral canal or the apex of a tooth, then a secondary pulpal infection may be induced. This is referred to as *retrograde pulpitis.* Retrograde pulpitis, if it exists, is quite rare.',[14,15,35,40]

The pain from **the loss of pulpal vitality is the most** common presenting complaint of patients with combined lesions. The symptoms reported are those most commonly found with pulpal disease. Thermal pulp testing provides information relative to the status of the pulp, and dental radiographs can confirm the presence of apical changes and the extent of bone loss. Careful probing confirms the presence and morphology of any periodontal pocket and permits the location of the communication with the apical lesion. The periodontal portion of the defect commonly has plaque, calculus, and/or root roughness as a finding. This contaminated root surface and the associated osseous defect is the major complication to treatment of combined lesions.

The extent to which the periodontal lesion con**tributes to the loss of bone is a key consideration** in diagnosis and treatment planning. Endodontic treatment is highly predictable, and when appropriately performed, the alterations in radiographic appearance and clinical probing disappear (Fig. 65-3). The periodontal component of a combined lesion is a more difficult problem. It cannot resolve as long as the endodontic lesion is present, yet effective endodontic treatment cannot eliminate the periodontal pocket. Even with periodontal treatment, the periodontal defect commonly does not

resolve to the same extent that the endodontic lesion does (Fig. 65-6, A *and B).* The ability to eliminate the periodontal component of the defect ultimately dictates treatment of the tooth. If the majority of the bony support has been lost from periodontitis, regardless of the predictability of endodontic therapy, the tooth may have a hopeless prognosis.

Once the decision to retain the tooth is made, endodontic therapy should precede attempts at periodontal pocket elimination.[14] After successful endodontics, the residual periodontal pocket that remains can be more predictably treated. The periodontal therapeutic objectives vary with the extent and configuration of the residual periodontal lesion. The elimination of etiologic factors, alterations in the depth and configuration of the pocket, and the facilitation of restorative dentistry may all be legitimate objectives. Thus periodontal treatment may include scaling and root planing, as well as various surgical treatments. If the endodontic lesion requires apical surgery, then the surgical treatment of both apical and periodontal lesions may be accomplished simultaneously.

PROGNOSIS OF COMBINED LESIONS

With proper treatment the healing of an endodontic lesion is highly predictable. However, the prognosis for teeth with combined lesions varies with the extent that each lesion contributes to the loss of attachment. Lesions resulting from pulpal disease tend to resolve with endodontic therapy, whereas the repair/regeneration of attachment loss from periodontitis is less predictable. The long-term prognosis for a tooth with a combined lesion is therefore closely related to the extent and configuration of the periodontal attachment loss. With advanced horizontal attachment loss, even an optimal endodontic result may not be sufficient to retain the tooth as a functioning member of the dentition. If the periodontal lesion is an advanced, multiwalled bony defect, the success of therapy likely depends on the ability to fill or regenerate attachment to obliterate the defect. Therefore the decision to treat and retain teeth with combined periodontal and endodontic lesions should be carefully considered in regard to the overall dental treatment plan as the time and cost of combined defect treatment may be considerable.

POTENTIAL COMPLICATIONS TO ENDODONTIC THERAPY

As with any therapeutic modality, complications may arise during endodontic treatment. Some are of an iatrogenic nature such as perforations of the floor of the pulp chamber or the root during access, canal instrumentation or preparation for a post (Fig. 65-7). These accidents may result in periodontal defects, and treatment should be instituted as soon as the perforation occurs. The healing of the lesion that occurs in the periodontium depends on whether bacterial infection can be excluded from the wound area by obturation of the site of perforation.[1,7] If the perforation occurs in the cervical area of the tooth, a surgical flap approach may provide sufficient access to expose the perforation and allow a successful seal. However, because of the difficulty in sealing a lateral perforation of the root, a guarded prognosis should be given to such a tooth.

Additional problems are root resorption and vertical root fracture. Resorption may be of an internal or external nature. External resorption may follow impact injuries such as luxation or tooth avulsion and is most commonly seen after reimplantation.

Vertical root fractures are fractures oriented more or less longitudinally toward the apex of the tooth. The cause and prevalence of such fractures is not clearly established. However, such fractures may result during canal obturation, pin or post placement, or cementation of intracoronal restorations.[2,3,24] In some cases, they appear to

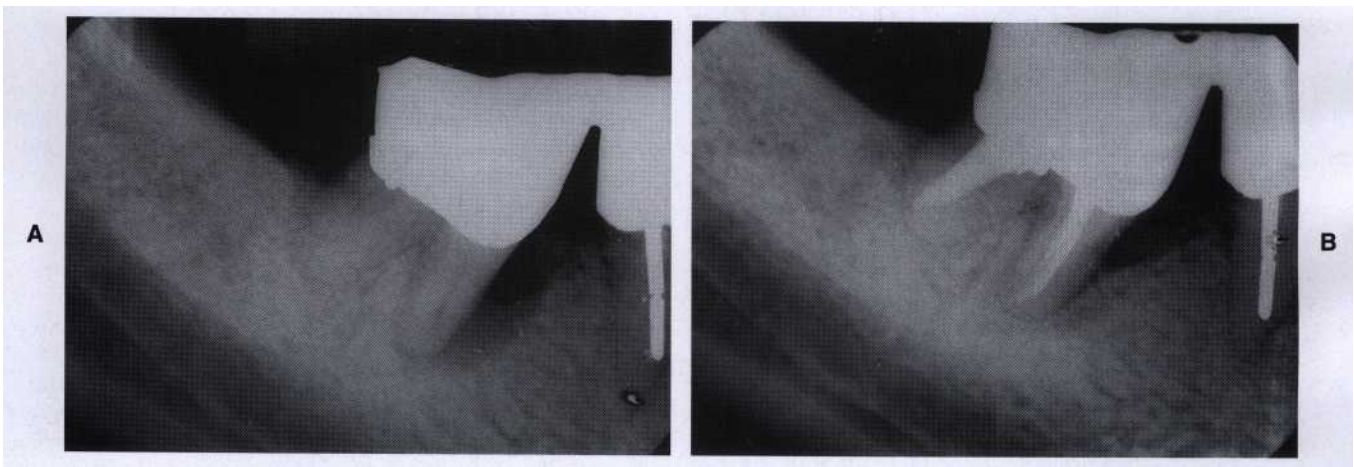

Fig. 65-6 Period ontal-endodontic lesion on a mandibular second molar. A, Pretreatment radiograph of a deep combination one- and two-walled bony defect on the mesial root of the second molar. Note the apparent involvement of the apex of the mesial root. B, Postendodontic therapy. The performance of the root canal has resulted in repair of the endodontic component of the defect. The periodontal component of the defect shows little change. The residual bony defect will require periodontal therapy. This is a "true" perio-endo lesion.

Fig. 65-7 Radiograph of mandibular right molar area. Endodontic perforation into the furcation area on the mesial root of a mandibular second molar. The curvature and deep distal fluting on the mesial root of mandibular molars increases the risk of inadvertant root perforation.

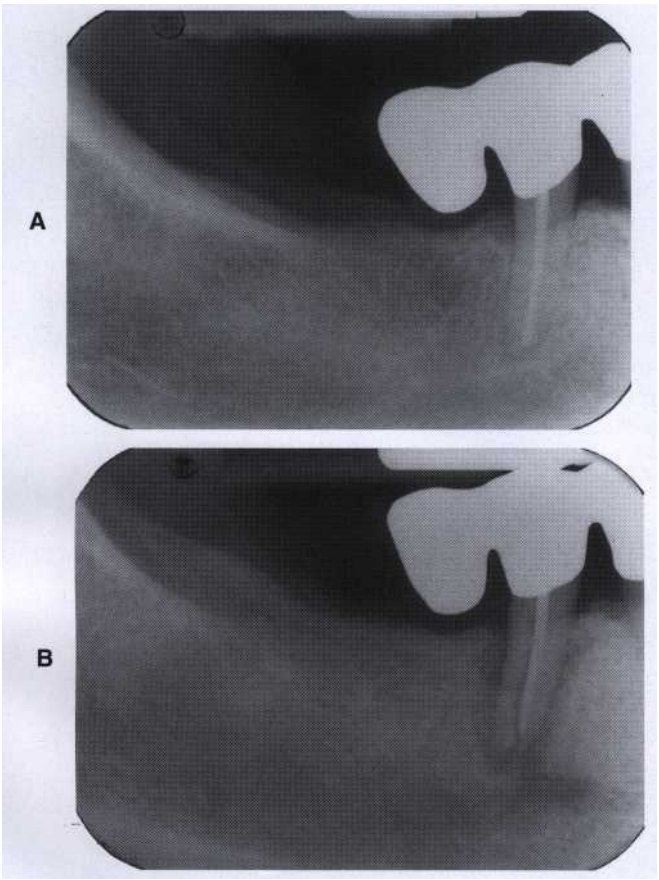

Fig. 65-8 Vertical root fractures. A, Radiograph of mandibular left second bicuspid with a cantilevered pontic. This tooth shows evidence of periodontal attachment loss at the mesial and distal surfaces and an apparent widening of the periodontal ligament space. B, Radiograph of the same bicuspid six months later. Note the advanced loss of attachment and the radiographic signs of a vertical root fracture (separation of fragments). The sectioning of the bridge and removal of the tooth was required.

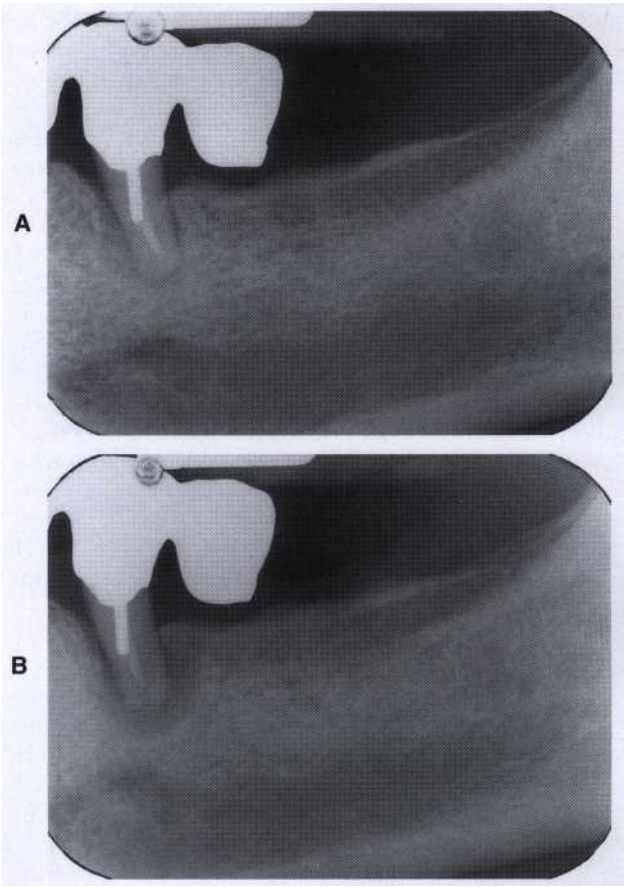

Fig. 65-9 Radiographs of vertical root fracture. A, Radiograph of the mandibular right second molar in the same patient as Fig. 65-8. The bicuspid, supporting a cantilevered pontic, has an endodontic post in the root. It also has radiographic evidence of loss of periodontal attachment and widening of the periodontal ligament space. Note the apical halolike radiolucency. B, Radiograph of no. 29 taken 10 months later showing advanced attachment loss around the apical area of the root and evidence of vertical root fracture. This tooth also required extraction.

occur spontaneously. They appear to occur more commonly in teeth treated with endodontics than in nonendodontically treated teeth. It has been postulated that endodontic treatment may result in the teeth becoming more brittle and less resistant to forces of mastication.

These fractures may occur years after endodontic treatment[23] and are not readily visible in radiographs unless the fragments are separated (Fig. 65-8, A *and B).* It has been suggested that a thin, halolike apical radiolucency is an indication of vertical root fracture[30] (Fig. 65-9, A *and B).* Fractures are often inferred from symptoms of pain or tenderness on mastication or the development of a localized periodontal defect or sinus tract that cannot be explained by other clinical findings. Both the application of an iodine stain or plaque-disclosing solution and indirect illumination are also useful diagnostic measures. However surgical exposure and direct visual examination is sometimes required to confirm the

fracture. Vertical root fracture generally results in a hopeless prognosis for the affected root.

RESTORATIVE IMPLICATIONS OF ENDODONTIC THERAPY

Ultimately, most root canal-treated teeth require restorations. Although the initial success rate for endodontics is quite high,[36] the long-term retention and function is dependent on, to a great extent, the ability to adequately restore the tooth. Restoration is complicated by the extent of crown loss from caries, fracture, and the size and placement of the access to the pulp chamber." Additional factors are the type of restoration to be used, the configuration and number of the pulp canals, root form, and the need for a post and core.[7,11,24,32,31] Although severely decayed and/or fractured teeth can often be successfully treated endodontically, such teeth may require periodontal surgery and yet be difficult or impossible to restore. Complex interdisciplinary treatment should be confined to teeth that are of critical importance to the overall treatment plan after due consideration of alternate treatment methods.

CRITERIA FOR SELECTION OF TECHNIQUES
SUMMARY

TERMINOLOGY

The term *mucogingival surgery* was initially introduced in the literature by Friedman[30] to describe surgical procedures for the correction of relationships between the gingiva and the oral mucous membrane with reference to three specific problems: those associated with attached gingiva, shallow vestibules, and a frenum interfering with the marginal gingiva. With the advancement of periodontal surgical techniques, the scope of nonpocket surgical procedures increased, encompassing now a multitude of areas that were not addressed in the past. Recognizing this, the 1996 World Workshop renamed mucogingival surgery as *periodontal plastic surgery,*[2] a term originally proposed by Miller in 1993, and broadened to include the following areas[1-2]:

Periodontal-prosthetic corrections
Crown lengthening
Ridge augmentation
Esthetic surgical corrections
Coverage of the denuded root surface
Reconstruction of papillae
Esthetic surgical correction around implants
Surgical exposure of unerupted teeth for orthodontics

Periodontal plastic surgery is defined as the surgical procedures performed to correct or eliminate anatomic, developmental, or traumatic deformities of the gingiva or alveolar mucosa. The term *mucogingival therapy is* a broader one, since it also includes nonsurgical procedures such as papilla reconstruction by means of orthodontics or restorative dentistry. Periodontal plastic surgery includes only the surgical procedures of mucogingival therapy.

This chapter deals only with the periodontal plastic surgical techniques that were traditionally included in the definition of mucogingival surgery-that is, widening attached gingiva, deepening of shallow vestibules; and resection of aberrant frena. Other aspects of periodontal plastic surgery such as periodontal-prosthetic surgery, esthetic surgery around implants, and surgical exposure of teeth for orthodontics are covered in Chapters 53, 70, and 74.

OBJECTIVES

The three objectives of periodontal plastic surgery to be addressed in this chapter are as follows:

1. Problems associated with attached gingiva
2. Problems associated with shallow vestibule
3. Problems associated with aberrant frenum

Problems Associated with Attached Gingiva

The ultimate goal of mucogingival surgical procedures is the creation and/or widening of attached gingiva around teeth and implants .z The width of the attached gingiva varies in different individuals and on different teeth of the same individual (see Chapter 31). Attached gingiva is not synonymous with keratinized gingiva because the latter also includes the free gingival margin.

The width of the attached gingiva is determined by subtracting the depth of the sulcus or pocket from the distance between the crest of the gingival margin to the mucogingival junction.

The original rationale for mucogingival surgery was predicated on the assumption that a minimal width of attached gingiva was required for optimal gingival health to be maintained. However, several studies have challenged the view that a wide attached gingiva is more protective against the accumulation of plaque than a narrow or a nonexistent zone. No minimum width of attached gingiva has been established as a standard necessary for gingival health. Persons who practice excellent oral hygiene may maintain healthy areas with almost no attached gingiva.

However, those individuals whose oral hygiene practices are less than optimal can be helped by the presence of keratinized gingiva and vestibular depth, which provide room for easier placement of the toothbrush and to avoid brushing on mucosal tissue. To improve esthetics, the objective is the coverage of the denuded root surface. The maxillary anterior area, especially the facial aspect of the canine, often presents extensive recession. In an individual with a high smile line, this recession may create an esthetic defect. The coverage of the denuded root for esthetic purposes also widens the zone of attached gingiva. There is also a need for a wider zone of attached gingiva around teeth that serve as abutments for fixed or removable partial dentures, as well as in ridge areas in relation to dentures. Teeth with subgingival restorations and narrow zones of keratinized gingiva have higher gingival inflammation scores than teeth with similar restorations and wide zones of attached gingiva." Therefore, in such cases, techniques for widening the attached gingiva are considered preprosthetic periodontal surgical procedures.

Widening the attached gingiva accomplishes the following three objectives:

1. Enhances plaque removal around the gingival margin
2. Improves esthetics
3. Reduces inflammation around restored teeth

Problems Associated with a Shallow Vestibule

Another objective of periodontal plastic surgery is the creation of some vestibular depth when this is lacking. Gingival recession displaces the gingival margin apically, thus reducing vestibular depth, which is measured from the gingival margin to the bottom of the vestibule. With minimal vestibular depth, proper hygiene procedures are jeopardized. The sulcular brushing technique requires the placement of the toothbrush at the gingival margin, which may not be possible with reduced vestibular depth.

Minimal attached gingiva with adequate vestibular depth may not require surgical correction if proper atraumatic hygiene is practiced with a soft brush. Minimal amounts of keratinized attached gingiva with no vestibular depth usually benefit from mucogingival correction. Adequate vestibular depth may also be necessary for proper placement of removable prostheses.

Problems Associated with an Aberrant Frenum

The final objective of periodontal plastic surgery is to correct frenal or muscle attachments. If there is adequate gingiva coronal to the frenum, there is usually no need to surgically remove it. A frenum that encroaches on the margin of the gingiva may interfere with plaque removal and tension on this frenum may tend to open the sulcus. In these cases, surgical removal of the frenum is indicated.

ETIOLOGIC FACTORS OF MARGINAL TISSUE RECESSION

The most common cause for these defects is abrasive and traumatic toothbrushing habits. Teeth positioned buccally tend to have greater recession. Recession of the gingival tissue and bone exposes the cemental surface, which allows abrasion and "ditching" of the cervical area.

Periodontal inflammation and the resultant loss of attachment results in reduced attached gingiva. Advanced periodontal involvement in areas of minimal attached gingiva result in the base of the pocket extending close to, or apical to, the mucogingival junction.

Frenal and muscle attachments that encroach on the marginal gingiva distend the gingival sulcus, fostering plaque accumulation, increasing the rate of progression of periodontal recession, and causing their recurrence after treatment (Fig. 66-1, A-C). The problem is more common on facial surfaces, but it may also occur on the lingual surface' (see Fig. 66-1, D).

Orthodontic tooth movement through a thin buccal osseous plate leading to a dehiscence beneath a thin gingival tissue can cause recession and/or loss of the gingiva (Fig. 66-2).36,80

FACTORS THAT AFFECT THE OUTCOME OF PERIODONTAL PLASTIC SURGERY

Irregularity of Teeth

Abnormal tooth alignment is an important cause of gingival deformities that require corrective surgery and likewise, an important factor in determining the outcome of treatment. The location of the gingival margin, width of the attached gingiva, and alveolar bone height and thickness are all affected by tooth alignment. On teeth that are tilted or rotated labially, the labial bony

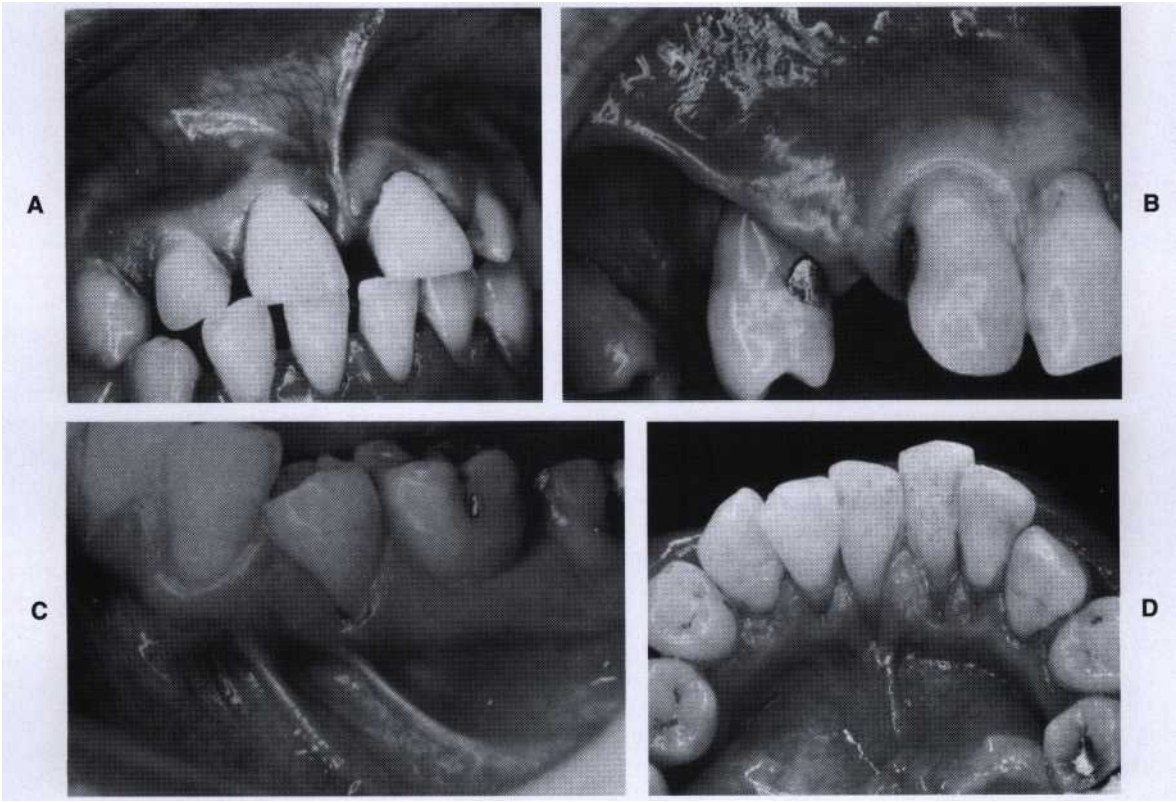

Fig. 66-1 High frenum attachments. A, Frenum between maxillary central incisors. B, Frenum on the mesial surface of the maxillary second premolar. C, Frenum attached to a pocket wall on a mandibular first premolar. D, Frenum attached to a pocket wall on the lingual surface of an incisor.

plate is thinner and located farther apically than on the adjacent teeth; therefore the gingiva is recessed so that the root is exposed.$° On the lingual surface of such teeth, the gingiva is bulbous, and the bone margins are closer to the cementoenamel junction (CEJ). The level of gingival attachment on root surfaces and the width of the attached gingiva after mucogingival surgery are affected as much by tooth alignment as by variations in treatment procedures.

Orthodontic correction is indicated when mucogingival surgery is performed on malposed teeth in an attempt to widen the attached gingiva or to restore the gingiva over denuded roots. If orthodontic treatment is not feasible, the prominent tooth should be reduced to within the borders of the alveolar bone, with special care taken to avoid pulp injury.

Roots covered with thin bony plates present a hazard in mucogingival surgery. Even the most protective type of flap, a partial-thickness flap, creates the risk of bone resorption on the periosteal surface.38 Resorption in amounts that ordinarily are not significant may cause loss of bone height when the bone plate is thin or tapered at the crest.

The Mucogingival Line (junction)

Normally, the mucogingival line in the incisor and canine areas is located approximately 3-mm apical to the

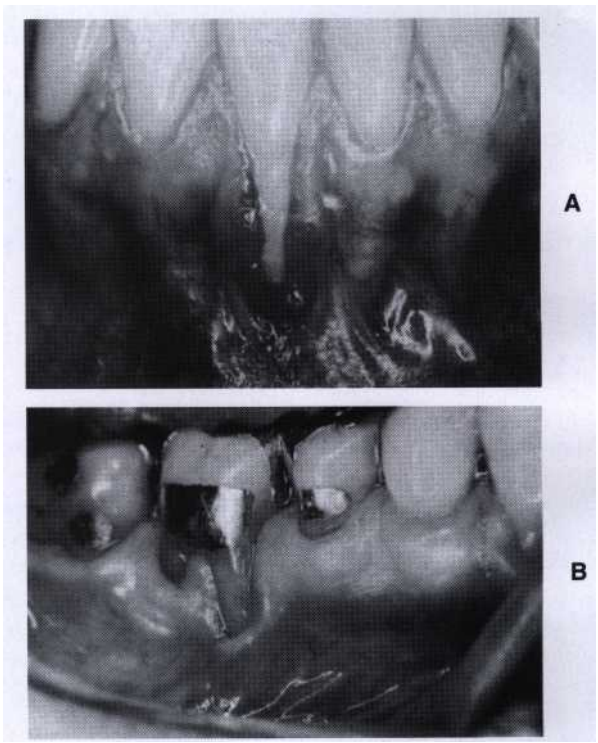

Fig. 66-2 A, Gingival recession and extreme inflammation around a lower central incisor. B, Advanced recession of mesiobuccal root of a first lower molar.

crest of the alveolar bone on the radicular surfaces and 5-mm interdentally.[69] In periodontal disease and on malposed, disease-free teeth, the bone margin is located farther apically and may extend beyond the mucogingival line. The distance between the mucogingival line and the CEJ before and after periodontal surgery is not necessarily constant. After inflammation is eliminated, there is a tendency for the tissue to contract and draw the mucogingival line in the direction of the crown.[23]

TECHNIQUES FOR INCREASING ATTACHED GINGIVA

To simplify and to better understand the techniques and the result of the surgery, the following classifications are presented:

Gingival augmentation apical to the area of recession. A graft, either pedicle or free, is placed on a recipient bed apical to the recessed gingival margin. No attempt is made to cover the denuded root surface where there is gingival and bone recession.

Gingival augmentation coronal to the recession (root coverage). A graft (either pedicle or free) is placed covering the denuded root surface. Both the apical and coronal widening of attached gingiva enhance oral hygiene procedures, but only the latter can correct an esthetic problem. For preprosthetic purposes, the combination of widening keratinized gingiva apical and coronal to the recession would satisfy this objective. Consideration of the objectives as apical, coronal, or both provides a better understanding of the techniques required to achieve the goals.

Widening of the keratinized attached gingiva (apical or coronal to the area of recession) can be accomplished by numerous techniques such as the free gingival autograft, free connective tissue autograft, and lateral pedicle flap, which can be used for either objective.

Gingival Augmentation Apical to Recession

Techniques for this procedure include the following: free gingival autograft, free connective tissue autograft,[3] and apically positioned flap

Free Gingival Autografts. Free gingival grafts are used to create a widened zone of attached gingiva. They were initially described by Bjorn' in 1963 and have been extensively investigated since that time.

THE CLASSIC TECHNIQUE

Step One: Prepare the Recipient Site. The purpose of this step is to prepare a firm connective tissue bed to receive the graft. The recipient site can be prepared by incising at the existing mucogingival junction with a #15 blade to the desired depth, blending the incision on both ends with the existing mucogingival line (Color Figs. 66-1 and 66-2). Periosteum should be left covering the bone.

Another technique consists of outlining the recipient site with two vertical incisions from the cut gingival margin into the alveolar mucosa (Fig. 66-3).

Extend the incisions to approximately twice the desired width of the attached gingiva, allowing for 50% contraction of the graft when healing is complete. The amount of contraction depends on the extent to which the recipient site penetrates the muscle attachments. The deeper the recipient site, the greater is the tendency for the muscles to elevate the graft and reduce the final width of the attached gingiva. The periosteum along the apical border of the graft is sometimes penetrated in an effort to prevent postoperative narrowing of the attached gingiva.

Insert a #15 blade along the cut gingival margin and separate a flap consisting of epithelium and underlying connective tissue without disturbing the periosteum. Extend the flap to the depth of the vertical incisions.

If a narrow band of attached gingiva remains after the pockets are eliminated, it should be left intact, and the recipient site should be started by inserting the blade at the mucogingival junction instead of at the cut gingival margin.

Suture the flap where the apical portion of the free graft will be located. Three to four independent gut sutures are placed. The needle is first passed as a superficial mattress suture perpendicular to the incision and then on the periosteum parallel to the incision (Fig 66-4).

Make an aluminum foil template of the recipient site to be used as a pattern for the graft (see Fig. 66-3, C and D).

Grafts can also be placed directly on bone tissue. For this technique, the flap should be separated by blunt dissection with a periosteal elevator. Reported advantages of this variant are less postoperative mobility of the graft, less swelling, better hemostasis,[24] and 1.5 to 2 times less shrinkage.[41,42] However, a healing lag is observed for the first 2 weeks.[12,15,28]

Step Two: Obtain the Graft from the Donor Site. The classic or conventional-free gingival graft technique consists of transferring a piece of keratinized gingiva of approximately the size of the recipient site. To avoid the large wound that this procedure sometimes leaves in the donor site, some alternative methods have been proposed. The original technique is described first, followed by several of the most common variants. For the classic technique (see Fig. 66-3 and Color Figs. 66-1 and 66-2), a partial thickness graft is used. The palate is the usual site from which donor tissue is removed. The graft should consist of epithelium and a thin layer of underlying connective tissue. Place the template over the donor site (see Fig. 66-3, D), and make a shallow incision around it with a #15 blade. Insert the blade to the desired thickness at one edge of the graft. Elevate the edge and hold it with tissue forceps. Continue to separate the graft with the blade, lifting it gently as separation progresses to provide visibility. Placing sutures at the margins of the graft helps control it during separation and transfer and simplifies placement and suturing to the recipient site.[3]

Proper thickness is important for survival of the graft. It should be thin enough to permit ready diffusion of nutritive fluid from the recipient site, which is essential in the immediate posttransplant period. A graft that is too thin may necrose and expose the recipient site. If the graft is too thick, its peripheral layer is jeopardized because of the excessive tissue that separates it from new

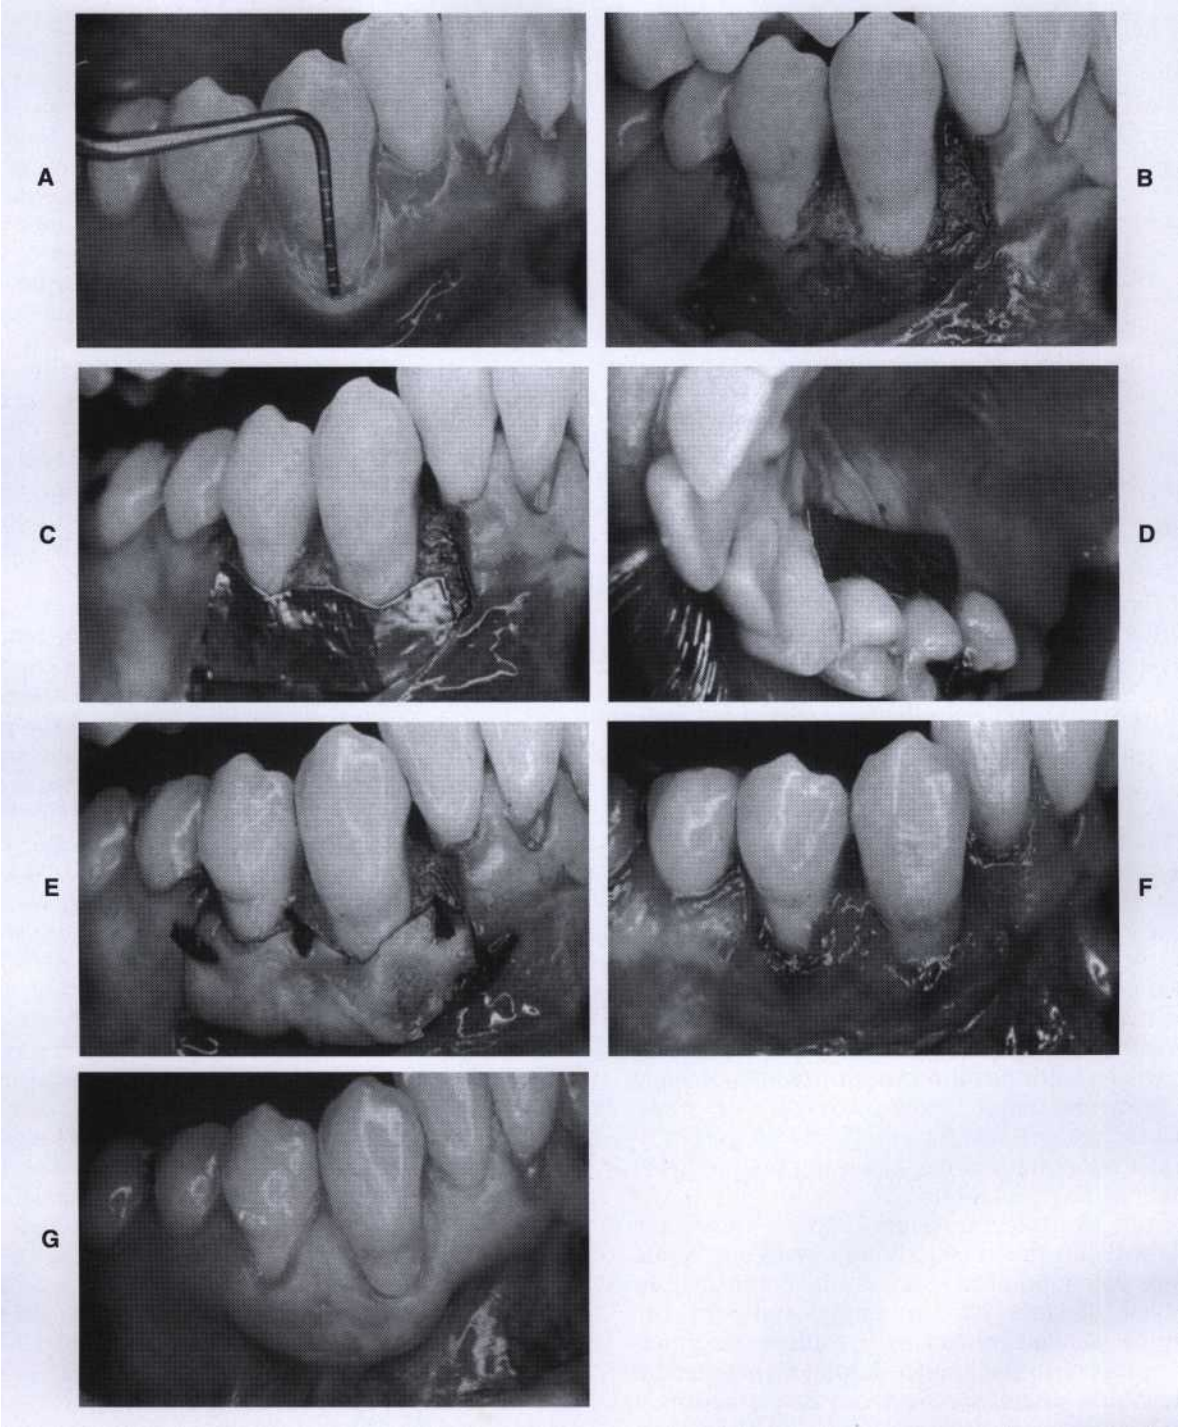

Fig. 66-3 Free gingival graft. A, Before treatment; sulcus extends into alveolar mucosa. B, Recipient site prepared for free gingival graft. C, Aluminum foil template of the desired graft. D, Template used to outline the graft in the donor site. E, Graft transferred. F, After 2 weeks. G, After 1 year, showing widened zone of attached gingiva.

circulation and nutrients. Thick grafts may also create a deeper wound at the donor site, with the possibility of injuring major palatal arteries." The ideal thickness of a graft is between 1.0 and 1.5 mm.53 After the graft is separated, remove loose tissue tabs from the undersurface. Thin the edge to avoid bulbous marginal and interdental contours. Special precautions must be taken with grafts from the palate.

The submucosa in the posterior region is thick and fatty and should be trimmed so that it will not interfere with vascularization. Grafts tend to reestablish their original epithelial structure so that mucous glands may occur in grafts obtained from the palate.

A thick graft can be thinned by holding it between two wet wooden tongue depressors and slicing it longitudinally with a sharp #15 blade.

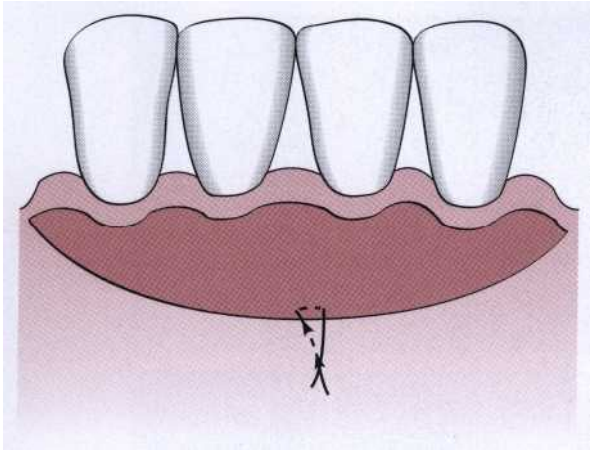

Fig. 66-4 Diagram of graft bed suture.

Step Three: Transfer and Immobilize the Graft. Remove the sponge from the recipient site; reapply it, with pressure if necessary, until bleeding is stopped. Remove the excess clot. A thick clot interferes with vascularization of the graft.[54]

Position the graft and adapt it firmly to the recipient site. A space between the graft and the underlying tissue (dead space) retards vascularization and jeopardizes the graft. Suture the graft at the lateral borders and to the periosteum to secure it in position (see Fig. 66-3, E and Color Figs. 66-1 and 66-2). Before suturing is completed, elevate the unsutured portion and cleanse the recipient bed beneath it with an aspirator to remove clots or loose tissue fragments. Press the graft back into position and complete the sutures. The graft must be immobilized. Any movement interferes with healing. Avoid excessive tension, which can distort the graft from the underlying surface. Every precaution should be taken to avoid trauma to the graft. Tissue forceps should be used delicately, and a minimum number of sutures used to avoid unnecessary tissue perforation.

Step Four. Protect the Donor Site. Cover the donor site with a periodontal pack for 1 week and repeat if necessary. Retention of the pack on the donor site can be a problem. If facial attached gingiva was used, the pack may be retained by locking it through the interproximal spaces onto the lingual surface. If there are no open interdental spaces, the pack can be covered by a plastic stent wired to the teeth. A modified Hawley retainer is useful to cover the pack on the palate and over edentulous ridges.

VARIANT TECHNIQUES. The following variants to the classic technique are described in this section: accordion technique, strip technique, or a combination of both. All are modifications of the free grafts:

The accordion technique has been described by Rateitschak and colleagues.[61] It attains expansion of the graft by alternate incisions in opposite sides of the graft.

The strip technique developed by Han and associates[37] consists of obtaining two or three strips of gingival donor tissue about 3- to 5-mm wide and long enough to cover the entire length of the recipient site (Fig. 66-5). These strips are placed side by side to form one donor tissue and sutured on the recipient site. The area is then covered with aluminum foil and surgical pack. The advantages of this technique are the rapid healing of the donor site. The epithelial migration of the close wound edges (3 to 5 mm) allows rapid epithelization of the open wound. The donor site usually does not require any suturing and heals uneventfully in 1 week.

In some cases, a combination technique can be performed as follows. Remove a strip of tissue from the palate, about 3- to 4-mm thick, place it between two wet tongue depressors, and split it longitudinally with a sharp #15 blade. Both will be used as free grafts. The superficial portion consists of epithelium and connective tissue and the deeper portion consists only of connective tissue. These donor tissues are placed on the recipient site as in the strip technique. The minimal donor site wound by obtaining two donor tissues from one site is the advantage of this technique.

HEALING OF THE GRAFT. The success of the graft depends on survival of the connective tissue (see Fig. 66-3 and Color Fig. 66-1). Sloughing of the epithelium occurs in most cases, but the extent to which the connective tissue withstands the transfer to the new location determines the fate of the graft. Fibrous organization of the interface between the graft and the recipient bed occurs within 2 to several days .[67]

The graft is initially maintained by a diffusion of fluid from the host bed, adjacent gingiva, and alveolar mucosa.[32] The fluid is a transudate from the host vessels and provides nutrition and hydration essential for the initial survival of the transplanted tissues. During the first day, the connective tissue becomes edematous and disorganized and undergoes degeneration and lysis of some of its elements. As healing progresses, the edema is resolved and degenerated connective tissue is replaced by new granulation tissue.

Revascularization of the graft starts by the second 6 or third day." Capillaries from the recipient bed proliferate into the graft to form a network of new capillaries and anastomose with preexisting vessels .[43]

Many of the graft vessels degenerate and are replaced by new ones, and some participate in the new circulation. The central section of the surface is the last to vascularize, but this is complete by the tenth day.

The epithelium undergoes degeneration and sloughing, with complete necrosis occurring in some areas .[13-56] It is replaced by new epithelium from the borders of the recipient site. A thin layer of new epithelium is present by the fourth day, with rete pegs developing by the seventh day.

The fact that heterotopically placed grafts maintain their structure (keratinized epithelium), even after the grafted epithelium has become necrotic and has been replaced by neighboring areas of nonkeratinized epithelium, suggests that there exists a genetic predetermination of the specific character of the oral mucosa that is dependent on stimuli that originate in the connective tissue .[44] This is the basis for the technique that uses grafts composed only of connective tissue obtained from areas where it is covered by keratinized epithelium.[10,22,28]

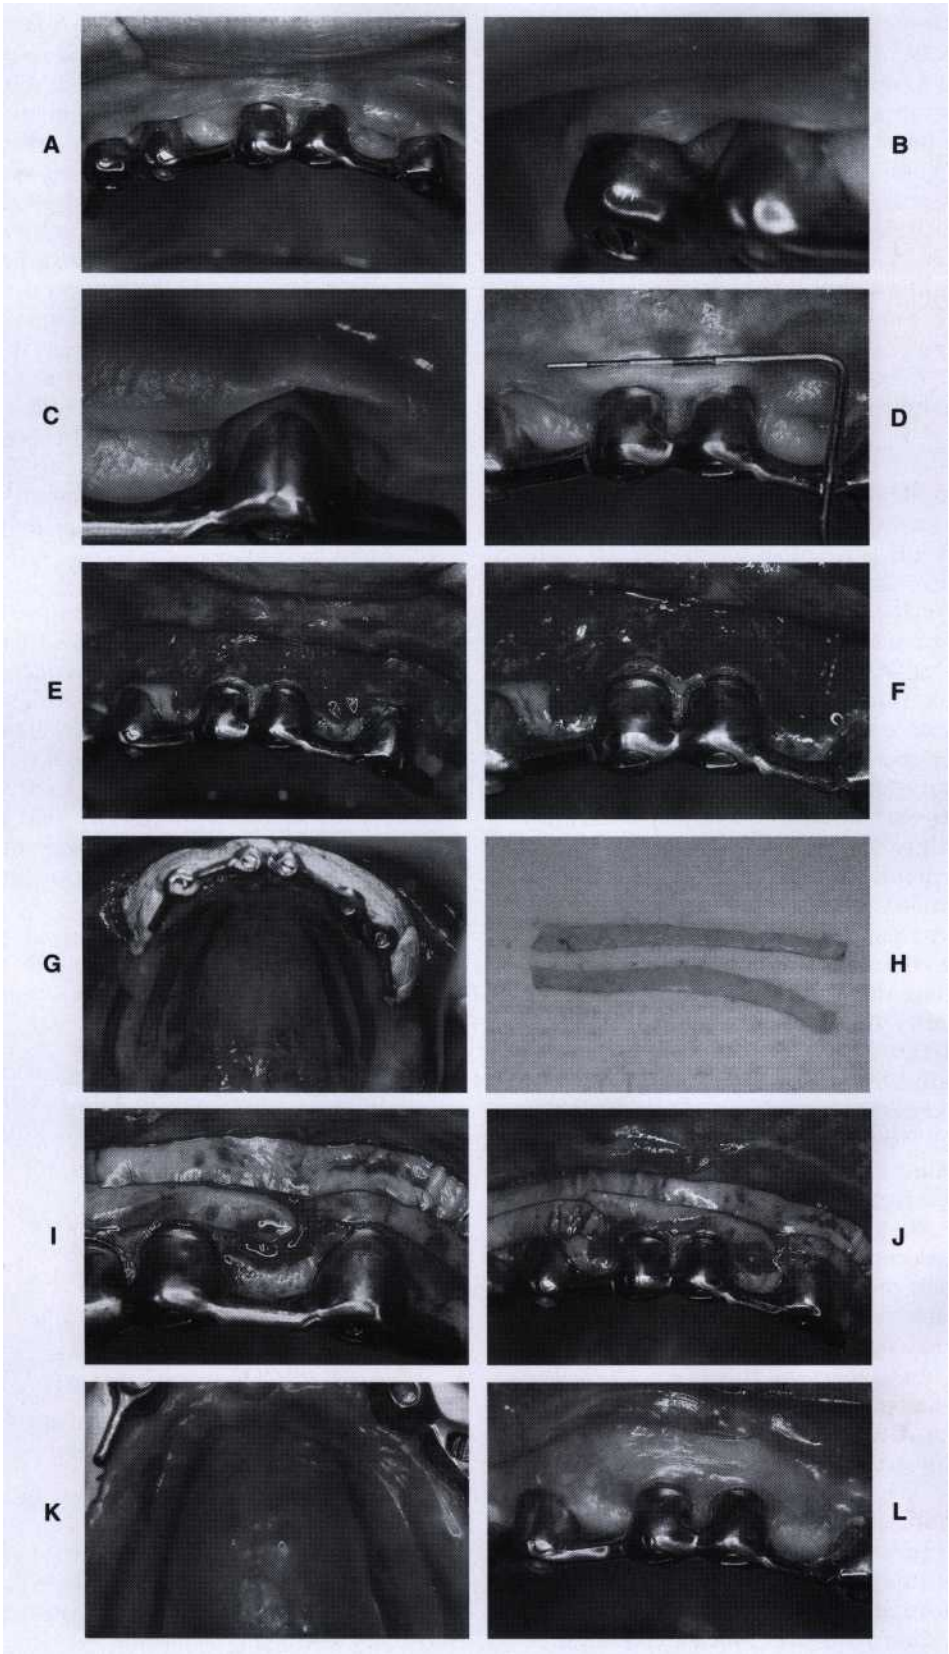

Fig. 66-5 Free gingival graft: strip technique. A-D, Mucosal tissue around implants. E and F, Recipient site prepared. G, Donor site with strips of free graft removed. H, Donor strips of free graft. I and J, Strips placed side by side on recipient site. K, Donor area one week after graft removal. L, Healing of recipient site after three months. Note good keratinized, attached gingiva.

As seen microscopically, healing of a graft of intermediate thickness (0.75 mm) is complete by 10.5 weeks; thicker grafts (1.75 mm) may require 16 weeks or longer.[33] The gross appearance of the graft reflects the tissue changes within it. At the time of transplantation, the graft vessels are empty, and the graft is pale. The pallor changes to an ischemic grayish white during the first 2 days until vascularization begins and a pink color appears. The plasmatic circulation accumulates and causes softening and swelling of the graft, which are reduced when the edema is removed from the recipient site by the new blood vessels. Loss of epithelium leaves the graft smooth and shiny. New epithelium creates a thin, gray, veil-like surface that develops normal features as the epithelium matures.

Functional integration of the graft occurs by the seventeenth day, but the graft is morphologically distinguishable from the surrounding tissue for months. The graft eventually blends with adjacent tissues, but sometimes, although pink, firm, and healthy, it is somewhat bulbous.

This ordinarily presents no problem, but if the graft traps plaque or is esthetically unacceptable, thinning of the graft may be necessary.

Thinning the surface of the grafted tissue does reduce the bulbous condition, because the surface epithelium tends to proliferate again. The graft should be thinned by making the necessary incisions to elevate it from the periosteum, removing tissue from its undersurface, and suturing it back in place.

ACCOMPLISHMENTS OF FREE GINGIVAL GRAFTS. Free gingival grafts effectively widen the attached gingiva. Several biometric studies have analyzed the width of the attached gingiva after the placement of a free gingival graft. After 24 weeks, grafts placed on denuded bone shrink 25%; whereas grafts placed on periosteum shrink 50%.[49] The greatest amount of shrinkage occurs within the first 6 weeks.

The placement of a gingival graft does not, per se, improve the status of the gingiva.[26,27,75] Therefore the indication for a free gingival graft should be based on the presence of progressive gingival recession and inflammation. When recession continues to progress after a period of a few months with good plaque control, a graft can be placed to prevent further recession and loss of attached gingiva.

Other materials have been used to replace gingival tissue in gingival extension operations. Attempts with lyophilized dura mater[66] and sclerall have not been satisfactory. The use of irradiated free gingival allografts showed satisfactory results,[64] but further research is necessary before they can be considered for clinical use.

Free autogenous gingival grafts have been found to be useful for covering nonpathologic dehiscences and fenestrations. *Nonpathologic* refers to openings of the bone through the tooth surface not previously exposed to the oral environment and found in the course of flap surgery.[25]

The use of free gingival autografts to cover denuded roots is described in the section entitled "Gingival Augmentation Coronal to the Recession."

FREE CONNECTIVE TISSUE AUTOGRAFTS. The connective tissue technique was originally described by Edel[28] and is based on the fact that the connective tissue carries the genetic message for the overlying epithelium to become keratinized. Therefore only connective tissue from a keratinized zone can be used as a graft.

This technique has the advantage that the donor tissue is obtained from the undersurface of the palatal flap, which is sutured back in primary closure; therefore healing is by first intention. There is less discomfort for the patient postoperatively at the donor site. In cases where resective flap surgery is planned for the palate, the connective tissue removed to thin the palatal flap can be used as the graft tissue to augment areas of recession. Fig. 66-6 shows a case in which the free connective tissue graft technique was used.

Another advantage is that better esthetics can be achieved because of a better color match of the grafted tissue to adjacent areas.

The Apically Positioned Flap. This technique uses the apically positioned flap, either partial thickness or full thickness, to increase the zone of keratinized gingiva. A step-by-step description of the surgical technique for apically positioned flaps is given in Chapter 61, and the procedure is shown in Fig. 66-7.

ACCOMPLISHMENTS OF THE APICALLY POSITIONED FLAP. The apically positioned flap operation increases the width of the keratinized gingiva but cannot predictability deepen the vestibule with attached gingiva.

Adequate vestibular depth must be present before the surgery to allow apical positioning of the flap. The edge of the flap may be located in three positions in relation to the bone:

1. *Slightly coronal to the crest of the bone.* This location attempts to preserve the attachment of supracrestal fibers; it may also result in thick gingival margins and interdental papillae with deep sulci and may create the risk of recurrent pockets.
2. *At the level of the crest (see Fig. 66-7, C).* This results in a satisfactory gingival contour, provided that the flap is adequately thinned.
3. *Two millimeters short of the crest (see Figs. 66-7, D; Fig. 66-8).* This position produces the most desirable gingival contour and the same posttreatment level of gingival attachment, as is obtained by placing the flap at the crest of the bone .[31] New tissue covers the crest of the bone to produce a firm, tapered gingival margin.

Placing the flap short of the crest increases the risk of a slight reduction in bone height,[21] but this is compensated for by the advantages of a well-formed gingival margin.

OTHER TECHNIQUES. The following techniques are briefly presented only because of their historical interest. The vestibular extension technique, originally described by Edlan and Mejchar," produces statistically significant widening of attached nonkeratinized tissue. This increase in width in the mandibular area reportedly persists in patients observed for periods of up to 5 years .[29,65,76] Currently, this technique is of historical interest only.

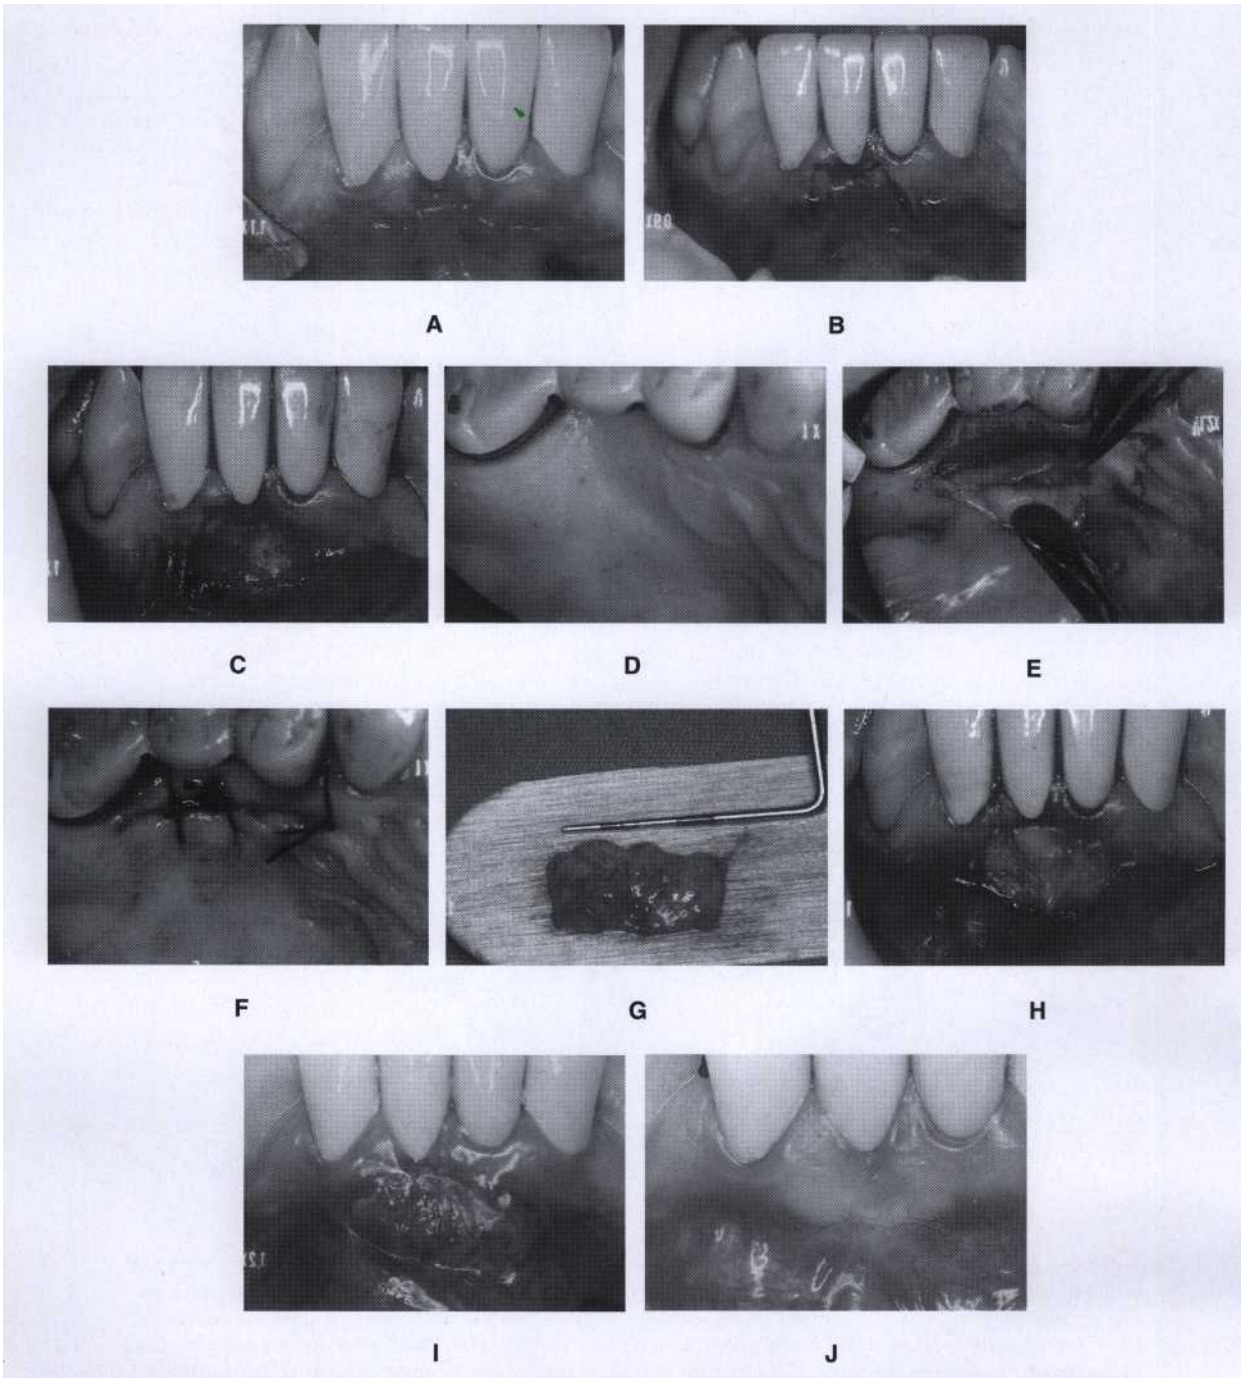

Fig. 66-6 Free connective tissue graft. A, Lack of keratinized, attached gingiva buccal to central incisor. B, Vertical incisions to prepare recipient site. C, Recipient site prepared. D, Palate from which connective tissue will be removed for donor tissue. E, Removal of connective tissue. F, Donor site sutured. G, Connective tissue for graft. H, Free connective tissue placed at donor site. 1, Ten days postoperative healing. 1, Final healing at 3 months. Note wide keratinized, attached gingiva.

The *fenestration operation* was designed to widen the zone of attached gingiva with a minimum loss of bone height.[62,63] It has also been called *periosteal separation.*[19] it used a partial thickness flap, except in a rectangular area at the base of the operative field, where the periosteum is removed, exposing the bone. This is the area of fenestration. Its purpose is to create a scar that is firmly bound to the bone." It prevents separation from the bone and postsurgical narrowing of the attached zone. Results obtained with this technique are not as predictable as with the free gingival graft; therefore it is not widely performed except for small, isolated areas.

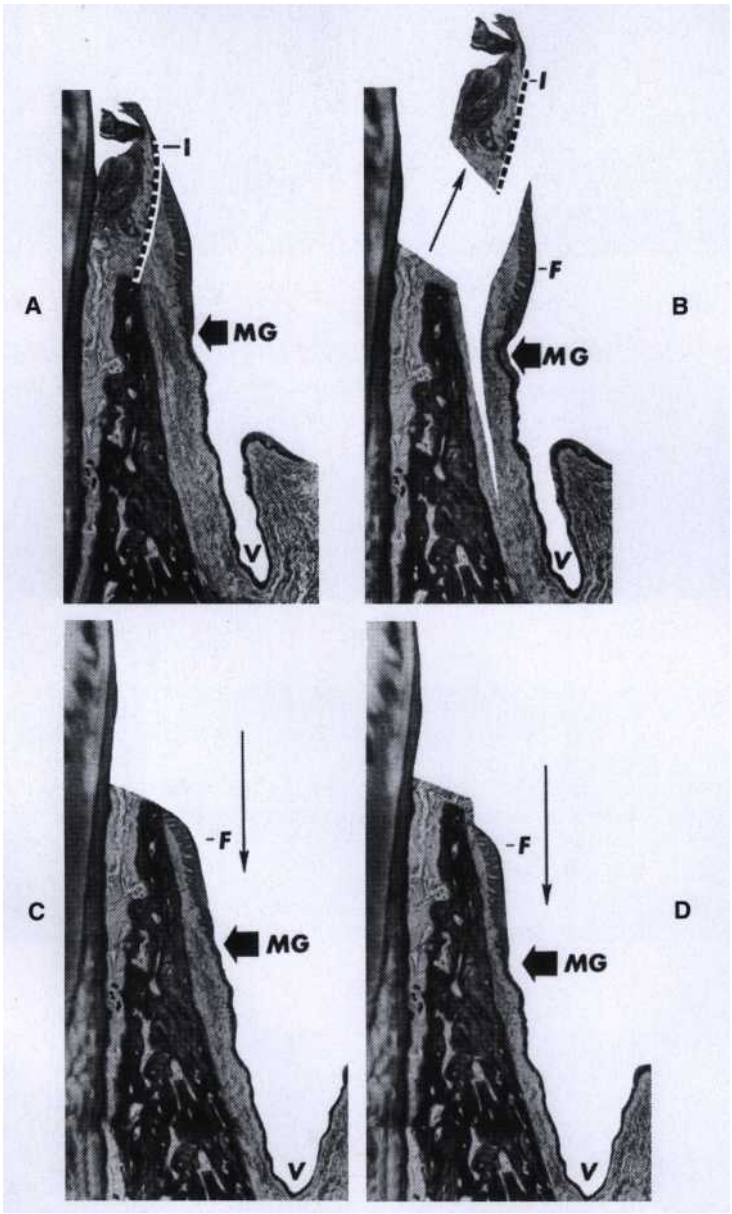

Fig. 66-7 Apically positioned partial-thickness flap. A, Internal bevel incision (1) separates inner wall of periodontal pocket. MG, Mucogingival junction; V, vestibular fornix. B, Partial-thickness flap (F) separated, leaving periosteum and a layer of connective tissue on the bone. The inner wall of the periodontal pocket (I) is removed, and the tooth is scaled and planed. C, Partial-thickness flap (F) positioned apically with the edge of the flap at the crest of the bone. Note that the vestibular fornix is also moved apically. D, Partial-thickness flap (F) displaced apically with the edge of the flap several millimeters below the crest of the bone.

Gingival Augmentation Coronal to Recession (Root Coverage)

The understanding and knowledge of the different stages and condition of gingival recession is necessary for predictable root coverage. Several classifications of denuded roots have been proposed. In the 1960s, Sullivan and Atkins" classified gingival recession into four morphologic categories: 1) shallow-narrow, 2) shallow-wide, 3) deep-narrow, and 4) deep-wide.

This early classification was helpful to better categorize the lesion but did not enable the clinician to predict the outcome of therapy. The predictability of root coverage can be enhanced by the presurgical examination and the correlation of the recession by using the classification proposed by Miller." The following is his classification (Fig. 66-9):

Class I. This includes marginal tissue recession that does not extend to the mucogingival junction. There is no loss of bone or soft tissue in the interdental area. This type of recession can be narrow or wide.

Class II. Class II consists of marginal tissue recession that extends to or beyond the mucogingival junction.

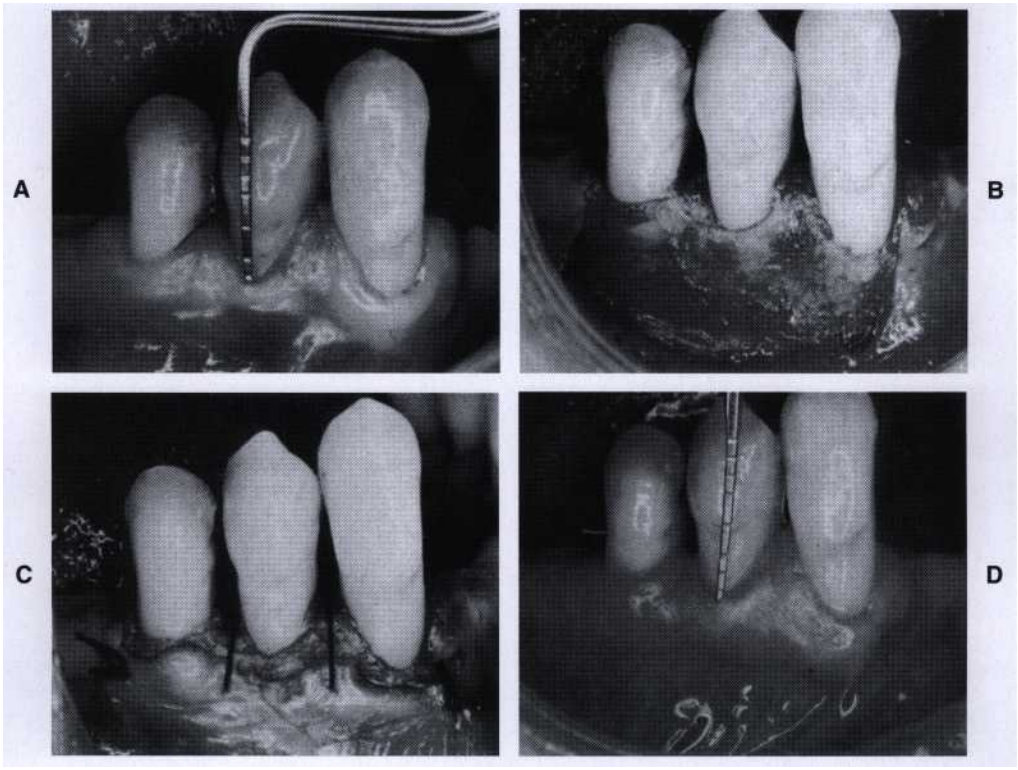

Fig. 66-8 Apically positioned partial-thickness flap. A, Before treatment, the base of pocket extends to the mucogingival line. B, Mucosal flap separated from the periosterum; teeth scaled and smoothed. C, Flap replaced below the crest of the bone. D, Eight months after treatment. Note the shallow sulcus and the widened zone of attached gingiva. Compare with A.

There is no loss of bone or soft tissue in the interdental area. This type of recession can be subclassified into wide and narrow.

Class III. In Class III, there is marginal tissue recession that extends to or beyond the mucogingival junction; in addition, there is bone and/or soft tissue loss interdentally or there is malpositioning of the tooth.

Class IV. There is marginal tissue recession that extends to or beyond the mucogingival junction with severe bone and soft tissue loss interdentally and/or severe tooth malposition.

Prognosis. In general, the prognosis for Classes I and II is good to excellent; whereas for Class III, only partial coverage can be expected. Class IV has a very poor prognosis with present-day techniques.

The following is a list of techniques used for gingival augmentation coronal to the recession (root coverage):

1. Free gingival autograft
2. Free connective tissue autograft
3. Pedicle autografts
   - Laterally (horizontally) positioned
   - Coronally positioned
   - Semilunar pedicle (Tarnow)
4. Subepithelial connective tissue graft (Langer)
5. Guided tissue regeneration
6. Pouch and tunnel technique

Some of the techniques used for widening the attached gingiva apical to the area of recession can also be used for root coverage. Both the free gingival and connective tissue autografts used for apical widening can be used for coronal augmentation by incorporating some modifications. In using the free grafts for root coverage, the recipient bed surrounding the denuded root surface must be extended wider to allow for better blood supply to the donor free graft since a portion of the donor tissue overlies the root surface that has no blood supply.

Free Gingival Autograft. In the last decade, successful and predictable root coverage has been reported using free gingival autografts.[51]

THE CLASSIC TECHNIQUE. Miller[52] applied the classic free gingival autograft described previously with a few modifications. The technique is as follows:

Step One: Root Planing. Root planing is performed, with application of saturated citric acid for 5 minutes with a cotton pledget, burnishing it on the root. The advantage of citric acid application has not been confirmed by other studies."

Step Two: Prepare the Recipient Site. Make a horizontal incision in the interdental papillae at right angles to create a margin against which the graft may have a butt joint with the incision. Vertical incisions are made at the proximal line angles of adjacent teeth, and the retracted tissue is excised. Maintain an intact periosteum in the apical area.

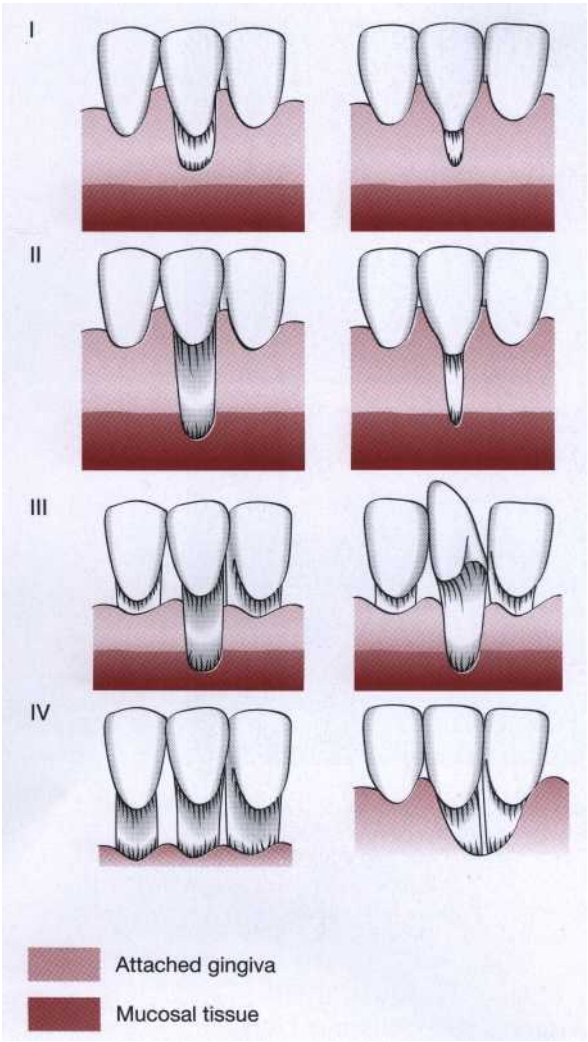

Fig. 66-9 P. D. Miller's classification of denuded roots.

Steps Three and Four. Refer to the step-by-step technique described for the classic gingival graft earlier in this chapter.

This technique results in predictable coverage of the denuded roots but may present esthetic color discrepancies with the adjacent gingiva due to a lighter color.

Free Connective Tissue Autograft. This technique was described by Levine in 1991.[46] The difference between this technique and the previous one is that the donor tissue is connective tissue. It consists of the following steps (see Fig. 66-6).

CONNECTIVE TISSUE TECHNIQUE

Step One: Divergent Vertical Incisions. Divergent vertical incisions are made at the line angles of the tooth to be covered, creating a partial-thickness flap to at least 5 mm apical to the receded area.

Step Two: Suturing. Suture the apical mucosal border to the periosteum using gut suture.

Step Three: Scaling and Planing. Thoroughly scale and plane the root surface, reducing any prominence of the root surface.

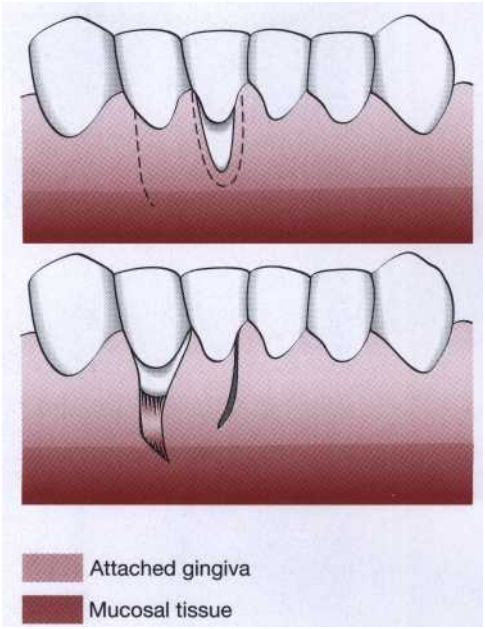

Fig. 66-10 Laterally positioned flap for coverage of denuded root. Top, Incisions removing the gingival margin around the exposed root and outlining flap. Bottom, After the gingiva around exposed root is removed, flap is separated, transferred, and sutured.

Step Four: Obtaining the Graft. From the palate, obtain a connective tissue graft. The donor site is sutured after the graft is removed.

Step Five: Transferring the Graft. Transfer the graft to the recipient site and suture it to the periosteum with gut suture. Good stability of the graft must be attained with adequate sutures.

Step Six: Covering the Graft. Cover the grafted site with dry aluminum foil and periodontal dressing.

Pedicle Autograft

LATERALLY (HORIZONTALLY) DISPLACED. This technique, originally described by Grupe and Warren in 1956,[35] was the standard technique for many years and is still indicated in some cases. The laterally positioned flap can be used to cover isolated, denuded roots that have adequate donor tissue laterally and vestibular depth. The following is a step-by-step procedure for this technique.

Step One: Prepare the Recipient Site. Make an incision, resecting the gingival margin around the exposed roots (Figs. 66-10 and 66-11). Remove the resected soft tissue and scale and plane the root surface (see Fig. 66-11, C).

Step Two: Prepare the Flap. The periodontium of the donor site should have a satisfactory width of attached gingiva and minimal loss of bone and without dehiscences or fenestrations. A full-thickness or partial-thickness flap may be used, but the latter is preferable because it offers the advantage of more rapid healing in the donor site and reduces the risk of loss of facial bone height, particularly if the bone is thin or the presence of a dehiscence or a fenestration is suspected. However, if the gingiva is thin, partial thickness may not be sufficient for flap survival.

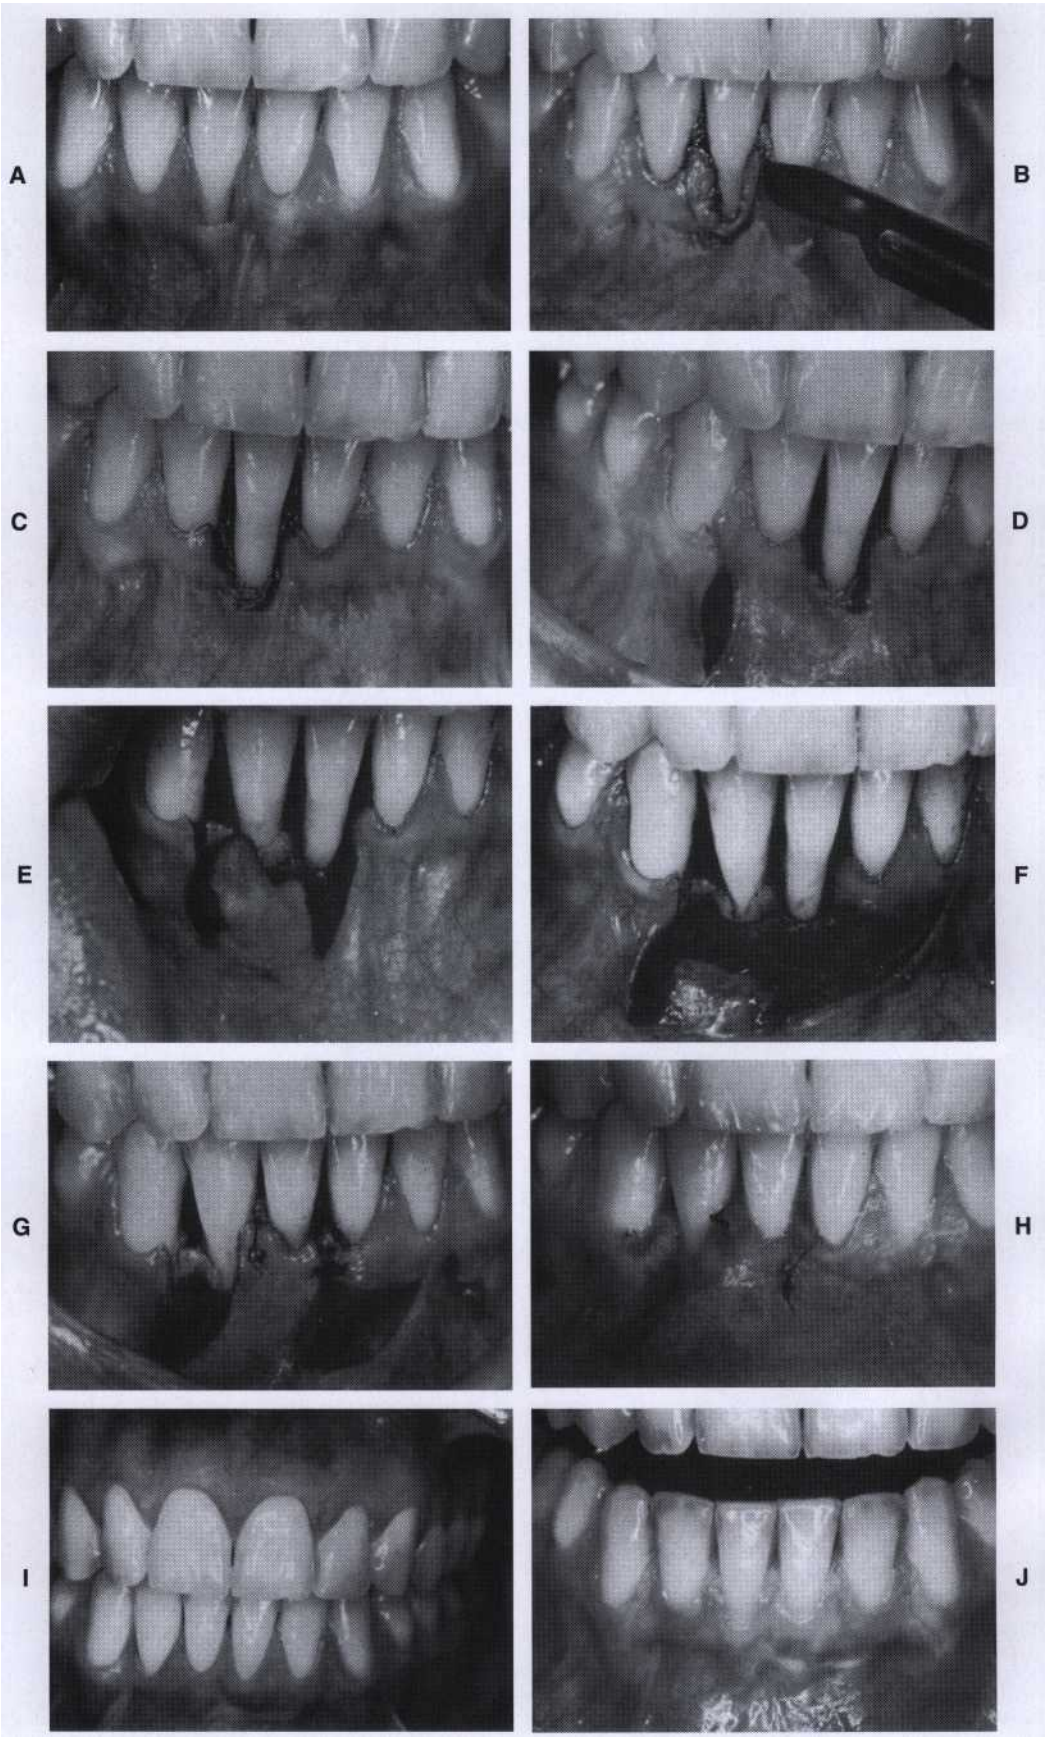

Fig. 66-11 Horizontally displaced flap combined with relocation of frenum attachment. A, Gingival defect of central incisor. B, Defect incised. C, Gingiva removed and tooth scaled and planed. D, Vertical incision on the canine for sliding flap. E, Sliding flap detached. Note high frenum attachment between the central incisors. F, Frenum detached and resected to level of vestibular fornix. G, Sliding flap positioned laterally on central incisor and fixed lateral and suspensory suture. H, One week after operation. Sutures to be removed. I, Five weeks after operation. j, Seven years after treatment. Note the preservation of gingival position and contour.

With a #15 blade, make a vertical incision from the gingival margin to outline a flap adjacent to the recipient site. Incise to the periosteum and extend the incision into the oral mucosa to the level of the base of the recipient site (see Fig. 66-11, D). The flap should be sufficiently wider than the recipient site to cover the root and provide a broad margin for attachment to the connective tissue border around the root. The interdental papilla at the distal end of the flap, or a major portion of it, should be included to secure the flap in the interproximal space between the donor and the recipient teeth.

Make a vertical incision along the gingival margin and interdental papilla and separate a flap consisting of epithelium and a thin layer of connective tissue, leaving the periosteum on the bone.

It is sometimes necessary to make a releasing incision to avoid tension on the base of the flap that can impair the circulation when the flap is moved (see Fig. 66-11, E). To do this, make a short oblique incision into the alveolar mucosa at the distal corner of the flap, pointing in the direction of the recipient site (see Fig. 66-11, F).

Step Three: Transfer the Flap. Slide the flap laterally onto the adjacent root, making sure that it lies flat and firm without excess tension on the base. Fix the flap to the adjacent gingiva and alveolar mucosa with interrupted sutures. A suspensory suture may be made around the involved tooth to prevent the flap from slipping apically (see Fig. 66-11, F).

Step Four. Protect the Flap and Donor Site. Cover the operative field with aluminum foil and a soft periodontal pack, extending it interdentally and onto the lingual surface to secure it. Remove the pack and sutures after 1 week (see Fig. 66-11, H).

VARIANT TECHNIQUES. There are many variations in the incisions for this operation. A common one is the use of converging oblique incisions over the recipient site and a vertical or oblique incision at the distal end of the donor site so that the transposed flap is slightly wider at its base. In another modification, the

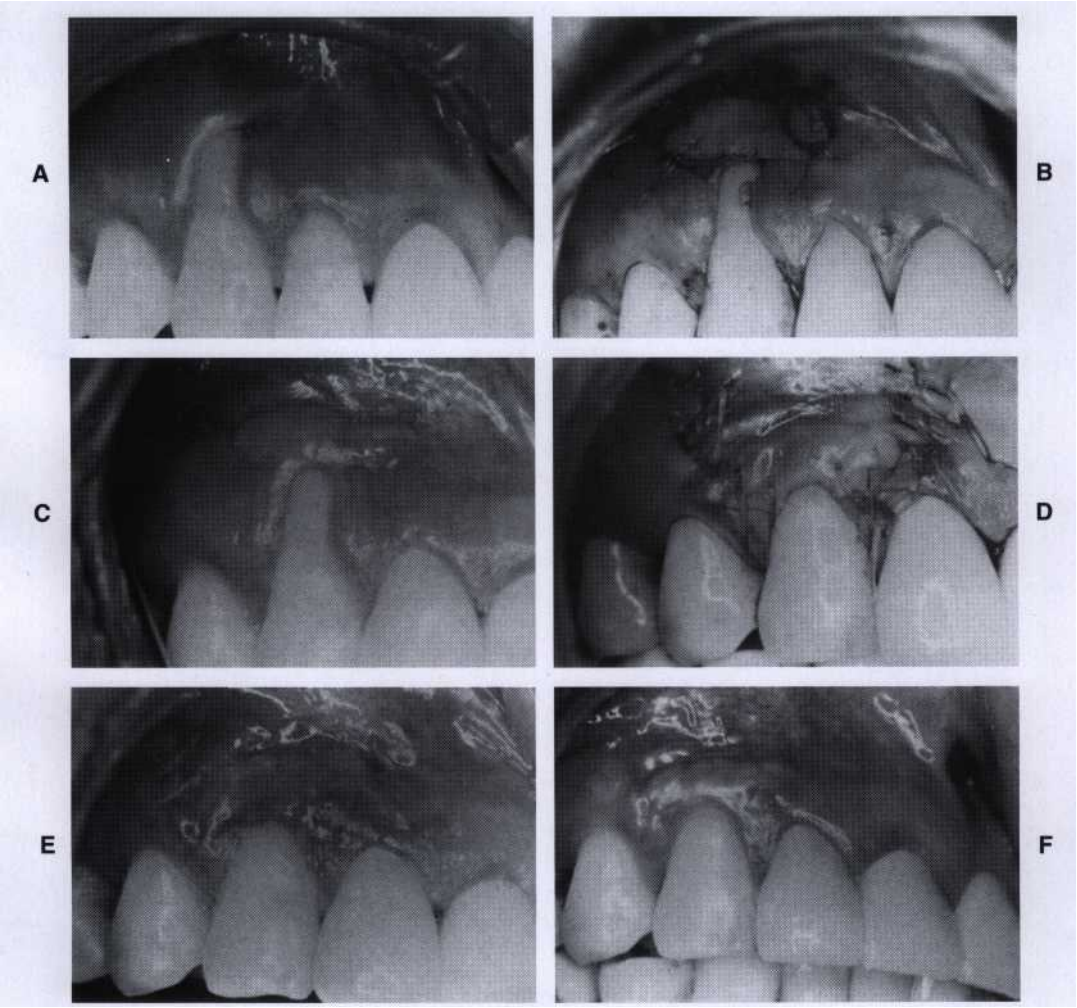

Fig. 66-12 Coronally positioned flap. A, Preoperative view. Note the recession and the lack of attached gingiva. B, After placement of a free gingival graft. C, Three months after placement of the graft. D, Flap including the graft, positioned coronally and sutured. E, After 2 weeks of healing. F, Six months later. Note the root coverage and the presence of attached gingiva. Compare with A. (Courtesy Dr. T. J. Han, Los Angeles, Calif.)

marginal attachment at the donor site is preserved to reduce the likelihood of recession and marginal bone resorption, but this requires a donor site with a wider zone of attached gingiva.

Sliding partial-thickness grafts from neighboring edentulous areas (pedicle grafts)[34] can be used to restore attached gingiva on teeth adjacent to edentulous spaces with denuded roots and a small, vestibular fornix, often complicated by tension from a frenum. The so-called double papilla flap attempts to cover roots denuded by isolated gingival defects with a flap formed by joining the contiguous halves of the adjacent interdental papillae.[18,39] Results with this technique are often poor because blood supply is impaired by suturing the two flaps over the root surface.

ACCOMPLISHMENTS OF THE PEDICLE AUTOGRAFT. Coverage of the exposed root surface with the sliding flap operation has been reported to be 60%,[32] 61%, and 72%.[61] Histologic studies in animals have reported 50% coverage.[17,79]

The extent to which the flap establishes a new attachment to the root with the formation of new cementum and the embedding of new connective tissue fibers has not been settled. New attachment on artificially denuded roots in experimental animals[79] and in some clinical studies in humans has been reported,[70,72] but it does not occur consistently enough to be predictable.

In the donor site, there is uneventful repair and restoration of gingival health and contours, with some loss of radicular bone (0.5 mm) and recession (1.5 mm) reported with full-thickness flaps.

Coronally Displaced Flap. The purpose of the coronally displaced flap operation is to create a split-thickness flap in the area apical to the denuded root and position it coronally to cover the root. Two techniques are available for this purpose.

FIRST TECHNIQUE FOR CORONALLY DISPLACED FLAP

Step One. With two vertical incisions, delineate the flap. These incisions should go beyond the mucogingival junction. Make an internal bevel incision from the gingival margin to the bottom of the pocket to eliminate the diseased pocket wall. Elevate a mucoperiosteal flap using careful sharp dissection.

Step Two. Scale and plane the root surface.

Step Three. Return the flap and suture it at a level coronal to the pretreatment position. Cover the area with a periodontal pack, which is removed along with the sutures after 1 week. The pack is replaced for an additional week if necessary.

VARIATIONS TO FIRST TECHNIQUE. Results with the coronally displaced flap technique are not often favorable[36] owing to the presence of insufficient keratinized gingiva. To solve this and increase the chance of success, a gingival extension operation with a free autogenous graft can be performed. (This technique was described earlier in this chapter.) This creates several millimeters of attached keratinized gingiva apical to the denuded root (Fig. 66-12, C).

Two months after this operation, a second-stage operation is performed, coronally positioning the flap that includes the free autogenous graft. The use of citric acid with a pH 1.0 for conditioning the root surface has been suggested[41] (see Fig. 66-12).

A significant degree of reduction in recession treated by this double-step operation was reported after 2 years by Bernimoulin and colleagues¢ and confirmed by other authors.[14,48,41]

SECOND TECHNIQUE FOR CORONALLY DISPLACED FLAP. Tarnow has described the semilunar coronally repositioned flap to cover denuded root surfaces." It is performed as follows (Fig. 66-13).

Step One. A semilunar incision is made following the curvature of the receded gingival margin and ending about 2 to 3 mm short of the tip of the papillae. This is very important, as the flap derives all of its blood supply from the papillary areas. The incision may have to reach the alveolar mucosa if the attached gingiva is narrow.

Step Two. Perform a split-thickness dissection coronally from the incision and connect it to an intrasulcular incision.

Step Three. The tissue will collapse coronally, covering the denuded root. It is then held in its new position for a few minutes with moist gauze; there is no need to suture or to pack.

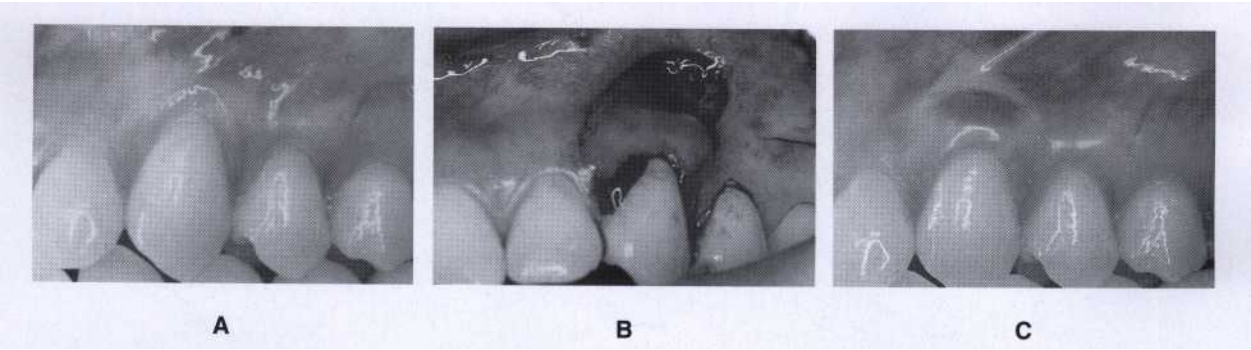

Fig. 66-13 Semilunar coronally positioned flap. A, Slight recession in facial of the upper left canine. B, After thorough scaling and root planing of the area, a semilunar incision is made and the tissue separated from the underlying bone. The flap collapses, covering the recession. C, Appearance after 7 weeks. Note coverage of the previous root denudation. (Courtesy Dr. Steven Kwan, Los Angeles, Calif.)

This technique is very simple and predictably provides 2 to 3 mm of root coverage. It can be performed on several adjoining teeth, but even though the incision may be continuous, extreme care should be exercised not to dissect the blood supply. The Tarnow technique is successful for the maxilla, particularly in covering root left exposed by the gingival margin receding from a recently placed crown margin. It is not recommended for mandibular teeth.

SUBEPITHELIAL CONNECTIVE TISSUE GRAFT (LANGER). This procedure is indicated for larger and multiple defects with good vestibular depth and gingival thickness to allow a split thickness flap to be elevated. Adjacent to the denuded root surface, the donor connective tissue is sandwiched between the split flap. It was described by Langer and Langer in 1985.[45] Similar approaches had been previously reported by Perez-Fernandez" and Raetzke.[60] The technique is as follows (Fig. 66-14).

Step One. Raise a partial-thickness flap with a horizontal incision 2 mm away from the tip of the papilla and two vertical incisions 1- to 2-mm away from the gingival margin of the adjoining teeth (Fig. 66-14). These incisions should extend at least one half to one tooth wider mesiodistally than the area of gingival reces-

Note apical portion of donor tissue is placed between the split flap. E, Recipient flap is closed.

Continued

sion. Extend the flap to the mucobuccal fold without perforations that could affect the blood supply.

Step Two. Thoroughly plane the root, reducing its convexity.

Step Three. Obtain a connective tissue graft from the palate by means of a horizontal incision 5 to 6 mm from the gingival margin of molars and premolars (Fig. 66-15). The connective tissue is carefully removed and all adipose and glandular tissue removed. The palatal wound is sutured in a primary closure.

Step Four. Place the connective tissue on the denuded root(s). Suture it with resorbable sutures to the periosteum.

Step Five. Cover the graft with the outer portion of the partial-thickness flap and suture it interdentally (see Fig. 66-14). At least one half to two thirds of the connective tissue graft must be covered by the flap for the exposed portion to survive over the denuded root.

Step Six. Cover the area with tinfoil and surgical pack. After 7 days, the dressing and sutures are removed. The esthetics are favorable with this technique since the donor tissue is connective tissue (see Fig. 66-15, F). The donor site heals by primary intention, with considerably less discomfort than after a free gingival graft.

A variant of the subepithelial connective tissue graft, called a *subpedicle connective tissue graft,* was described by Nelson in 1987.[51] This technique uses a pedicle over the connective tissue that covers the denuded root surface. Therefore the blood supply is increased over the donor tissue.

GUIDED TISSUE REGENERATION TECHNIQUE FOR ROOT COVERAGE. Pini-Prato and colleagues have described a technique based on the principle of guided tissue regeneration. Theoretically, guided tissue regeneration (GTR) should result in reconstruction of the attachment apparatus, along with coverage of the denuded root surface. This technique consists of the following steps (Figure 66-16).

Step One. A full-thickness flap is reflected to the mucogingival junction continuing as a partial-thickness flap 8 mm apical to the mucogingival junction.

Step Two. A microporous membrane is placed over the denuded root surface and the adjacent tissue. It is trimmed and adapted to the root surface and covers at least 2 mm of marginal periosteum.

Step Three. A suture is passed through the portion of the membrane that will cover the bone. This suture is knotted on the exterior and tied to bend the

membrane, creating a space between the root and the membrane. This space allows the growth of tissue beneath the membrane.

Step Four. The flap is then positioned coronally and sutured. Four weeks later, a small envelope flap is performed, and the membrane is carefully removed. The flap is then again positioned coronally to protect the growing tissue and sutured. One week later, these sutures are removed.

Tinti and colleagues74 have used titanium-reinforced membranes to create space beneath the membrane. Resorbable membranes have also been used to achieve root coverage. The inability to create space between the resorbable membrane and the denuded root, due to its softness, may present a problem, even though there is the advantage of not necessitating a second surgery.

Clinical studies comparing this technique with the coronally positioned flap have shown that the GTR technique is better when the recession is greater than 4.98 mm apico-oronally.59 Histologically, one case reported 3.66 mm of new connective tissue attachment associated with 2.48 mm of new cementum and 1.84 mm of bone growth .z°

POUCH AND TUNNEL TECHNIQUE. To minimize incisions and reflection of flaps and to provide abundant blood supply to the donor tissue, the placement of subepithelial donor connective tissue into pouches beneath papillary tunnels allows for intimate contact of donor tissue to the recipient site. s' After positioning the graft, the coronal placement of the recessed gingival margins completely covers the donor tissue. Therefore the esthetic result is excellent. This technique is especially effective for the maxillary anterior area where vestibular depth is adequate and there is good gingival thickness (Fig. 66-17). One of the advantages to this technique is the thickening of the gingival margin

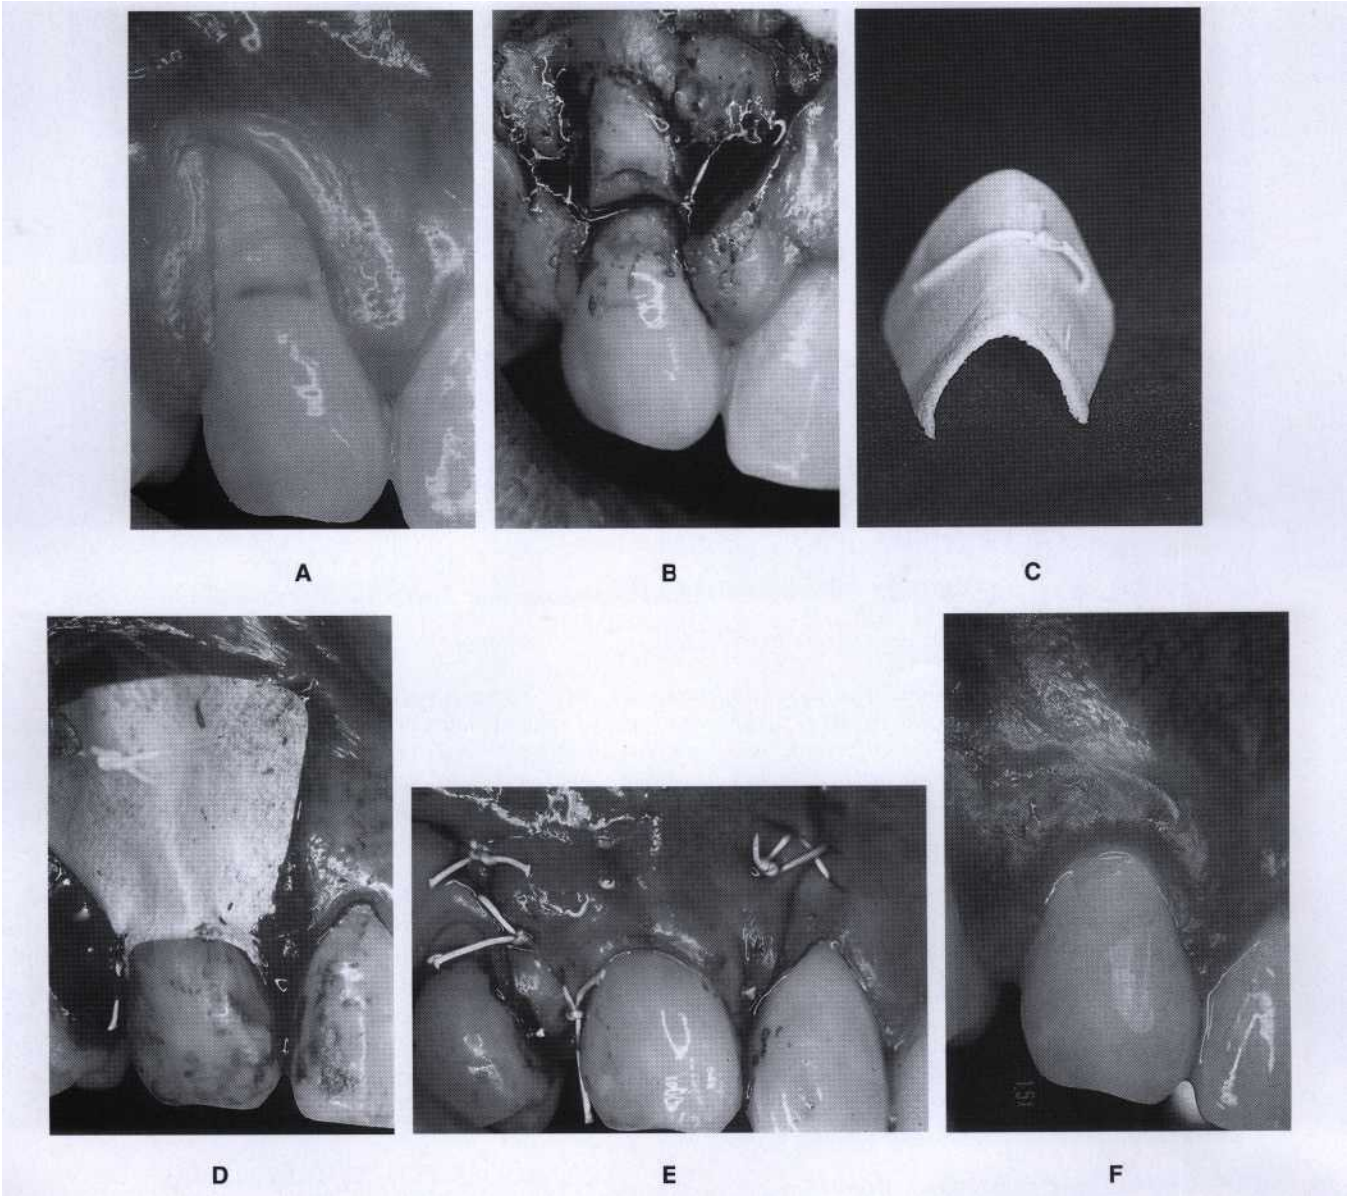

Fig. 66-16 Guided tissue regeneration technique for root coverage. A, Marked recession in the upper right cuspid. B, Incisions made and flap elevated. C, Membrane trimmed and bent with suture. D, Membrane placed on exposed root and covering bone margin. E, Sutures in place. F, After healing, the root is completely covered. (Courtesy Dr. Carlo Tinti, Milano, Italy.)

after healing. The thicker gingival margin is more stable to allow for the possibility of "creeping reattachment" of the gingival margin. The use of small, contoured blades enables the surgeon to incise and split the gingival tissues to create the recipient pouches and tunnels (Fig. 66-18). This technique consists of the following steps (see Fig. 66-17).

Step One. Using a no. 15C or 12D blade, a sulcular incision is made around the teeth adjacent to the recession. This incision separates the junctional epithelium and the connective tissue attachment from the root.

Step Two. Using either a curette or a small blade such as the no. 15C, a tunnel is created beneath the adjacent buccal papilla, into which the connective tissue is placed.

Step Three. A split-thickness pouch is created apical to the papilla, which has been tunneled, and the adjacent radicular surface. This pouch may extend 10- to 12-mm apical to the recessed gingival margin and papilla and 6- to 8-mm mesial and distal to the denuded root surface.

Step Four. The size of the pouch that includes the area of the denuded root surface is measured so an equivalent size connective tissue donor can be procured from the palate.

Step Five. Using sutures, curettes, and elevators, the connective tissue is placed under the pouch and tunnel with a portion covering the denuded root surface.

Step Six. The mesial and distal ends of the donor tissue are secured by gut sutures. The gingival margin of

the flap is coronally placed and secured by horizontal mattress sutures that extend over the contact of the two adjacent teeth. If the teeth are not in contact, a small amount of composite material may be placed temporarily between the two teeth to allow the placement of the suture over the closed contact.

Step Seven. Other holding sutures are placed through the overlying gingival tissue and donor tissue to the underlying periosteum to secure and stabilize the donor tissue beneath the gingiva.

Step Eight. A periodontal dressing is used to cover the surgical site.

TECHNIQUES TO DEEPEN THE VESTIBULE

The presence of adequate vestibular depth is important for both oral hygiene and retention of prosthetic appliances. Numerous surgical techniques have been proposed to accomplish this objective. The classic clinical studies in the early 1960s by Bohannan[7,8,9] indicated that deepening of the vestibule by nonfree graft procedures were not successful when evaluated years later. Predictable deepening of the vestibule can only be accomplished by the use of free autogenous grafts and its variants. Discussion on free grafts are covered in this chapter.

TECHNIQUES FOR THE REMOVAL OF THE FRENUM

A frenum is a fold of mucous membrane, usually with enclosed muscle fibers, that attaches the lips and cheeks to the alveolar mucosa and/or gingiva and underlying periosteum. A frenum becomes a problem if the attachment is too close to the marginal gingiva. Tension on the frenum may pull the gingival margin away from the tooth. This condition may be conducive to plaque accumulation and inhibit proper brushing of the teeth.

Frenectomy or Frenotomy

The terms *frenectomy* and *frenotomy* signify operations that differ in degree. Frenectomy is complete removal of the frenum, including its attachment to underlying bone, and may be required in the correction of an abnormal diastema between maxillary central incisors. Frenotomy is the incision of the frenum. Both procedures are used, but frenotomy generally suffices for periodontal purposes-that is, relocating the frenal attachment so as to create a zone of attached gingiva between the gingival

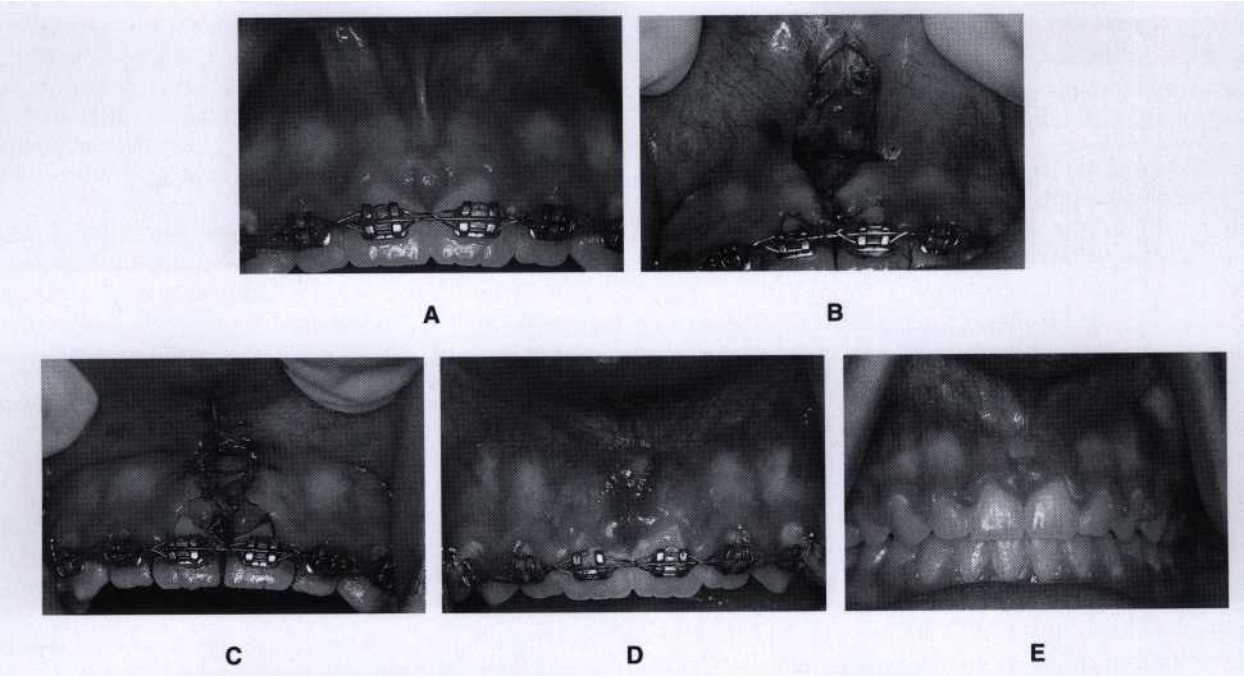

Fig. 66-19 Removal of the frenum. A, Preoperative view of frenum between the two maxillary central incisors. B, Removal of the frenum from both the lip and gingiva. C, The site is sutured after it is placed over the wound. D, Postoperative view after two weeks. E, Postoperative view after three months.

margin and the frenum. Frenectomy and frenotomy are usually performed in conjunction with other periodontal treatment procedures but occasionally are done as separate operations. Frenal problems occur most often on the facial surface between the maxillary and mandibular central incisors and in the canine and premolar areas[78] (see Fig. 66-1, D). They occur less often on the lingual surface of the mandible.

Technique for the Removal of the Frenum. If the vestibule is deep enough, the operation is confined to the frenum. It is often necessary to deepen the vestibule to provide space for the repositioned frenum. This is accomplished as follows (Fig. 66-19):

1. After anesthetizing the area, engage the frenum with a hemostat inserted to the depth of the vestibule.
2. Incise along the upper surface of the hemostat, extending beyond the tip.
3. Make a similar incision along the undersurface of the hemostat.
4. Remove the triangular resected portion of the frenum with the hemostat. This exposes the underlying brushlike fibrous attachment to the bone.
5. Make a horizontal incision, separating the fibers, and bluntly dissect to the bone.
6. If necessary, extend the incisions laterally and suture the labial mucosa to the apical periosteum. Sometimes the area is covered with a free gingival or connective tissue graft.
7. Clean the field of operation and pack with gauze sponges until bleeding stops.
8. Cover the area with dry aluminum foil and apply the periodontal pack.
9. Remove the pack after 2 weeks and repack if necessary. One month is usually required for the formation of an intact mucosa with the frenum attached in its new position.

High frenal attachments on the lingual surface are uncommon. To correct these without involving the structures in the floor of the mouth, approximately 2 mm of the attachment is separated from the mucosa with a periodontal knife at weekly intervals until the desired level is reached. The area is covered with a periodontal pack in the intervals between treatments.

CRITERIA FOR SELECTION OF TECHNIQUES

Different techniques have been presented for solving mucogingival problems outlined in this chapter. The proper selection of the numerous techniques must be based on the predictability of success which, in turn, is based on the following criteria (see also Box 66-1):

1. *Surgical site free of plaque, calculus, and inflammation:* Periodontal plastic surgical procedures should be undertaken in a plaque- and inflammation-free environment to enable the clinician to manage gingival tissue that is firm. Meticulous, precise incisions and flap reflection cannot be achieved when the tissue is inflamed and edematous. Careful and thorough scaling, root planing, and meticulous plaque removal by the patient must be accomplished before any surgical procedure.

BOX 66-1

Criteria for Selection of Techniques for Solving Mucogingival Problems

Surgical site free of plaque, calculus, and inflammation
Adequate blood supply to the donor tissue
Anatomy of the recipient and donor site
Stability of the grafted tissue to the recipient site
Minimal trauma to the surgical site

2. *Adequate blood supply: To* obtain the maximum amount of blood supply to the donor tissue, gingival augmentation apical to the area of recession will provide a better blood supply than coronal augmentation, since the recipient site is entirely periosteal tissue. Root coverage procedures present a portion of the recipient site (denuded root surface) without blood supply. Therefore if esthetics is not a factor, gingival augmentation apical to the recession may be more predictable. A pedicle-displaced flap has a better blood supply than a free graft, with the base of the flap intact. Therefore, in root coverage, if the anatomy is favorable, the pedicle flap or any of its variants may be the best procedure.

   The subepithelial connective tissue graft (Langer) and the pouch and tunnel techniques use a split flap with the connective tissue sandwiched in between the flap. This flap design maximizes the blood supply to the donor tissue. If large areas require root coverage, these sandwich-type recipient sites provide the best flap design for blood supply.

3. *Anatomy of the recipient and donor sites:* The anatomy of the recipient and donor sites are an important consideration in selecting the proper technique. The presence or absence of vestibular depth is an important anatomic criteria at the recipient site for gingival augmentation. If gingival augmentation is indicated apical to the area of recession, there must be adequate vestibular depth apical to the recessed gingival margin to provide space for either a free or pedicle graft. If a vestibule is necessary, only a free graft can accomplish this objective apical to the recession.

   Mucogingival techniques such as free gingival grafts and free connective tissue grafts can be used to create vestibular depth and widen the zone of attached gingiva. Other techniques require vestibular depth to be present before the surgery. These procedures include pedicle grafts (lateral and coronal); subepithelial connective tissue graft (Langer); and pouch and tunnel procedures.

   The availability of donor tissue is another anatomic factor that must be considered. Pedicle displacement of tissue necessitates the presence of an adjacent donor site that presents gingival thickness and width. Palatal tissue thickness is also necessary for the connective tissue donor autograft. Gingival thickness is also required at the recipient site for techniques using split thickness, sandwich-type flap, or the pouch and tunnel techniques.

4. Stability of the grafted tissue to the recipient site: Good communication of the blood vessels from the grafted donor tissue to the recipient site requires a stable environment. This necessitates sutures that stabilize the donor tissue firmly against the recipient site. The least amount of sutures and maximum stability should be achieved.

5. Minimal trauma to the surgical site: Like all surgical procedures, periodontal plastic surgery is based on the meticulous, delicate, and precise management of **the oral tissues.** Unnecessary tissue trauma due to poor incisions, flap perforations, tears, traumatic and excessive placement of sutures can lead to tissue necrosis. The selection of proper instruments, needles, and sutures are mandatory to minimize tissue trauma. The use of sharp, contoured blades (see Fig. 66-18); smaller diameter needles; and resorbable, monofilament sutures are all important factors in achieving atraumatic surgery.

SUMMARY

New techniques are constantly being developed and are slowly incorporated into periodontal practice. The practitioner should be aware that, at times, new methods are published without adequate clinical research to ensure the predictability of the results and the extent to which the techniques may benefit the patient. Critical analysis of newly presented techniques should guide our constant evolution toward better clinical methods.

CHAPTER OUTLINE

MAGNIFICATION SYSTEMS
Magnifying Loupes
Magnification Range of Surgical Loupes
The Operating Microscope
PERIODONTAL MICROSURGERY
Root Preparation
SUMMARY

The use of magnification in periodontics is not an isolated development. It is part of a broader trend in medicine and dentistry toward the application of minimally invasive techniques for procedures that previously required extensive surgical incisions [2,3,10,13] *Microsurgery is* defined as a refinement in operative technique by which visual acuity is enhanced through the use of the surgical operating microscope. It is a methodology, through which surgical techniques are modified to accommodate the improved motor coordination made possible through magnification. [12] In addition to clinical microsurgery, magnification in periodontics may be applied to diagnostic and nonsurgical procedures as a result of the improved visual acuity and motor coordination.

MAGNIFICATION SYSTEMS

A variety of simple and complex magnification systems are available to dentists, ranging from simple loupes to prism telescopic loupes and surgical microscopes. Each magnification system has its specific advantages and limitations. Although magnification improves the accuracy of clinical and diagnostic skills, it requires an understanding of optical principles that govern all magnification systems. The assumption that more magnification is better must always be weighed against a decrease in field of view and depth of focus that can occur as magnification increases. This is a problem more common with dental loops than with surgical operating microscopes.

Magnifying Loupes

Dental loupes are by far the most common system of optical magnification used in periodontics. Loupes are fundamentally two monocular telescopes with side-by-side lenses converged to focus on the operative field. The magnified image they form has stereoscopic properties by virtue of their convergence. A convergent lens optical system is also called a *Keplerian optical system.*

Although dental loupes are widely used, they have a considerable disadvantage. The clinician's eyes must converge to view the operative field. This may result in eyestrain, fatigue, and even pathologic vision changes, especially after prolonged use of poorly fitted loupes.

Three types of Keplerian loupes are commonly used in periodontics: simple or single-element loupes, compound loupes, and prism telescopic loupes. Each type may differ widely in optical sophistication and individual design.

Simple Loupes. Simple loupes consist of a pair of single meniscus lenses (Fig. 67-1). Simple loupes are primitive magnifiers with limited capabilities. Each lens is limited to just two refracting surfaces. Only increasing their lens diameter or thickness can increase their magnification. Size and weight limitations make simple loupes impractical for magnification beyond 1.5 diameters. Another disadvantage of simple loupes is that they are highly affected by spherical and chromatic aberration, which distorts the shape and color of, objects being viewed.

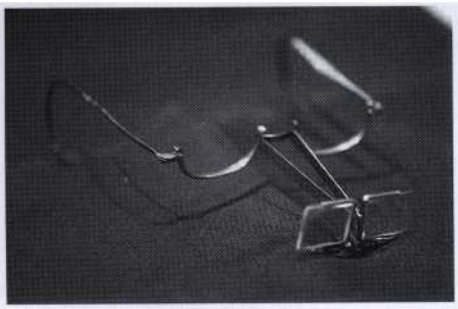

Fig. 67-1 Simple loupes.

Fig. 67-3 Eyeglass-mounted prism loupes.

Fig. 67-2 Compound loupes.

Fig. 67-4 Coaxial lighted prism loupes.

Compound Loupes. Compound loupes use multi-element lenses with intervening air spaces to gain additional refracting surfaces (Fig. 67-2). This allows increased magnification with more favorable working distance and depth of field. Compound loupes can be adjusted to some clinical needs without excessive increase in size or weight.

In addition to offering improved optical performance, compound lenses can be achromatic. This is an optical feature that clinicians should always choose when selecting magnifying loupes. Achromatic lenses consist of two glass lenses, joined together with clear resin. The specific density of each lens counteracts the chromatic aberration of its paired lens to produce a color-correct image. Multi-element compound loupes become optically inefficient at magnifications above 3.0 diameters.

Prism Telescopic Loupes. The most advanced type of loupe magnification currently available is the prism telescopic loupe. Such loupes employ Schmidt or rooftop prisms to lengthen the light path through a series of switchback mirror reflections within the lens elements. This arrangement literally folds light so that the barrel of the telescopic loupes can be shortened. Prism loupes produce better magnification, wider depths of field, longer working distances, and larger fields of view than other types of loupes. The barrels of prism loupes are short enough to be mounted on either eyeglass frames (Fig. 67-3) or headbands. However, the increased weight of prism telescopic loupes with magnification above 3x makes headband mounting more comfortable and stable than eyeglass frame mounting. Recent innovations in prism telescopic loupes include coaxial fiberoptic lighting incorporated in the lens elements to improve illumination (Fig. 67-4).

Magnification Range of Surgical Loupes

Dental loupes provide a limited range of magnification (1.5x to 10x). Those delivering magnification of less than 2.5X are usually inadequate for the visual acuity necessary for periodontal microsurgery. Those providing magnification of more than 4.5X are awkward to use because of their small field of view, shallow depth of focus, and excessive weight. The latter makes it quite difficult for a surgeon to maintain a stable visual field.

For some periodontal procedures, prism telescopic loupes with magnification of 4x provide an adequate combination of magnification, field of view, and depth of focus. However, the surgical operating microscope provides much higher magnification and superior optical properties than any of the loupe optical systems previously discussed.

The Operating Microscope

The surgical operating microscope provides superior magnification and better optical performance compared with dental loupes (Fig. 67-5). Although the microscope is expensive, it is durable and can withstand an entire clinical career. An operating microscope requires a period of adjustment to reach clinical proficiency, but it offers far better clinical performance and versatility than loupes. Operating microscopes designed for use in dentistry

employ Galilean optical principles' and have binocular eyepieces joined by offsetting prisms with parallel optical axes. Galilean optics allows stereoscopic viewing of the operative field without eye convergence. This positions the eyes as if they were focused on infinity to permit a relaxed viewing of the operative field without eyestrain or fatigue. The operating microscope incorporates fully coated optics with achromatic lenses to provide the highest optical resolution with the most efficient illumination.

Perhaps the greatest advantage of the surgical operating microscope is its ability allow the dentist to easily change working magnification to a level appropriate for the clinical task at hands Operating microscopes have a rotating variable magnification element that easily varies magnification to match the immediate surgical demands. Some operating microscopes incorporate electronic foot-controlled focus and magnification for further convenience. Because the optical elements of surgical microscopes are more sophisticated than those found in loupes, depth-of-focus and field-of-view characteristics are quite enhanced.

The periodontal surgeon must establish adequate working distance between the surgical field and the microscope objective lens. This permits the surgical assistant to retract tissues and to irrigate or evacuate the surgical site. Such assistant aided control of surgical access is essential for microsurgical visibility. Assistant eyepiece attachments are available for all surgical microscopes and can greatly aid the progress of microsurgical procedures. Surgical microscopes are available with objective lenses with various working distances. The useful range in dentistry is 250 to 350 mm. Because operating with indirect mirror vision adds 100 to 150 mm to the working distance, a ready means of changing working distances is valuable. Quick-change objective lenses are available for many surgical microscopes.

For practical use in periodontics, the surgical microscope must have both maneuverability and stability. Microscope mountings are available for ceiling, wall, or floor. Inclining eyepieces also lend flexibility to the clinical use of the surgical microscope in periodontics. Maneuverability must always be sufficient to meet the clinical requirements for visual access to the various posterior regions of the oral cavity and the anatomic tissues dealt with during periodontal microsurgery. Optical performance of most microscope lenses is almost identical. Maneuverability is, therefore, more important than optical configuration in choosing an appropriate microscope for periodontal microsurgery procedures.

Illumination of the microsurgical field is an extremely important consideration. Periodontists are accustomed to lateral illumination from side-mounted dental lights. Clinicians who work with loupes often require a headlamp to compensate for the decreased light-gathering ability of loupes compared with normal vision. Coaxial fiberoptic illumination had been a major advantage of the operating microscope over surgical loupes. Coaxial lighting positions the light source exactly parallel to the microscope's optical axis. With coaxial lighting, no shadows are produced. The surgeon can view perfectly the deepest reaches of the oral cavity, including into subgingival pockets and angular bony defects. Definitive visualization of root surface deposits and irregularities is only possible at magnification levels provided by a surgical microscope. Through the microscope, surgeons can view normal and abnormal periodontal anatomy never before possible. Clinical decisions can be made based on certain visual knowledge of altered or normal anatomy rather than based on blind educated guesses.

Documentation of periodontal procedures has become increasingly important for dental-legal reasons as well as for patient and professional education. The surgical operating microscope is ideal for documenting periodontal pathology and procedures of all types; 35-mm slides can easily be produced using a beam splitter camera attachment (Fig. 67-6). With a foot-operated shutter control, the surgeon can compose the photographic field as the procedure unfolds without interrupting the surgery. In addition, the photographic slide represents the surgical field exactly as seen by the surgeon, as opposed to a photographer's view produced over the surgeon's shoulder as he or she works. Excellent video documentation is also available through the operating microscope using a video beam splitter attachment. High-resolution cameras with video and slide printers are currently replacing 35-mm camera photography in many microsurgical disciplines. High-resolution digital video cameras bring new capabilities for live or recorded video of periodontal procedures for educational purposes.

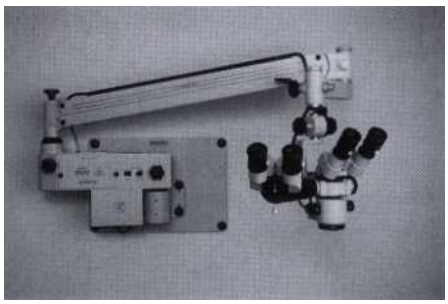

Fig. 67-5 Surgical operating microscope.

Fig. 67-6 Microscope camera and beam splitter.

PERIODONTAL MICROSURGERY

In recent years periodontics has seen increasing employment of procedures requiring progressively more intricate surgical skills. Regenerative and resective surgical procedures, periodontal plastic surgery, and dental implants all demand clinical performance levels that challenge the technical motor skills of periodontal surgeons beyond a range possible with unassisted vision.

Periodontal microsurgery introduces the potential for a less invasive surgical approach in periodontics. This is exemplified by a lessened need for vertical releasing incisions and smaller surgical sites. Periodontal surgeons, like other microsurgeons, continue to be surprised by the extent to which reduced incision size and surgical retraction are directly related to reduced postoperative pain and rapid healing."

Root Preparation

The importance of root debridement is recognized universally as an essential component of periodontal therapy.[4,7.8,11] Research in clinical dentistry has shown that magnification-enhanced vision more ideally accomplishes the established clinical goals of endodontic and restorative dentistry. In periodontics, studies demonstrate that root debridement, performed without magnification, was incomplete. When debrided roots were examined with the aid of a microscope, substantial deposits remained. It may be inferred that magnification-enhanced vision in periodontics may permit more definitive root debridement.

Among the primary aims of periodontal surgery is visual access to the root surface for plaque and calculus removal and for removing pathologically altered tooth structure. Magnification greatly improves the surgeon's ability to create a clean, smooth root surface (Fig. 67-7). The root surface represents one opposing edge of the periodontal wound. Root planing is, therefore, analogous to establishing a clean, right-angled, soft tissue incision. Magnification permits preparation of both hard and soft tissue wound surfaces so they may be joined together according to the commonly held microsurgical principle of butt-joint wound approximation. This encourages primary wound healing and enhanced periodontal regeneration. Wound healing studies show epithelial anastomosis of microsurgically joined surgical wounds in animals within 48 hours .[6-14]

Surgery Under Magnification. Viewing periodontal surgery under magnification cannot help but ¡mpress the periodontal surgeon with the coarseness of conventional surgical manipulation. What appears to the unaided eye as gentle handling is revealed, under magnification, as gross crushing and tearing of delicate tissues. Periodontists have always attempted to treat the surgical site atraumatically and to achieve primary wound closure. However, the limits of normal vision dictate the extent to which this goal was possible. Periodontal microsurgery is the natural transition from conventional surgical principles to a surgical ethic in which the microscope is employed to permit more accurate and atraumatic handling tissues to enhance wound healing.

Microsurgical Instruments. In addition to the use of magnification and reliance on atraumatic technique, microsurgery entails the use of specially constructed microsurgical instruments designed specifically to minimize trauma. An important characteristic of microsurgical instruments is their ability to create clean incisions that prepare wounds for healing by primary intention. Microsurgical incisions are established at a 90-degree angle to the surface using ophthalmic microsurgical scalpels (Fig. 67-8). Microscopy permits easy identification of ragged wound edges for trimming and freshening. For primary wound closure, microsutures in the range of 6-0 to 9-0 are needed to approximate the wound edges (Fig. 67-9). Microsurgical wound apposition minimizes gaps or voids at the wound edges. This encourages rapid healing with less postoperative inflammation and with less pain.

Figures 67-10 through 67-15 illustrate periodontal surgery cases treated using microsurgical techniques.

Ergonomics. The ergonomics of hand position and body posture is closely related to the improved motor skills made possible by a microsurgical approach to therapy. Studies show that motor coordination is greatly improved when surgeons use microsurgical instruments specifically designed to employ a precision grip of the hand. Microsurgical instruments are circular in cross

section to permit precise rotational movements. They are manufactured of titanium because of its strength, lightness, and nonmagnetizing characteristics. The various postural and ergonomic ways of reducing unwanted hand movements results in more precise surgeries and greatly reduces surgical fatigue and the development of spinal and occupational pathology. In the long term, this beneficial ergonomic aspect of microscopy may be the most influential in its adoption by the dental profession at large.

SUMMARY

Microsurgery offers new possibilities for periodontal surgery that can improve therapeutic results for a variety of procedures. Its benefits include improved cosmetics, rapid healing, minimal discomfort, and enhanced patient acceptance. Periodontics of the future will see increasing use of magnification in all areas of practice, including implantology.

Biologic Aspects of Dental Implants

George W. Bernard, Fermin A. Carranza, and Sascha A. Jovanovic

CHAPTER OUTLINE

BIOMATERIALS
- **Metals and Metal Alloys**
- **Ceramics and Carbons**
- **Polymers and Composites**

THE PERIIMPLANT MUCOSA
THE IMPLANT-BONE INTERFACE

Developing artificial replacements for missing teeth has been an elusive goal for more than 1500 years. A fine, dark stone, shaped like a tooth, was found implanted in a Mayan skull in Central America from 600 AD, and there are reports of implant attempts in ancient Egypt and the Middle East. Interest in developing artificial teeth anchored to the jaws has continued to the present.

The present surge in the use of implants was initiated in 1952 by Branemark, who conducted extensive experimental and clinical studies. Branemark and associates described the relationship between titanium and bone, for which they coined the term *osseointegration,* as the "direct structural and functional connection between ordered, living bone and the surface of a load-carrying implant."

BIOMATERIALS

Many biologically compatible materials can be used for the manufacturing of implants. Currently, interest is centered on metals and metal alloys, but research continues with biomaterials such as ceramics and carbons, as well as polymers and composites.

Metals and Metal Alloys

Metallic biomaterials have been extensively used, particularly titanium and alloys of titanium, aluminum, and vanadium. Early work also tested combinations of cobalt, chromium, and molybdenum, as well as iron, chromium, and nickel. Precious metals such as gold and platinum and their alloys are less frequently used. The most widely used dental implant material is titanium and its alloy; the most available clinical and experimental data concern this material.

Ceramics and Carbons

This group includes aluminum oxide (alumina and sapphire) ceramics, carbon, and carbon-silicon compounds.[32] Hydroxyapatite has been proposed as a solid material, and as a surface coating, it is also widely used. Because coatings are used on load-bearing metals, there

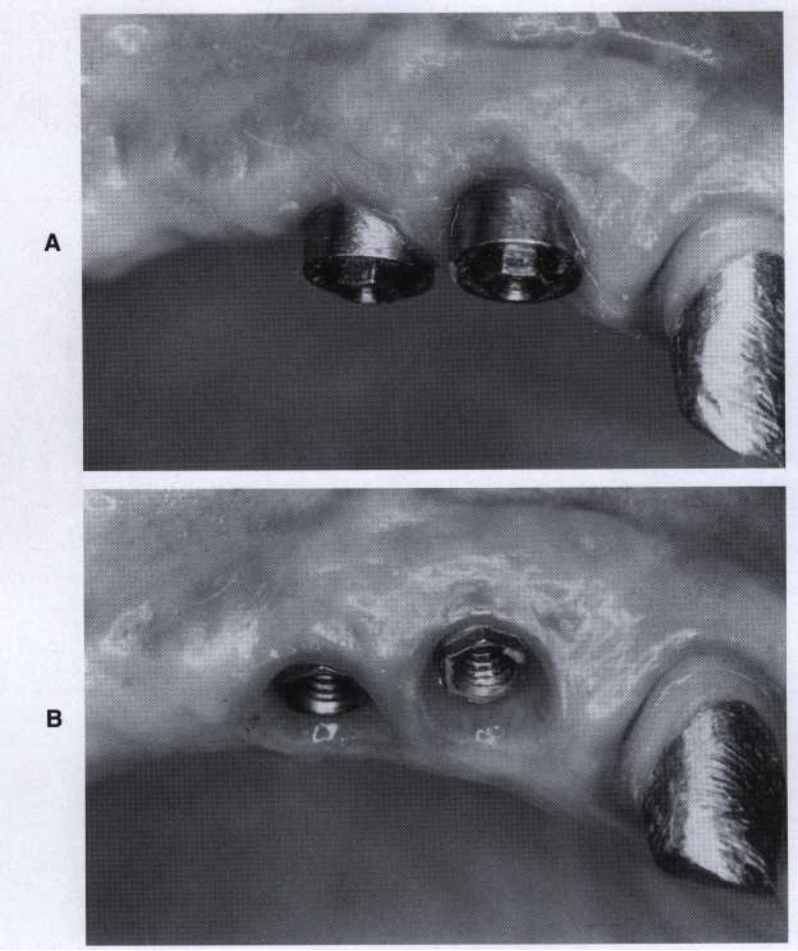

Fig. 68-1 A, Clinically normal gingival mucosa next to two implants. B, Normal epithelium lining the implant after removal of the cover screw.

is a need for high interfacial shear strength and resistance to resorption.

Polymers and Composites

These include cross-linked polymers such as polymethylmethacrylate, silicone rubber, and polyethylene. They are not in general use at present, but technologic developments may bring an increased use of these materials in the future.[34,31]

THE PERIIMPLANT MUCOSA

The mucosal tissues around intraosseous implants form a tightly adherent band consisting of a dense collagenous lamina propria covered by stratified squamous keratinizing epithelium (Figs. 68-1 and 68-2).[26] In general, the term biologic *width/height is* being used when describing the soft tissue dimensions around implants.

The implant-epithelium junction is analogous to the junctional epithelium around natural teeth, in that the epithelial cells attach to the titanium implant by means of hemidesmosomes and a basal lamina. Evidence for an adhesive junctional epithelium attachment to ceramic implants has also been presented.[32,33] This evidence supports the concept that a viable biologic seal can exist between the epithelial cells and the implants.

A sulcus forms around the implant lined with a sulcular epithelium. The depth of a normal, noninflamed or minimally inflamed sulcus around an intraosseous implant has not yet been accurately determined but is assumed to be between 1.5 and 2.0 mm.[7,14,17,31] Studies on sulcus and pocket depth around normal teeth have determined that the penetration of the probe, particularly if inflammation is present, will be stopped by the first attached collagen fibers. Because these are not present around implants, the probe would be expected to attain deeper measurements. Bleeding on gentle probing rarely occurs in healthy mucosal tissues around implants. The presence of bleeding indicates the presence of plaque-induced inflammation, although false-negative results have been reported.[31]

The sulcus around an implant is lined with sulcular epithelium that is continuous apically with the junctional epithelium. Normal tissues around implants have an

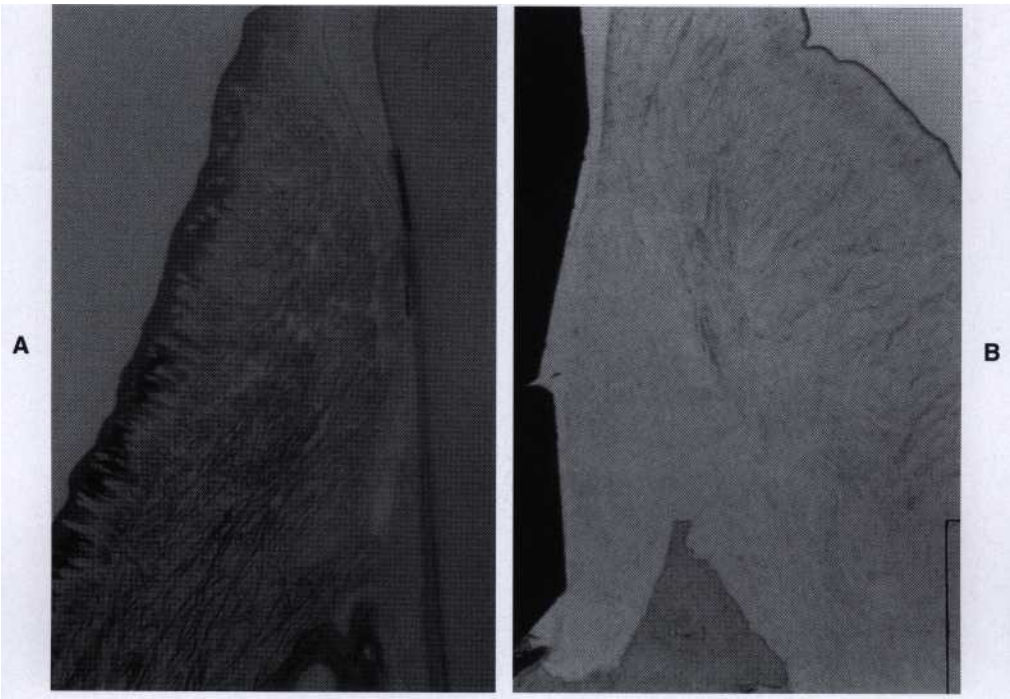

Fig. 68-2 A, Micrograph showing normal periodontium surrounding a tooth. B, Micrograph showing normal periimplant tissues.

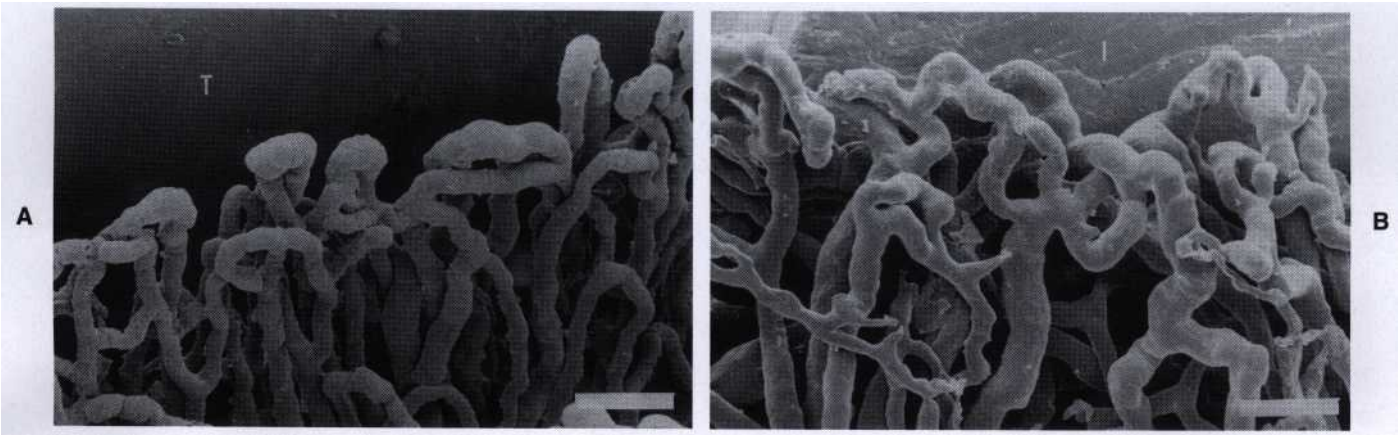

Fig. 68-3 Microvascular topography surrounding a tooth (A) and an implant (B). Bar = 5 tkm. (Courtesy Drs. N. Selliseth and K. Selvig; Bergen, Norway.)

intact epithelial lining and about the same number of inflammatory cells as are found around a nature tooth. [1,6,29]

Capillary loops in the connective tissue under the junctional and the sulcular epithelia appear to be anatomically similar to those found in the normal periodontium (Fig. 68-3).[6,39] Some investigators, however, have found reduced vascularity close to the implant surface compared with that around teeth and are of the opinion that this may make periimplant tissues more vulnerable to pathogenic insults.[14,31]

Although some investigators have suggested that the amount of inflammation is not affected by the quality of periimplant soft tissues, others have found an increased chance of periimplant mucositis in patients without keratinized mucosa. [7,33,43]

Collagen fibers are nonattached and run parallel to the implant surface, owing to the lack of cementum. This is an important difference between periimplant and periodontal tissues.[6] However, some reports have suggested that microscopic irregularities and porosities like those found on plasma-sprayed titanium surfaces may favor the appearance of fibers oriented perpendicularly to the implant surface' [1,14,37] and in turn, orient fibroblasts in specific directions."

The marginal portion of the periimplant mucosa contains significantly more collagen and fewer fibroblasts

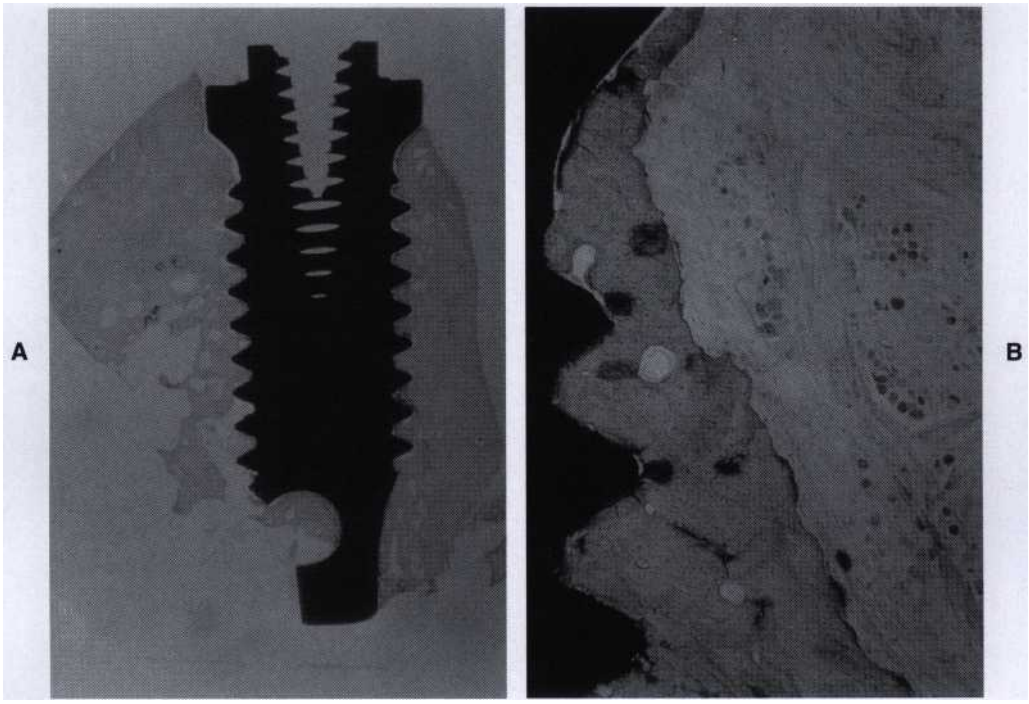

Fig. 68-4 Periimplant supporting tissues around an implant at the light microscopy level. A, Topographic view. B, Higher magnification showing direct apposition of bone and implant.

than the corresponding gingival tissue, which may indicate that tissue turnover in the periimplant mucosa is less rapid than that in the gingva[6]

IHE IMPLANT-BONE INTERFACE

The relationship between endosseous implants and bone consists of one of two mechanisms: osseointegration, when the bone is in intimate but not ultrastructural contact with the implant, or fibrosseous integration, in which soft tissues such as fibers and/or cells, are interposed between the two surfaces.

The proponents of the fibrosseous system of implant retention suggest that the presence of a dense collagenous tissue between implant and bone may act as an osteogenic membrane .[42] However, there is no wide support for this concept.

The osseointegration concept proposed by Branemark et all and called *functional ankylosis* by Schroeder" states that there is an absence of connective tissue or any nonbone tissue in the interface between the implant and the bone. A more accurate term, *microinterlock, is* used in orthopedic implantology, where tissue and implant are juxtaposed, providing a bioinert fixation with surface porosities, grooves, or beads." It is important to note that *osseointegration* refers to the direct contact of bone and implant at the *light microscope level* (Fig 68-4). Furthermore, even with this definition, osseointegration never occurs on 100% of the implant surface. Successful cases have between 30% and 95% of the implant surface, as measured by light microscopy, in contact with bone.

Under the light microscope, bone appears to be in direct contact with the implant. By virtue of its excellent regenerative potential, bone is seen to grow around the ridges and grooves of screw-type implants and through the openings of blade- and hollow cylinder-type implants. Remodeling of bone occurs constantly as part of the normal physiology of bone and continues to occur after the implant has been placed.

Histologic sections of the bone-implant interface, however, are usually thick (20 to 150 Am) and do not permit an accurate view of the interface. These thick sections have been the primary standard of viewing the interface and may have led to the premature definition of the interface as an osteointegrative one.

Although some ultrastructural investigations have reported mineralized matrix in direct contact with titanium without the presence of any amorphous layer others have reported the interposition of connective tissue.[19,35,38]

Reports using conventional transmission and high-voltage electron microscopy have contradicted the direct bone-to-implant results. These studies suggested a close approximation of calcified tissue to the implant surface but found no conclusive evidence of any molecular bonds between the metal oxide surface of titanium and the adjacent bone .[41] An amorphous, cell-free layer, ranging in width from 20 to 1000 nm and composed of glycosaminoglycans and proteoglycans, has been reported to be interposed between bone and titanium .[38] There may also be a lamina limitans-like line[31] that is 50 nm thick and a layer of noncalcified collagen adjacent to the titanium surface. Complete mineralization is seen only 2000 nm (2 Am) from the metal. [38]

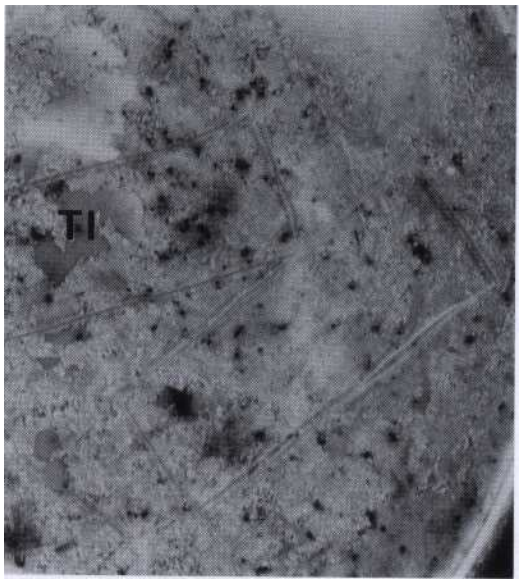

Fig. 68-5 Petri dish with many dark bone colonies. Evaporated titanium (TI) in areas denuded of cells. Original magnification X].

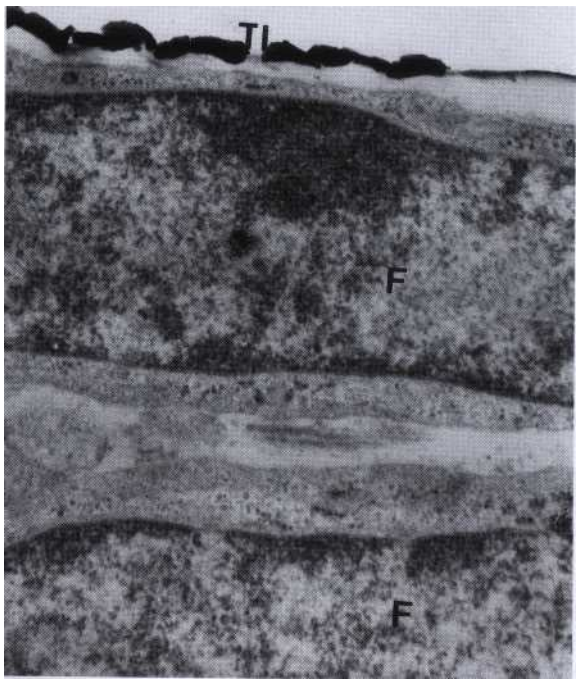

Fig. 68-6 Transmission electron micrograph of the interface of bone colonies on evaporated titanium (TI). Portions of two fibroblasts (F) are seen with a clear zone between the innermost cells and the titanium. Original magnification x20,000.

An in vitro technique devised by Holden and Bernard[23] has provided a reproducible system to analyze the bone-implant interface. With this technique Petri dishes are coated with titanium, titanium alloy, or cobalt/chrome, and then bone is grown on the thinly coated implant materials. Semi-thin (2 ttm) and thin (80 nm) sections can then be prepared and analyzed using light and transmission electron microscopy.

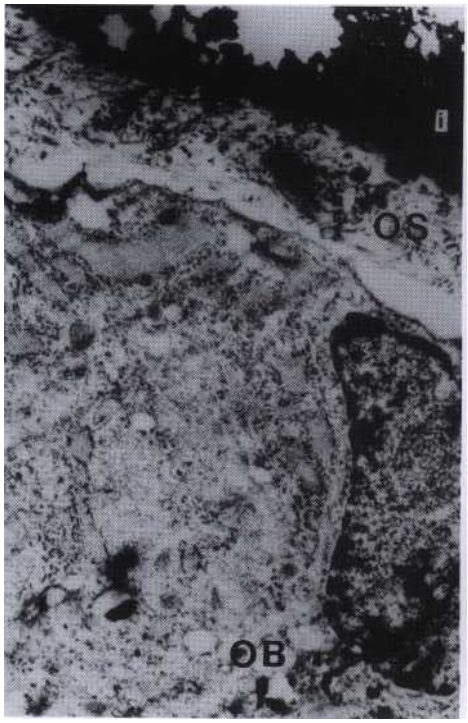

Fig. 68-7 Transmission electron micrograph showing a portion of an osteoblast (OB) and osteoid with initial calcification (OS) juxtaposed to the hydroxyapatite surface of the implant (i). Original magnification x18,000.

The compatibility of bone and titanium can be demonstrated by the large number of bone colonies that grow on titanium (Fig. 68-5); a lesser amount grow on titanium alloy, and almost none grow on cobalt/chrome.

Electron microscopy of the bone-titanium interface using this technique shows that there is always connective tissue between the implant and the bone (Fig. 68-6). A carbohydrate-rich adhesive substrate is invariably found on the metal adjoining the fibroblasts in vitro. With in vivo studies, as with in vitro, bone is never found in direct contact with titanium.[19,35]

Plasma-sprayed hydroxyapatite in Petri dishes is even more receptive to bone growth than titanium, forming larger and more numerous colonies. At the interface with hydroxyapatite, fibroblasts and osteoblasts can be demonstrated (Fig. 68-7). Where osteoblasts have developed, collagen is seen in the interface with hydroxyapatite molecularly bonded with the implant hydroxyapatite.[20]

The absence of cementum on the implant surface prevents the attachment of collagen fibers to the implants. This lack of cementum is interpreted as being due to the absence of cementum progenitor cells in the area receiving the implant.[30] When these cells are available, cementum can form on the implant surface, and a functional collagen attachment can attach to it. Buser and associates have described the presence of a distinct layer of cementum on the implant surface and a periodontal ligament with fibers oriented perpendicularly when the implant was placed close to retained roots that had a periodontal ligament.[12]

Increasing the surface area on the implant would increase the tissue implant contact to increase implant stability.[11,28,44] Acid etching and blasting are two techniques used to enhance implant surface topography with micro- to macroscopic hills, valleys, and indentations. When pure titanium surfaces are roughened with 22 tLm or 150 um aluminum oxide blasting, removal torque of the implant from the bone was significantly increased with both blasted surfaces. This demonstrated that the increase of blasted surface topography observed after 1 year increased bone fixation compared with machined surfaces. The increased surface created by blasting substantiated earlier findings of grit blasting and acid etching to increase the surface of the implants. Buser et all' used morphometric histologic analysis to conclude that grit-blasted and acid-etched surfaces increase bone opposition.

It is important to note that when undecalcified bone interfaces with titanium, whether in vivo or in vitro, electron microscopy has always shown connective tissue interposed between the two surfaces.

This brings up two considerations. In the first place, inflammatory cells are potential constituents of connective tissue, and improper loading of the implant may trigger an inflammatory response leading to bone resorption. The second is possibly a positive factor in that connective tissue may provide a cushioning structure between the hard surfaces of metal and bone. Furthermore, hydroxyapatite surfaces of implants have true osseointegration but only in a macular fashion with connective tissue in the intervening sites. There is also reason to believe that plasma-sprayed hydroxyapatite with less than optimal crystallinity may not have a long half-life, although long-term studies have not been reported.

The fundamental work of Branemark and associates in the 1960s demonstrated that commercially pure titanium implants can be anchored to the jawbone and used successfully for tooth replacement in edentulous arches. Controlled clinical research showed excellent long-term results achieved after appropriate selection of cases, adequate preparation of biomaterials, and careful handling of patients' soft and hard tissues. The relationship between the bone and the implant was called *osseointegration* (see Chapter 68). Branemark presented his research for the first time in North America at the conference held in Toronto, Ontario, Canada, in 1982, and his findings were unanimously considered a breakthrough in dental prosthetics and oral rehabilitation and the opening of a new era in clinical dentistry.

Since the mid-1980s, clinical and laboratory research in dental implantology has resulted in the development of numerous implant systems and different techniques for surgical placement and subsequent prosthetic reconstruction. This chapter presents some basic concepts in implant dentistry and will attempt to clarify the indications, advantages, and disadvantages of the various systems.

CLINICAL MANAGEMENT OF DENTAL IMPLANTS

To achieve an osseointegrated dental implant with a high degree of predictability, [10-12] the implant must be 1) sterile, 2) made of a highly biocompatible material such as titanium, 3) inserted with an atraumatic surgical technique that avoids overheating of the bone during preparation of the recipient site, 4) placed with initial stability, and 5) not functionally loaded during the healing period of 4 to 6 months.

When these clinical guidelines are followed, successful osseointegration occurs predictably for submerged" and nonsubmerged[34] dental implants. Well-controlled studies of patients with good plaque control and appropriate occlusal forces have demonstrated that osseointegrated implants show little change in bone height around the implant.' After an initial remodeling in the first year that results in 1.0 to 1.5 mm of bone reduction,' the bone level around healthy functioning implants remains stable for many years, allowing implants to be a predictable means for tooth replacement. The first patient with osseointegrated implants was treated in 1965 in Sweden, and long-term studies have shown excellent survival rates of implants over 20 years.'

Bone quality at the recipient site influences the interface between bone and implant.[21] Compact bone offers a much greater surface area for mineralized tissue-to-implant contact than cancellous bone. Clinical studies have shown that areas of the jaw exhibiting thin layers of cortical bone and large cancellous spaces, such as the posterior maxilla, have significantly lower success rates than areas of denser bone structures.[21] The best results are obtained when contact between bone and implant is most intimate at implant placement.

The surgical preparation of the tissues at the recipient site may also markedly affect healing. Drilling of the bone without proper cooling results in production of temperatures that inflict thermal injury to the tissues and an increased failure rate to osseointegrate.[38]

Indications and Contraindications

The treatment indications for dental implants are extensive and can include patients with partially and fully edentulous arches, as well as patients with maxillofacial deformities. Many patients can benefit from the osseointegration procedure as long as they fulfill specific requirements for surgical and prosthetic rehabilitation. Patients who are unable to wear removable dentures and have adequate bone for the placement of dental implants are especially good candidates.

However, each patient must be evaluated individually according to rigorous clinical parameters. Important criteria are oral hygiene, periodontal health (in partially edentulous patients) or history of periodontal health in an edentulous patient, jaw relationship, tooth positions, tooth restorations present, level of decay activity, cause for previous tooth loss, amount of bone quantity and quality available, and patient motivation. In addition, a restorative treatment plan needs to establish that the patient is a good candidate for tooth replacement with implants or if conventional prosthetic means are better suited for the patient. It is conceivable that a patient may not be a good candidate at the time of consultation, but that further dental treatment can prepare the patient for implant placement.

Patients must be in good general health. Uncontrolled or even controlled diabetes, chronic steroid therapy, high-dose irradiation, and smoking and alcohol abuse[6,16] can increase the occurrence of early and late implant complications. A thorough physical examination is mandatory if any questions arise about the health status of the patient.

The overall preoperative requirement regarding the local health of oral tissues is that no pathologic conditions are present in any of the hard or soft tissues of either jaw. All oral lesions, including periodontal inflammation, should be treated in advance and evaluated at a later date for resolution. The presence of nontreated or unsuccessfully treated periodontal disease is a contraindication to implant placement, since the bacterial flora in periodontitis can jeopardize the healing of the implant sites. Only when the periodontitis has been resolved can implant treatment be considered. The quality and quantity of soft tissue present in the anticipated implant site is also important, since keratinized, attached mucosa has better functional and aesthetic results for implant restorations.

After the patient has gone through the initial screening of being a good implant candidate, based on good general health, good oral health, and appropriate restorative needs, the amount of available bone is the next most important criteria for selection. The minimal width of the jawbone needs to be 6 mm, and the minimal height should be 10 mm. These dimensions are based on an implant with a diameter of 4 mm and should be used as a guide and not as an absolute term. These bone dimensions have to be evaluated in a 3-dimensional view, since the implant has to be placed in the appropriate prosthetic position. Minimum requirements of bone might be available in the anticipated implant site, but they might not be in the appropriate location to place an implant necessitating a grafting procedure.[35]

Although the traditional implant placement calls for a healed ridge, implant placement immediately after extraction has been attempted with success.[23] Covering the implant with a barrier membrane placed under the flap or placing a bone graft significantly increases the success rate of implants placed in extraction sockets.[23,37] Immediate placement of implants in extraction sockets of single-rooted maxillary and mandibular teeth has been documented in cases of severe periodontal breakdown, root fractures, or endodontic failures, provided the following conditions are met:

1. After tooth extraction, the alveolar socket must have sufficient residual bone walls.
2. The extraction socket must be free of pathosis.
3. The available soft tissue should allow primary closure.
4. Apical to the socket, a sufficient volume of healthy jawbone must be available to ensure good initial stabilization of the implant.

If the amount of bone is not sufficient to place an implant, the advanced bone augmentation surgery described in Chapter 71 can be employed. It is important to note that procedures to enhance the amount of bone have increased risks and failure rates and need the clinician to gain more training and experience before commencing these reconstructive procedures.

Selection of Cases and Preoperative Diagnosis

The possibility of implant installation can be determined after studying the jaw structures that are present. Wide variations in jaw anatomy are encountered, and it is therefore important to analyze the anatomy of the maxillofacial and intraoral region via clinical and radiographic examinations before any surgery is started.

The preoperative diagnosis is necessary to predict the amount of bone available for implant placement and to evaluate presurgically whether the patient is a suitable candidate for implant treatment. Clinical examination of the jawbone consists of palpation and probing through the soft tissue (intraoral bone mapping) to assess the thickness of the soft tissues at the proposed surgical site. Appropriate radiographic procedures, including periapical and panoramic views, lateral cephalometric views, and orthopantomograms can help identify vital structures such as the floor of the nasal cavity, maxillary sinus, mandibular canal, and mental foramen.

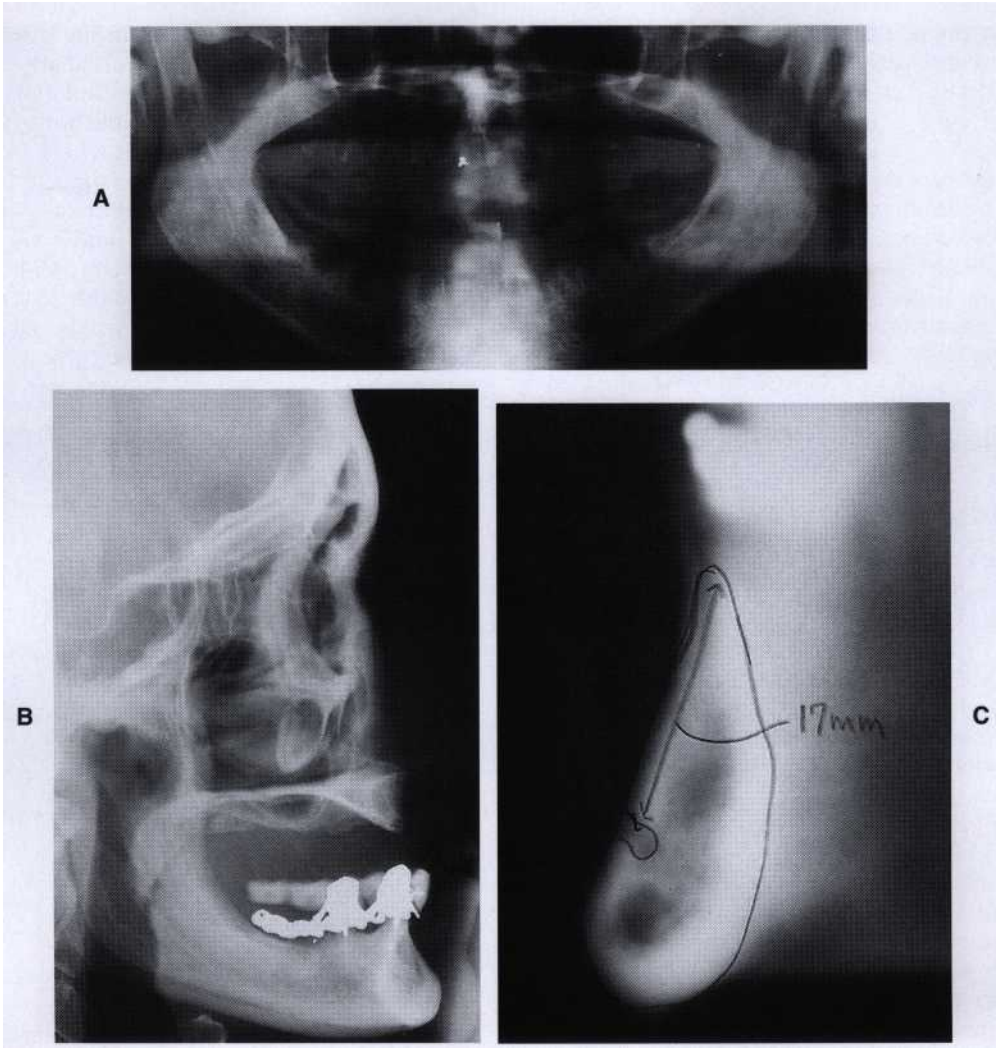

Fig. 69-1 Different radiographic procedures used in implant dentistry. A, Panoramic radiograph. B, Lateral cephalometric radiograph. C, Tomogram of mandibular premolar area.

When only periapical radiographs are used, such findings are severely limited.

The orthopantomogram allows a more comprehensive view of the mandible and maxilla. In the totally edentulous patient, the lateral cephalometric view is very beneficial, especially in the mandible, because it shows angulation, thickness, and vertical bone height. With newer diagnostic techniques such as conventional linear tomograms (Fig. 69-1, C) and computed tomographic (CT) scans (Fig. 69-2), it is possible to go beyond the standard two-dimensional radiographs mentioned previously.[32] Exact cross-sectional (three-dimensional) radiographic views of residual bone are possible via specialized software programs. This technology is costly and has increased risk for radiation, but it allows a more predictable diagnosis, since it demonstrates whether there is inadequate height and width of bone and the location of vital anatomic structures.[30] Newer clinical data show that even the quality of bone in an anticipated implant site can be evaluated.

VARIOUS IMPLANT SYSTEMS

Several implant systems are used for tooth replacement. These differ mainly in biomaterial, design, and surgical procedure. The four most often used biomaterials are commercially pure titanium, micro-enhanced pure titanium, plasma-sprayed titanium surfaces, and plasma-sprayed hydroxyapatite surfaces.

The three main implant designs are the screw-shaped implant form, cylinder-shaped form, and tapered screw-shaped form.

Surgical procedures can be performed in two interventions (two-stage) or in one stage. In the two-stage procedure, the first operation is for implant insertion and the second operation, several months later, is for uncovering the implant, and attaching a prosthetic abutment. Implants requiring a one-stage procedure are inserted and left exposed to the oral environment; they are not loaded, however, during the healing period. Chapter 70 describes in detail the surgical procedures for one-stage and two-stage implant placement.

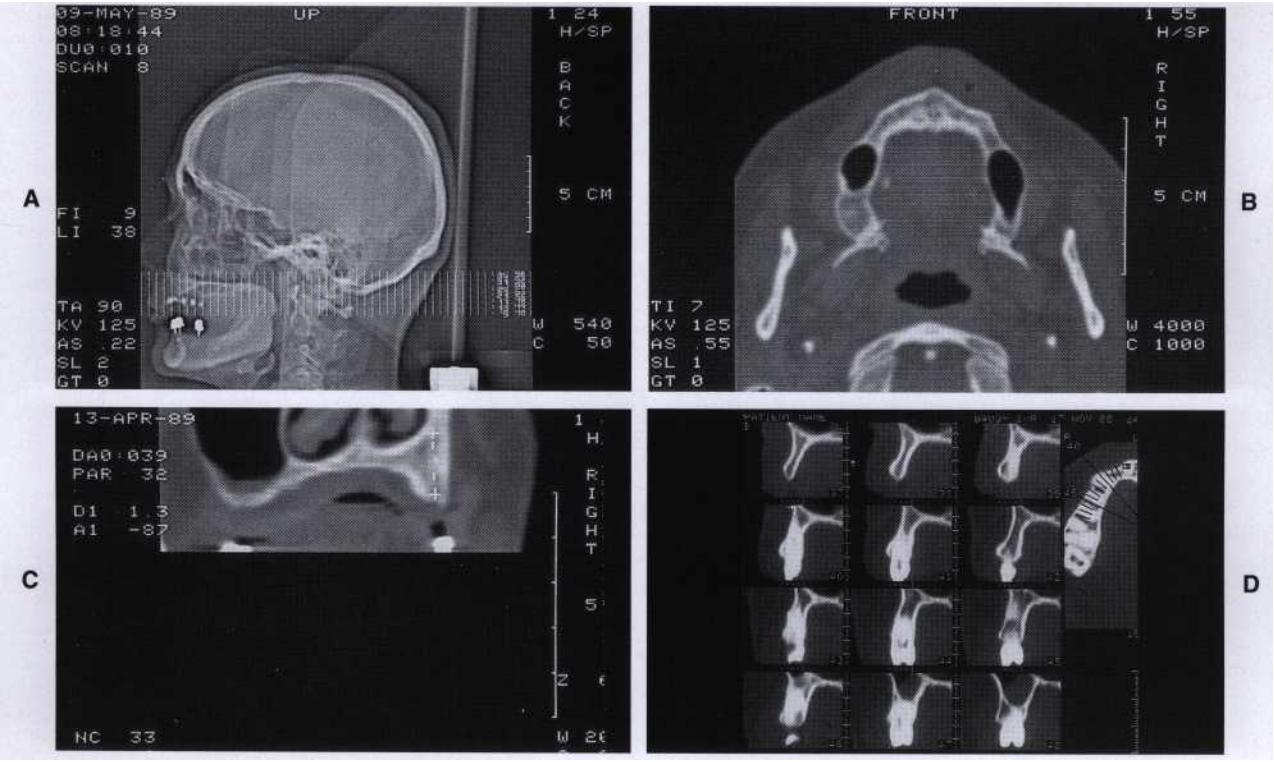

Fig. 69-2 Computed tomographic scans. A, Sagittal view. B, Occlusal view. C, Cross-sectional view. D, Cross-sectional reformatted view.

Most implant systems offer a variety of implant lengths (7 to 20 mm) and widths (3.25 to 6 mm) to accommodate the available bone quantity. In addition, they include an internally or externally irrigated precision drill set, as well as precisely matched components for surgical and prosthetic needs.

More than 50 different types of implants are available worldwide. Many systems use the term *osseointegration* but lack short- and long-term data to support their claims.[3,36] For this reason, only implant systems with appropriate clinical and experimental research are presented in the following descriptions (Table 69-1).

Nobel Biocare System

The Branemark system consists of a screw-shaped dental implant, made of commercially pure titanium and applied in a two-stage surgical procedure. The titanium implant surface is machined and forms and maintains an oxide layer without apparent breakdown or corrosion under physiologic conditions. This system was developed by Branemark in Sweden in the early 1960s, and the term *osseointegration* was coined to designate the relationship of the implant to the bone *at the light microscopic level.* Recently, a new surface treatment to the implant has been added by increasing the thickness of the oxide layer (Ti-unite).

The Branemark implant is by far the most extensively researched system, with long-term prospective follow-up studies carried out in fully edentulous and partially edentulous patients. The major advantage of this system is its excellent long-term data (>20 years) and its very meticulous testing in the preclinical stage. New implant designs and surfaces have been added to the system in recent years and have increased success rates in poor quality bone sites.

The Steri-Oss system is part of the Nobel Biocare product line and has a large variety of different implant designs and implant surfaces. The most used implant of this system is a tapered titanium screw (Replace), which comes in an acid-etched, TPS and HA coating.

International Team for Oral Implantology (ITI) System

In Switzerland, Schroeder and colleagues initiated clinical and experimental studies evaluating one-stage hollow cylinder implants in the early 1970s.[34] They demonstrated that one-stage implants can also result in direct bone-to-implant contact and in 1976, called this phenomenon functional ankylosis. The ITI implant system" has shown good results in long-term retrospective studies on fully edentulous patients and in short-term prospective studies on partially edentulous patients.

This implant system can accommodate several different designs, from the original hollow cylinder (Fig. 69-3, *right)* to a full-body screw design. The initial surface characteristics (plasma-sprayed titanium coating) have changed in the recent years to a sand-blasted, acid-etched surface.[14,11] Because this implant system

TABLE 69-1

Principal Features of Commonly Used Implant Systems

System	Design	Number of Surgery Stages	Surface	Indication	ADA Accepted	Follow-up Since
Nobel Biocare (Branemark)	Screw and tapered screw	Two	Pure Ti machined and Ti-unite	Full/partial edentulism	Yes	1965
ITI Straumann	Screw, cylinder, and basket	One	Ti plasma-sprayed and SLA	Full/partial edentulism	Yes	1977*
Nobel Biocare (Steri-Oss)	Screw, cylinder, and tapered screw	Two and one	Acid-etched, Ti and HA plasma-sprayed	Full/partial edentulism	Yes	1988
Integral	Cylinder, screw	Two	HA plasma-sprayed	Full/partial edentulism	Yes	1985
Paragon/ Core-Vent	Screw, cylinder, hollow basket	Two	Acid-etched Ti + HA plasma-sprayed	Full/partial edentulism	Yes	1984
Friadent	Tapered cylinder and screw	Two	Acid-etched Ti	Full/partial edentulism	Yes	1991
Astra	Screw	Two	Pure Ti blasted	Full/partial edentulism	Yes	1990
3i	Screw, cylinder	Two and one	Osseotite and Ti + HA plasma-sprayed	Full/partial edentulism	Yes	1990

* Follow-up of the new-generation ITI dental implant since 1986.

ADA, American Dental Association; *HA,* hydroxyapatite; 1T1, International Team for Oral Implantology; 3i, Implant Innovations, Inc.; Ti, titanium.

protrudes through the mucosa from the day of insertion, it does not require a second intervention, but there is an increased risk of premature loading during the healing period and the danger of titanium showing in the marginal mucosal area.

3i (Implant Innovations) System

The 3i implant system[27] was developed by Lazzara and Beaty in 1988 and has gone through several changes and additions since its early phase. The system is based on the research of Branemark and colleagues and includes a 2-stage commercially pure titanium screw and cylinder with either an acid etched, a plasma-sprayed titanium-coated (TPS) or a plasma-sprayed hydroxyapatite (HA)-coated surface. Recently one-stage implant was introduced to the market, which is largely based on the research of Schroeder and colleagues. Another implant concept was recently introduced by roughening the middle and more apical part of the implant for better bone integration and keeping the coronal part a smooth surface for better maintenance properties. The system went into clinical trials in 1990, and several retrospective studies of its implant survival have been reported .[27]

Astra Dental Implant System[19,20]

Another implant system presenting significant research and clinical studies was developed in the 1980s in Sweden. It consists of a self-tapping screw made of pure titanium and is characterized by a conical abutment that fits tightly into the coronal part of the implant. The system

has a titanium oxide-blasted surface and a special single-tooth implant with a wider microthreaded, tapered collar. The screw-shaped titanium implants are presented with a titanium oxide-blasted coating.

Other Systems

The Paragon/Core-vent system,[18] Integral System,[25] IMZ system, Friadent system, and the TPS system[4] offer a variety of implant designs, from screw-shaped to cylinder type, as well as implant surface characteristics, from machined pure titanium to HA to plasma-sprayed titanium coatings. These systems have been developed since the early to mid-1980s and resemble some of the previously described systems. Some long-term follow-up data of their clinical results are available.

Hydroxyapatite coated implants have been recommended for compromised bone sites, because the HA coating accelerates bone apposition to the implant surface in the early healing period and significantly improves the anchorage in bone (see Chapter 70). However, long-term results have reported that the HA coating is biologically unstable over time and shows signs of resorption in histologic studies.[22] This might be one of the factors responsible for controversial data about the increasing rate of complications reported after a 3- to 5-year functional period.[9,25]

IMPLANT RECONSTRUCTION AND AESTHETICS

The patients who seem to benefit most from dental implants are those with fully edentulous arches. In these patients, removable and fixed implant prosthetic devices can restore almost normal stomatognathic function. The original design of the edentulous arch was a fixed bone-anchored bridge that used five to six implants in the anterior area of the mandible or the maxilla and a cantilever through the premolar area. Most implant bridges currently used are screwed into place and can easily be removed by loosening the fixation screws. This adds a retrievability characteristic to the treatment, which increases the overall comfort and reliability for the patient.

Another treatment option for the rehabilitation of an edentulous arch is the overdenture retained by clips to a bar splinting two to six implants. This treatment results in less prosthesis stability but is still far superior to conventional complete dentures (see Chapter 72).[39]

Partially edentulous patients with single or multiple missing teeth represent another viable treatment population for osseointegrated implants, but the remaining natural dentition (i.e., its occlusal schemes, periodontal health status, vertical dimension problems, and aesthetics) introduces an additional challenge to achieve a long-lasting, successful rehabilitation.[28] In general, osseointegrated implants can support a freestanding fixed partial denture. Adjacent natural teeth are not necessary for additional support. However, the close proximity of anatomic structures and the limited bone quantity require special attention to diagnosis and treatment planning.[7] The major advantage of implant-supported restorations in partially edentulous patients is that they are less invasive to adjacent teeth (i.e., preparation of abutment teeth becomes unnecessary), and larger edentulous spans can be restored with fixed bridges.[31] Obtaining ideal aesthetic results, however, poses interesting and difficult challenges for the restorative/surgical team.[7]

The single-tooth restoration (Fig. 69-4) requires detailed planning and careful management to achieve perfect harmony among implant position, bone level, soft tissue aesthetics, and tooth form and color.[17,24] The replacement of single missing teeth with implants has two major advantages over replacement with conventional fixed prostheses. First, there is no need to prepare adjacent teeth, and second, the ridge will be maintained by the implant. The primary candidates for single-tooth implants are all anterior teeth, from central incisor to second premolar in the maxilla and mandible provided that no lateral forces are induced by the single standing implant. Molar replacements with single implants are less indicated, owing to the high stresses generated in the posterior region of the mouth and the insufficient force distribution over one implant, leading to potential bone resorption.

Early on, the UCLA (University of California, Los Angeles) abutment[29] was developed by Beumer and colleagues to allow direct connection between the implant-supported restoration and the top of the implant, thereby eliminating the need for the transmucosal abutment cylinder and improving the aesthetic result dramatically, since porcelain rather than titanium emerges from the tissues. Similar techniques have since evolved, and aesthetically pleasing implant restorations are a reality. No significant difference in fully implant-supported bridges or implant-and-tooth-supported bridges have been found in the short term, but the fully implant-supported bridges may have a better long-term outlook.

Although 10-year data for the partially edentulous patient are still missing, the less invasive dental implant approach is promising and is increasingly preferred by patients and their treatment teams.

Complications

Less than 10% of implants will show some form of complication over the life of the implant.' Complications can be detected during the treatment phase (early onset) and/or during the maintenance phase (late onset). When a dental implant demonstrates any degree of mobility after the healing period, it is considered a failure. Implant mobility suggests a fibrous connective tissue interface that does not function well over time. When this mobility is detected, the implant, with its surrounding fibrous capsule, must be removed. After an appropriate healing time it is possible to place another implant.

During the maintenance phase, once osseointegration is established, complications can be divided into adverse tissue reactions such as mucosal inflammation and progressive bone loss and mechanical problems such as component fractures or screw loosenings (see Chapter 73).

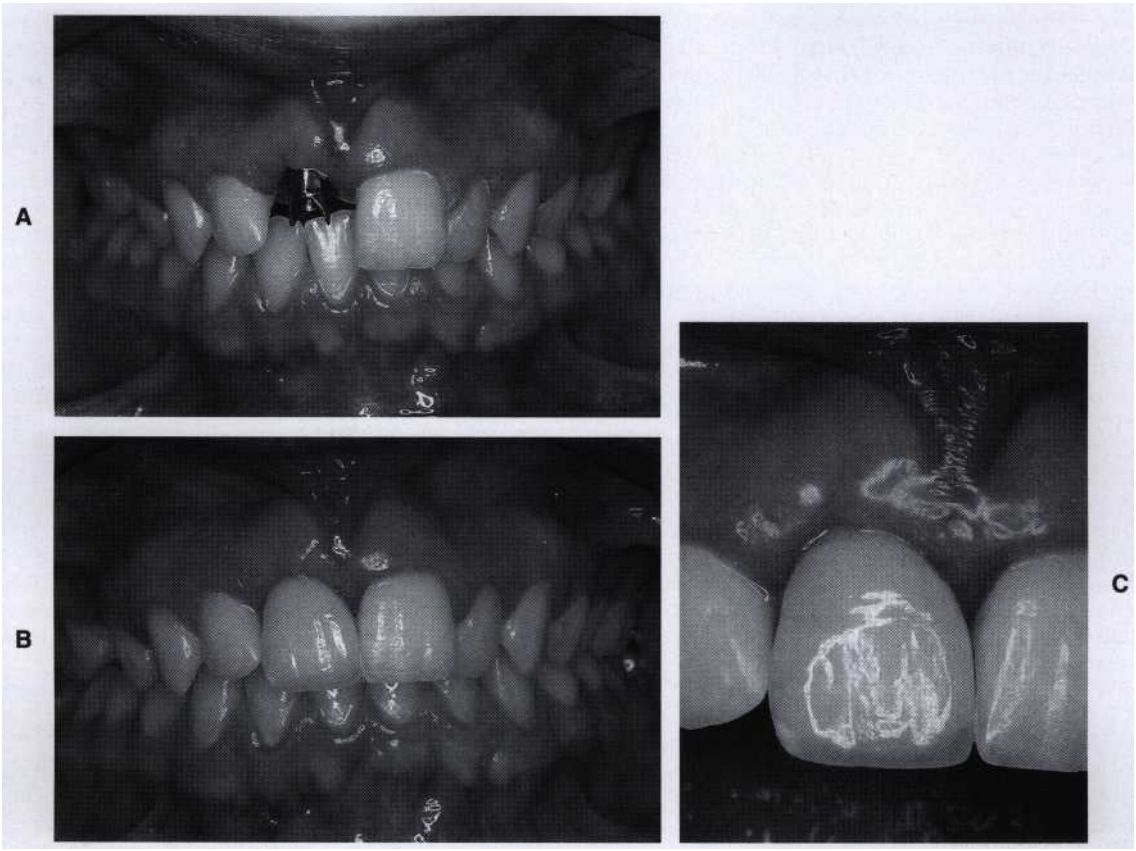

Fig. 69-4 Single tooth replacement. A, Implant in place. B, Metalloceramic crown. C, Close-up view.

Maintenance Phase

Proper oral hygiene and appropriate occlusal forces are critical for long-term function of an implant prosthesis, as poor hygiene and occlusal trauma have been related to marginal bone loss. Plaque control should be started immediately after the implant is exposed to the intraoral environment and monitored over time. Implant superstructures are often bulky and overcontoured, which makes traditional home care procedures more difficult. In addition, implant patients usually have a history of less than ideal home care, which has resulted in their partially or totally edentulous state. Patient recalls should be at 3-month intervals for the first year and then on a semiannual basis. However, some patients may require more frequent follow-up care. Recall visits should include an evaluation of oral hygiene compliance, occlusal harmony, implant and prosthesis stability, overall soft and hard peri-implant tissue health, and radiographic follow-up.

One-Stage Endosseous Implant Surgery
ADJUNCTIVE ADVANCED SURGICAL TECHNIQUES

CONSIDERATIONS OF FIXTURE DESIGN AND SURFACE CHARACTERISTICS FOR IMPLANT SURGERY

The root form implant surgical techniques are mostly based on the researches performed on the biologic, physiologic, and mechanical aspects of the Nobelpharma implant system developed by Per-Ingvar Branemark and colleagues in Sweden approximately three decades ago. Since then, many different designs of root form implants have been studied, and presently more than 50 implant manufacturers exist worldwide.

The root form implants can be divided according to their body shapes (macrodesign) and surface topography (microdesign).

Screw-Threaded and Threadless, Cylinder-Shaped Implants (Macrodesign)

In consideration of surgical protocol, the root form implants can be divided into two basic groups: one has threads, and the other is threadless and in cylinder form (Fig. 70-1). The first type is threaded into the bone recipient site like a screw with a handpiece or wrench after drilling a hole slightly smaller in diameter than the implant. The cylinder-shaped, threadless implants are tapped into a recipient hole that is similar to the diameter of the implant body. The threaded implants are more widely used today because they usually provide superior initial stability in bone, and vertical positioning of the implant during placement can be more precisely controlled. The high initial stability is crucial when considering placing a provisional restoration on the implant immediately after implant placement. In dense bone, it may be necessary to "tap" the bone for easier placement. Some threaded implants are shaped conically to minimize apical bone fenestration, and these are useful in placing implants into anterior extraction sockets immediately (Fig. 70-2).

Surface Topography of Implant (Microdesign)

It is generally believed that the textured surfaces accelerate the initial healing phase through the adsorption of bioactive components of bone, and a stronger bond between implants and bone is achieved faster. Titanium plasma-sprayed (TPS) and hydroxyapatite (HA) surfaces are considered highly textured surfaces (Fig. 70-3, A, B). Although these surfaces achieve secondary stability and integration earlier, progressive bone loss can occur if the rough surface of the implant becomes exposed to oral fluid and microorganisms. Therefore when using these types of surface implants, care must be taken to ensure complete submersion of the rough surface in bone with sufficient crestal bone thickness around the implant. Thinner crestal bone can resorb during function, and the subsequent exposure of the rough surface to oral

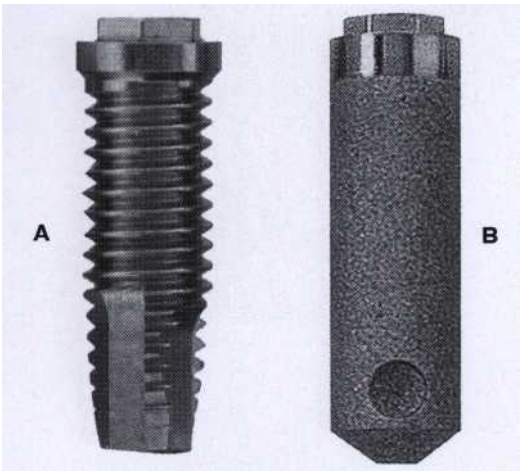

Fig. 70-1 Two basic groups of the root form implants (Macrodesign). One is with threads (A), and the other is threadless (B).

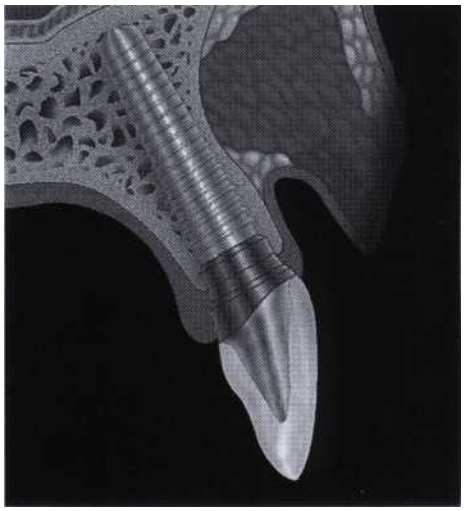

Fig. 70-2 A conically shaped, threaded implant is helpful to minimize apical bone fenestration and also useful in placing implants into extraction sockets immediately. (Courtesy Nobel Biocare, Yorba Linda, Calif.)

fluid can initiate progressive bone loss and result in eventual failure of the implant. Smooth surface implant is much more resistant to bacterial contamination and progressive bone loss, but it provides weaker secondary stability and consequently has a lower success rate in soft or grafted bone (Fig. 70-3, C). Therefore medium-textured implants with blasted/etched (for example, RBM surface of Lifecore system, SLA surface of ITI system) or etched/etched (for example, Osseotite surface of 3i system, Etched titanium implant of Steri-Oss system) surfaces have gained favor recently because they have stronger bonding capacity with minimal likelihood of progressive bone loss due to bacterial contamination (Fig. 70-3, D).

ONE-STAGE VERSUS TWO-STAGE IMPLANT SURGERIES

The most threaded endosseous implant can be placed either as one stage, meaning the coronal portion stays exposed through gingiva during the healing period (Fig. 70-4, *A, B),* or two stage, meaning the top of the implant is completely submerged under gingiva (see Fig. 70-4, C). In two-stage implant surgery, the head of the implant needs to be surgically exposed with a second surgery. Some implants, notably from the ITI system, TG implant of 3i system, and Lifecore single-stage system are specifically designed to have the coronal portion of the implant extend through the gingiva during the healing period (see Fig. 70-4, A).6 However, most other systems require attaching a healing abutment to the implanted fixture before it can be used in one-stage surgery (see Fig. 70-4, B).

The advantages of the one-stage surgical approach are that the mucogingival management around the implant is easier, patient comfort increases because less surgeries are involved, and the esthetic management is easier in many cases. However, if extensive bone loss occurs at the implant site, vertical bone augmentation is necessary, interproximal bone of the adjacent teeth is lacking, and/or bone quality is poor, then the two-stage surgical approach is recommended.

Because some fundamental differences in flap management for both two-stage and one-stage endosseous implant surgeries exist, the two surgical techniques are described separately.

In the two-stage implant surgical approach, the first-stage surgery ends by suturing the soft tissues over the implant so that it remains excluded from the oral cavity. *In the mandible, the implants are left undisturbed for 2 to 3 months, whereas in the maxilla, they remain covered for approximately 4 to 6 months because of slower healing due to less dense bone.* During this period, the healing bone makes direct contact with the implant surface (osseointegration) and sometimes grows to its occlusal surface, even covering it. In the second-stage surgery, the buried implant is uncovered, and a titanium abutment is connected to allow access to the implant from the oral cavity. The restorative dentist then proceeds with the prosthodontic aspects of the implant therapy.

In the one-stage implant surgical approach, a second intervention is not needed because the implant is left exposed after the first surgery. Again the implants are left unloaded and undisturbed for a period similar to the implants placed in the two-stage approach.

Regardless of the type of surgical approach, the implant must be placed in healthy bone to achieve osseointegration, and an atraumatic and aseptic technique must be followed to avoid damage to vital structures. Generally, implant surgery is done under local anesthesia, but oral or intravenous (IV) sedation can also be used if necessary. The surgical site should be kept aseptic and the patient appropriately prepared and draped for an intraoral surgical procedure. The patient should rinse with chlorhexidine gluconate for 30 seconds immediately before the procedure. Every effort should be made to mini-

mize the risk of contamination of the implant surfaces by such items as gloves, instruments, suction tubing, or saliva.

This chapter presents general surgical considerations and guidance on some of the most commonly used implant systems. The great variety of implant systems with their own specific armamentarium makes it advisable in each case to follow the detailed, step-by-step description usually found in the manufacturer's manual.

Two-Stage Endosseous Implant Surgery

First-Stage Surgical Technique

FLAP DESIGN AND INCISION. Two types of incisions-crestal or remote-can be used. In the latter, the incision is made away from the implant site, usually 1 to 2 mm inferior to the mucogingival junction. A back-action chisel or a periosteal elevator is then used to reflect a mucoperiosteal (full-thickness) flap. For the crestal design flap, the incision is made along the crest of the

ridge, bisecting the existing zone of keratinized mucosa (Fig. 70-5, A).

The remote incision has the advantage of covering the implant without sutures over its top. The crestal incision, however, is preferred in most instances because it results in less bleeding, easier flap management, less edema, less ecchymosis, less vestibular change postoperatively, faster healing, and easier denture reline. Sutures placed over the implant generally do not interfere with proper healing. When extensive bone augmentation is planned, a remote incision with layer suturing technique is used to minimize the incidence of bone graft exposure.

FLAP ELEVATION. A full-thickness flap is raised buccally and lingually to the level of the mucogingival junction, exposing the alveolar ridge of the implant sites (see Fig. 70-5, B). Elevated flaps may be sutured to the buccal mucosa or the opposing teeth to keep the surgical site open during the surgery.

If a bone augmentation technique, with or without membranes, is anticipated, the flap can be extended by making a partial-thickness flap beyond the mucogingival junction. This lengthens the flap while providing flexibility to close it without tension after the implantation and ridge augmentation procedure (see Fig. 70-5, C, D).

For a knife-edge alveolar process with sufficient alveolar height and distance from vital structures such as the sinuses or the inferior alveolar nerve or mental nerves, a suitable round bur is used to recontour the bone to provide a reasonably flat bed for the implant site (see Fig. 70-5, B).

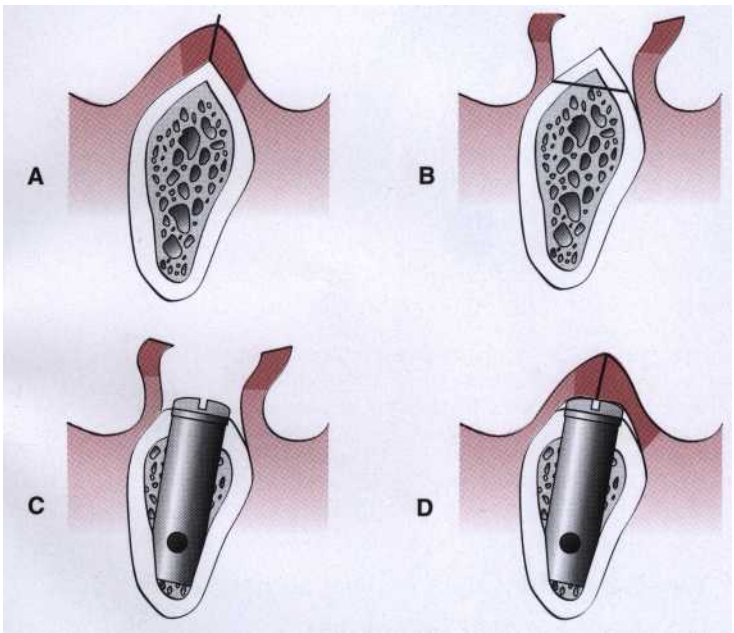

Fig. 70-5 A, Crestal incision made along the crest of the ridge, bisecting the existing zone of keratinized mucosa. B, A full-thickness flap is raised buccally and lingually to the level of the mucogingival junction. A sharp ridge can be surgically contoured to provide a reasonably flat bed for the implant. C, A partial-thickness flap is raised apically from the mucogingival junction to provide extension of the flap. D, Crestal flap closure without tension.

IMPLANT PLACEMENT. Once the implant site is prepared, a surgical guide or stent is placed intraorally, and a small round bur or spiral drill is used to mark the implant sites. The stent is then removed, and the sites are checked for their appropriate faciolingual location. Slight modifications may be necessary to avoid obvious ridge defects.

The site is then marked to a depth of 1 to 2 mm, breaking through the cortical bone (Fig. 70-6, A). A small spiral drill, usually 2 mm in diameter and marked to indicate appropriate depth, is used next to establish the depth and align the axis of the implant recipient site (see Fig. 70-4, B). This drill may be externally or internally irrigated. In either case, the spiral drill is used at a speed if approximately 800 to 1000 rpm with copious irrigation to prevent overheating the bone.

If the vertical height of the bone is reduced during the ridge preparation, this must be taken into account when selecting the length of the implant. When multiple implants are used to support one prosthesis, a paralleling or direction-indicating pin should be used to align subsequent implants correctly. The relationship to neighboring vital structures can be determined by taking a periapical radiograph with a radiographic marker placed at the bottom of the prepared site. Implants should be at least 3 mm apart to ensure sufficient room for adequate oral hygiene once the prosthesis is in place.

The next step is to use a series of drills to systematically widen the size to accommodate the selected size of the implant. The shapes of the drills may slightly differ among systems, but their general purpose is to prepare a recipient site that is accurate in size, both in diameter and in length, for the selected implant without unduly traumatizing the surrounding bone.

Usually after the 2-mm spiral drill, a pilot drill with 2-mm diameter at the lower part and wider diameter at the upper part is used to enlarge the osteotomy site to allow easy insertion of the following drill. Then a wider diameter spiral drill can be used to drill to the depth reached with the 2-mm spiral drill. When it is necessary to place the height of the cover screw slightly under the crestal bone to avoid a risk of premature exposure from the pressure of the temporary denture and minimize the thread exposure due to the inclined ridge, the countersink drilling is recommended (see Fig. 70-6, E). Implant therapy in posterior areas of the mouth often requires wide diameter implants. When a large-diameter drill is used for site preparation, it is necessary to reduce the drilling speed to approximately 500 rpm to prevent overheating the bone. Copious external irrigation is mandatory, and internal irritation is helpful.

Regardless of the system used, it is very important that the final diameter drilling be accomplished with a steady hand, without wobbling. Some techniques help accomplish this. If the final drill hits the bottom of the recipient site before reaching the desired depth, the added hand pressure necessary to achieve the proper depth often causes wobbling and funneling of the recipient site. This is especially true with cannon drills that have been used for the cylinder-type implant. To minimize this effect, during the preparation of the recipient site with the smaller-diameter drill, the operator should

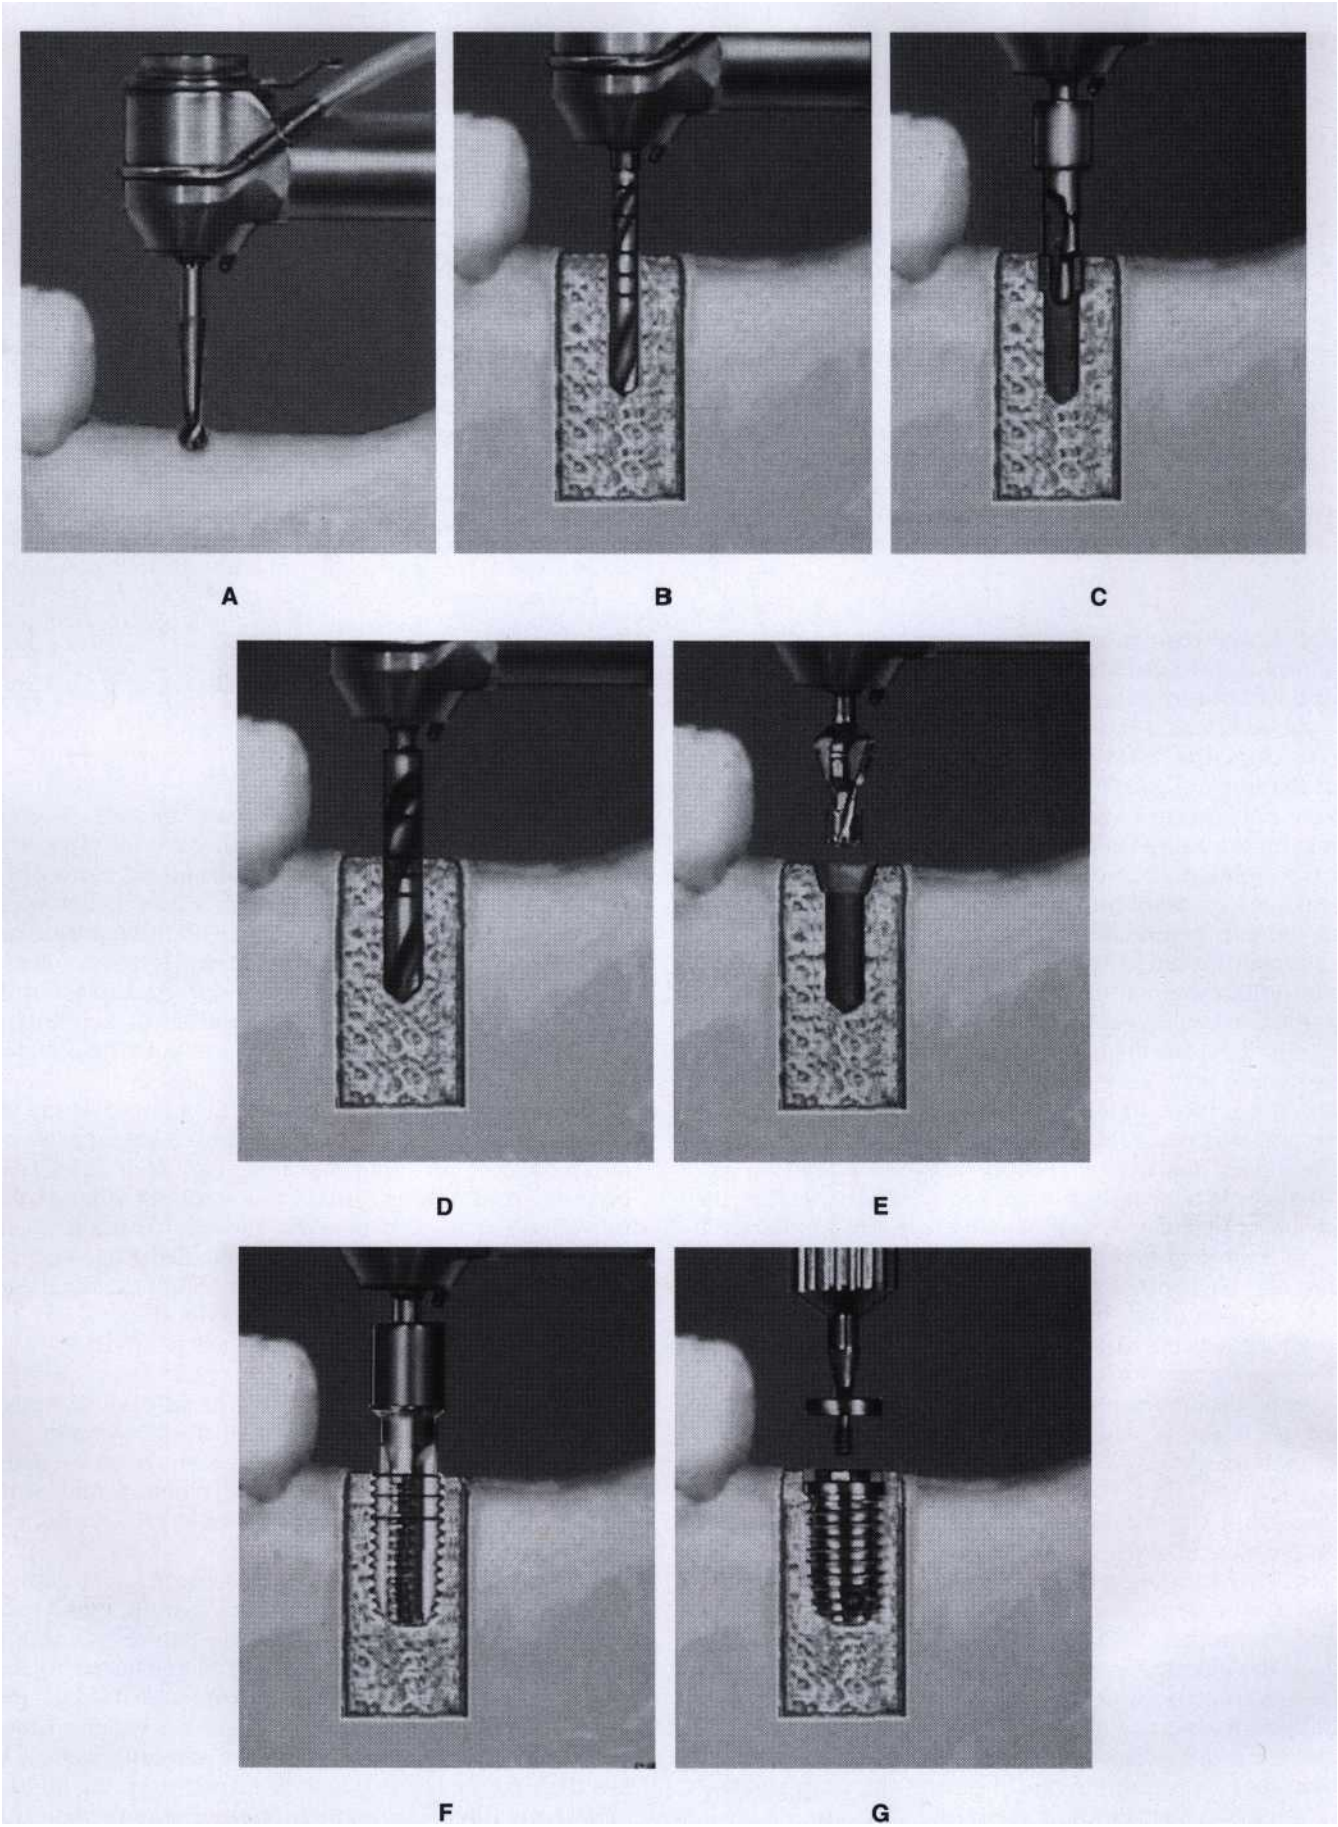

Fig. 70-6 A, initial site preparation for screw-type implant. B, Use of a 2-mm drill to establish depth and align the implant. C, A wider-diameter pilot drill is used to increase the size of the recipient site. D, A final-size drill is used to finish the preparation of the recipient site. E, A countersink drill is used to widen the entrance of the recipient site. F, A tap is used to create screw threads. G, The implant is screwed into the recipient site, and the cover screw is placed. (Courtesy 3i/Implant Innovations, Inc., Palm Beach Gardens, Fla.)

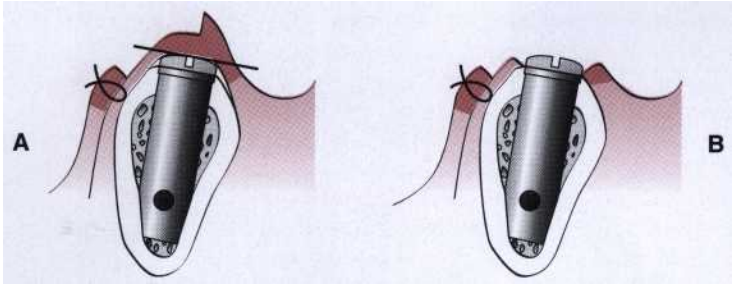

Fig. 70-7 A, A partial-thickness flap is apically sutured to the periosteum, and excess connective tissue coronal to the cover screw is excised by gingivectomy. B, A sharp blade is used to eliminate all tissue coronal to the cover screw.

drill to approximately 0.5 mm deeper than needed. This allows the desired depth to be reached with the final drill without touching the bottom.

In addition, if the final drill is inserted at an inaccurate angle, the result is funneling of the coronal portion of the implant site. To minimize this when drilling multiple implant sites, the operator should always keep a direction indicator in adjacent site. For single implant cases, some type of direction reference guide should be used. When dealing with very dense bone, a precise recipient site can be achieved more predictably if there is minimal diameter change from drill to drill. For example, going from 3.0 to 5.0 mm is far more difficult than going from 3.0 to 3.3 to 4.2 to 5.0 mm.

For the placement of threaded implants, a tapping procedure may be necessary. With self-tapping implants becoming increasingly popular, there is less need for a tapping procedure, but in very dense bone or when placing longer implants, it is prudent to use a tap (see Fig. 70-6, F). When dealing with a very soft bone (e.g., in posterior maxillary areas), tapping is not recommended.

It is important to create a recipient site accurate in size and angulation. In partially edentulous cases, a limited opening of the mouth may prevent appropriate positioning of the drills in posterior edentulous areas. Therefore a combination of longer drills or shorter drills, with or without extensions, may be necessary. Anticipating these needs facilitates the procedure and improves the results.

CLOSURE OF THE FLAP. Once the implants are screwed in and the cover screws are placed (Fig. 70-6, G), proper closure of the flap over the implant is very important. One suturing technique that consistently provides the desired result is a combination of inverted mattress and interrupted sutures. The inverted mattress sutures keep the bleeding edges of the flap close together, while the interrupted sutures seal the edges. However, the most important aspect of flap management at this stage is *closure of the* flap *without tension.* It is better to use a suture that does not require removal during the postoperative visit, such as a 4.0 chromic gut suture.

POSTOPERATIVE CARE. Patients are premedicated with antibiotics (amoxicillin, 500 mg tid) starting immediately before the surgery and continuing for at least 1 week afterward (see Chapter 55). Swelling is likely to occur, and the patient should apply ice packs extraorally intermittently for the first 24 hours. Chlorhexidine gluconate mouthrinses should be used twice daily because oral hygiene and plaque control will be difficult to perform. Adequate pain medication should be prescribed (see Chapter 55). Patients should have a liquid or semisoft diet for the first few days and then gradually return to a normal diet. Patients should also refrain from tobacco and alcohol use for 1 to 2 weeks postoperatively.

Color Fig. 70-1 shows all steps of first-stage implant placement surgery in a clinical case.

Second-Stage Surgical Technique. The objectives of the second-stage surgery are as follows:

1. To expose the submerged implant without damaging the surrounding bone.
2. To control the thickness of the soft tissue surrounding the implant.
3. To preserve or create attached keratinized tissue around the implant.
4. To facilitate oral hygiene.
5. To ensure proper abutment seating.

Thin soft tissue with an adequate amount of keratinized attached gingiva, along with good oral hygiene, ensures healthier periimplant soft tissues and better clinical results. The need for keratinized tissue is somewhat controversial, depending on the type of implant prosthesis and location of the implant. But one long-term study indicated that, at least in the posterior mandible and in partially edentulous cases, the presence of keratinized tissue is strongly correlated with soft and hard tissue health.[3]

In areas with sufficient zones of keratinized tissue, either the gingiva covering the head of the implant can be punched out or a full-thickness flap technique that places a band of keratinized tissue on both sides of the implants is used. If deficient keratinized tissue is available, the following partial-thickness flap-gingivectomy technique can be used to predictably fulfill the objection of the second-stage surgery listed previously.

PARTIAL-THICKNESS FLAP-GINGIVECTOMY TECHNIQUE

Flap Design and Incisions. The initial incision is made approximately 2 mm coronal to the facial mucogingival junction, with vertical incisions both mesially and distally (Color Fig. 70-2, A, B). When dealing with anterior implants, the flap design should preserve the adjacent papilla.

Flap Elevation and Apical Displacement. A partial-thickness flap is then raised in such a manner that a relatively firm periosteum remains. The flap, containing a band of keratinized tissue, is then placed facial to the emerging head of the implant fixture and fixed to the periosteum with 5.0-gut suture (Fig. 70-7; see also Color Fig. 70-2, C). If the initial amount of keratinized tissue is less than 2 mm, the flap may be started from the lingual part of the ridge, positioning facially the entire band of keratinized tissue. When a partial-thickness flap is apically displaced in this manner, not exposing the alveolar bone, a band of attached keratinized tissue is maintained or created around the implants.

Gingivectomy. Once the flap is positioned facially, the excess tissue coronal to the **cover screw is excised, usually using a gingivectomy technique (see Fig.** 70-7 and Color Fig. 70-2, D). However, if a gingivectomy technique would compromise the lingual keratinized tissue around the implant(s), a similar partial-thickness flap can be made on the lingual side.

Once the excess tissue coronal to the cover screw is removed, the outline of the cover screw is visible. A sharp blade is used to eliminate all tissues coronal to the cover screw (see Fig. 70-7, *B* and Color Fig. 70-2, E). The cover screw is then removed, the head of the implant is thoroughly cleaned of any **soft or hard tissue overgrowth, and the healing abutments or standard abutments are placed on the fixture (see** Color Fig. 70-2, F). The fit of the implants to the healing abutments can often be visually evaluated.

Postoperative Care. Once the implant is exposed, it is important to remind the patient of the need for good oral hygiene around the implant. A chlorhexidine rinse is highly recommended for at least the initial 2 weeks while the tissues are healing. At this time, there should not be any direct pressure to the area from dentures. Fabrication of the suprastructure can begin in about 2 weeks.

Color Fig. 70-2, G and H shows the postoperative results in a clinical case after 2 to 3 weeks and 4 months, respectively.

MAXILLARY ANTERIOR SECOND-STAGE SURGERY. **The partial-thickness gingivectomy technique can be used in maxillary edentulous cases in** which implant overdenture is the restorative goal. However, when placing individual implant dentition or an implant fixed bridge where maximal gingival vertical height is important for esthetic reasons, the soft tissue thickness should be maintained as much as possible. Therefore the partial-thickness gingivectomy technique should not be used. When the amount of keratinized tissue is sufficient, the punch biopsy technique can be used. If the flap reflection is necessary, vertical incisions should be avoided if at all possible. When the vertical incision is necessary, it should be made at least one tooth away from the implant site to minimize the facial clefting or indentation in esthetic areas.

One-Stage Endosseous Implant Surgery

In **the two-stage surgical approach, the implant is placed flush with the bone crest, and the soft tissue covering is purposely kept thick to minimize the chances of a premature exposure of the cover screws.** In the one-stage surgical approach, the implant or **the healing abutment protrudes about** 2 to 3 mm from the bone crest, and the flaps are adapted around the implant. In **posterior areas of the mouth, the flap is** thinned and sometimes placed apically to increase the zone of keratinized attached gingiva.

Surgical Technique

FLAP DESIGN AND INCISIONS. The flap design for the one-stage surgical approach is always a crestal incision bisecting the existing keratinized tissue. Vertical incisions may be needed in one or both ends. Facial and lingual flaps in **posterior areas should be carefully thinned before total reflection to minimize the soft tissue thickness. The soft tissue is not thinned in anterior or other aesthetic areas of the** mouth to prevent the metal collar from showing. **Full-thickness flaps are elevated facially** and lingually.

PLACEMENT OF THE IMPLANT. The implant site preparation to place the implants in one surgery is identical in principle to the two-stage implant surgical approach. The only difference is that the implant or the healing abutment extension of the implant is placed in such way that the head of the implant protrudes about 2 to 3 mm from the bone crest.

CLOSURE OF THE FLAP. The keratinized edges of **the flap are tied with independent sutures around the implant. When keratinized tissue is abundant, scalloping around the implant(s) provides better flap adaptation.**

POSTOPERATIVE CARE. The postoperative care for one-stage surgical approach is same as that for the two-stage surgical approach.

ADJUNCTIVE ADVANCED SURGICAL TECHNIQUES

Oral implantology is often complicated by anatomic limitations of the jaw. Advanced surgical techniques are designed to overcome these difficulties, but often these procedures are very technique sensitive and expensive and have a high degree of postoperative morbidity. It is important to carefully weigh the benefits versus the risks of these procedures. Consider that if the patient has functioned relatively well with a conventional prosthesis before the implants were considered, it may be wise to continue with the traditional type of tooth replacement rather than perform surgical correction of unfavorable anatomic conditions.

One of the most often encountered anatomic limitations in both jaws is a narrow ridge. *Bone augmentation techniques* using the principle of guided bone **regeneration and various kinds of bone graft material are indicated." However, the regenerated bone is weaker and requires that the stability of the initial** and **early loaded stages come from integration with the preexisting** bone. If most of the implant surface is exposed and an extensive amount of bone needs to regenerate to cover the implant, the risk of deintegration during the early-loaded stage is higher.

A new approach to implant therapy in esthetic areas combines surgical and restorative procedures to *provisionalize the implant immediately after implantation into extraction socket.* Simultaneous perigingival bone grafting is often performed. The obvious advantage of this approach is to increase the patient's satisfaction esthetically and phonetically during the provisional period, and studies have shown that an immobile immediate provisional restoration can enhance soft tissue management. [1,2,7,14-16] When a provisional restoration similar in shape and size to the natural tooth is placed in the extraction socket, it can support the periimplant mucosa and thus maintain the papillary height and gingival outline and form throughout the osseointegration period.",''

Another common anatomic limitation of the maxillary arch is *excessive pneumatization of the maxillary sinus,*

leaving a very thin inferior wall or floor of the maxillary sinus. Various techniques are available for elevating the floor of the sinus and augmenting the bone to accommodate the length of the implants.,[12,18] These techniques are generally successful and, if done properly, benefit the patient. The sinus lift-augmentation can be performed as an initial separate procedure or combined in one intervention with the placement of the implants. To accomplish both objectives in one operation, the height of bone must be sufficient (usually greater than 5 mm) to provide the initial stability of the implant. In addition, if the existing bone height is sufficient but the bone is very soft, it is better to perform the sinus lift and implantation in separate interventions. When the sinus lift and the implantation are done in two stages, the bone should be allowed to mature for approximately 6 months before placing the implants. The implants are usually placed in a one-stage approach.

In the partially edentulous mandibular arch with severely resorbed ridges, a *mandibular nerve repositioning is* an option.$ This procedure requires extensive manipulation of the mandibular nerve and often results in extended periods of paresthesia and dysesthesia of the lower lip. In most cases, the patient returns to normal sensation in about 6 months. Patients should be carefully selected for these procedures and clearly informed in writing of all possible side effects.

LONG-TERM RESULTS OF IMPLANTS PLACED WITH/AFTER BONE AUGMENTATION PROCEDURES

CONCLUSIONS

The use of dental implants in the partially and fully edentulous patient with deficient jawbones creates a new demand for bone reconstruction before or simultaneously with implant therapy, especially when natural esthetics is required. The most critical aspect of creating an implant restoration is the surgical placement of the implant in a prosthetically driven position so as to restore the natural position and emulate the natural emergence of a tooth from the soft tissues. Implants placed without regard for prosthetic position often result in dental restorations that are functionally and esthetically compromised, and patients are left with a less-than-optimal end result.

Periodontal bone loss, tooth extraction, and long-term use of removable appliances typically result in advanced alveolar bone loss that prevents the placement of implants in an optimal prosthetic position. Fortunately, continuous innovations in surgical techniques along with advances in the biologic understanding of bone regenerative techniques have resulted in advanced implant procedures and an increased predictability to reconstruct alveolar ridge defects.[27,40]

Conventional implant surgery, as described in Chapter 70, is based on adequate bone volume and quality in the desired implant location. The time-tested protocol allows for adequate remodeling and maturation of bone, with healing periods of 4 and 6 months for the mandible and maxilla, respectively. Advanced implant procedures often challenge these original conventions by placing implants in areas with inadequate bone volume, simultaneously augmenting bone and restoring or loading implants after shorter healing periods. This chapter presents an overview of advanced implant surgical and bone augmentation procedures currently used to overcome anatomic deficiencies for the optimal placement of dental implants.

GUIDED BONE REGENERATION

Much of what can be achieved with implant surgery and bone augmentation procedures is directly related to our achievements and understanding of guided bone regeneration. Historically, augmentation or "regeneration" of alveolar bone lost as a result of tooth extraction, resorption, or trauma presented a significant challenge for clinicians. Allowed to heal without the intervention of regenerative procedures, extraction site defects (especially those lacking a self-supporting bone structure) healed with fibrous connective tissue or scar formation and often did not fill with bone. The surrounding soft tissues collapsed, leaving an anatomic deficiency with respect to the natural tooth position. If a removable prosthetic appliance was used, the alveolar ridge resorbed even more.

Periodontal studies during the last several decades have led to new techniques and a new treatment approach referred to as *guided tissue regeneration (GTR).* Briefly, this concept is based on the principle that specific cells contribute to the formation of specific tissues. Exclusion of the faster-growing epithelium and connective tissue from a periodontal wound for a period of *6* to 8 weeks allows the slower growing tissues to occupy the space adjacent to the tooth. Osteoblasts, cementoblasts, and periodontal ligament cells are then afforded the opportunity to regenerate a new periodontal attachment (new bone and new connective tissue fibers inserted into newly formed cementum) on the previously diseased root surface. See Chapter *63* for a complete discussion on the concepts of GTR as it relates to periodontal regeneration.

The same basic principle of GTR has been applied to alveolar bone defects to regenerate new bone. [12] Using a canine model, Schenk and co-workers demonstrated with histology that bone regeneration in membrane-protected defects healed in a sequence of steps that simulated bone formation after tooth extraction.48 They found that after blood clot formation, bone regeneration was initiated by the formation of woven bone initially along new blood vasculature at the periphery of the defect. The new vascular supply emanated from surgically created perforations in the cortical bone. The woven bone was subsequently replaced by lamellar bone, which resulted in mature bone anatomy. Ultimately, bone remodeling occurred with new secondary osteons being formed. This concept employed the same principles of specific tissue exclusion but was not associated with teeth. Hence the term applied to this technique was *guided bone regeneration (GBR).* Because the objective of GBR is to regenerate a single tissue, namely bone, it is theoretically easier to accomplish than GTR, which strives to regenerate multiple tissues in a complex relationship.

It is interesting to note that long before the current concepts of guided bone regeneration were introduced, Murray and Roschlau demonstrated that when a cavity with a source of osteoblasts and a blood supply was isolated from adjacent soft tissues, it could fill with bone, whereas if the space were not protected, it would fill with fibrous connective tissue.[42] In addition to this observation, they suggested that a bone graft placed in the space might interfere with bone formation because the graft would need to be resorbed before bone could occupy the space.

Bone is a unique tissue that has the capacity to completely regenerate itself. However, due to its rigid calcified structure, bone has specific requirements that must be respected to achieve regeneration. Because the calcified structure of bone is not conducive to perfusion, new bone formation is critically dependent on establishing an adequate blood supply via new vasculature while maintaining rigid fixation or stabilization for bone formation. Any movement of the segments of bone relative to one another (even micromotion) during healing results in disruption of the blood supply and a change in the type of tissue formed in the site from bone to fibrous connective tissue. Table 71-1 lists the biologic requirements for bone regeneration along with the associated component of GBR surgical procedures needed to accomplish bone regeneration.

TABLE 71-1

Requirements for Bone Regeneration

Biologic Requirements	Surgical Procedure
Blood supply	Cortical perforations
Stabilization	Fixation screws, membrane tacks
Osteoblasts	Autogenous bone graft
Confined space	Barrier membrane
Space maintenance	Tenting screws, bone graft materials
Wound coverage	Flap management, tension-free suturing

Barrier Membranes

Barrier membranes are bio-inert materials that serve to protect the blood clot and prevent soft tissue cells (epithelium and connective tissue) from migrating into the bone defect, allowing osteogenic cells to be established. Membranes have been manufactured from biocompatible materials that are nonresorbable and resorbable in nature. The ideal properties of a barrier membrane are 1) biocompatibility, 2) space maintenance, *3)* cell-occlusiveness, 4) good handling properties, and 5) resorbability. Advantages and disadvantages of the resorbable versus nonresorbable membranes are described here.

Nonresorbable Barrier Membranes. Various nonresorbable materials have been used as barrier membranes, including latex and teflon. Teflon, an expanded polytetrafluoroethylene membrane (e-PTFE, Gore-Tex Periodontal and Bone Regenerative Membranes, Gore and Associates, Flagstaff, AZ), has been used extensively as a barrier membrane in both GTR and GBR procedures. A variety of shapes and sizes have been designed to custom fit around teeth and osseous defects. These barrier membranes are nonresorbable and thus require a subsequent surgical procedure to remove them. The advantage of a nonresorbable barrier membrane is its ability to

maintain separation of tissues over an extended time. Unless the barrier is exposed, it can remain in place for several months to years. Typically, GBR membranes are removed after 6 to 12 months.

The disadvantage of a nonresorbable barrier membrane is that if it becomes exposed, it will not heal spontaneously. Exposed membranes become contaminated with oral bacteria, which may lead to infection of the site and result in bone loss. Hence exposed membranes must be removed. Early removal may also result in less bone regeneration.

Space can be maintained under a barrier membrane with bone graft material or tenting screws, thereby facilitating the regeneration of increased bone volume. Stiffer or titanium-reinforced (TR) membranes (Gore and Associates, Flagstaff, AZ) with space-maintaining capabilities have been demonstrated to regenerate bone without bone grafts or tenting apparatus. Stiffer membranes are able to promote significant amounts of new bone and maintain sufficient space without the addition of supportive devices. Ridge augmentation can be enhanced with a titanium-reinforced membrane in conjunction with implant placement in localized bone defects [23]

Resorbable Barrier Membranes. There has been a recent surge of interest regarding the use of resorbable membranes. Co-polymers of polylactide and polyglycolide (PLA/PGA) or collagen have been used to construct biodegradable membranes. The primary advantage of a resorbable membrane is the elimination of a surgical reentry for a membrane removal. In the case of subsequent implant placement procedure (or exposure surgery), this may not be a significant advantage.

A possible disadvantage is that most resorbable membranes degrade before bone formation is completed and the degradation process is associated with varying degrees of inflammation. [65] Fortunately, the mild inflammatory reaction caused by bioresorbable membranes does not seem to interfere with osteogenesis. Another disadvantage is that resorbable membranes are quite pliable. The lack in stiffness results in a collapse of the membrane into the defect area. [48]

Human histology demonstrating the effectiveness of resorbable membranes is lacking, and further clinical research is needed before conclusions can be made about their use in bone regeneration. At the present time, it can be stated that biodegradable membranes have the potential to support bone formation if they are supported by bone graft material to resist collapse and if they are long-lasting enough to maintain their barrier function for extended periods in small to moderate bone defects. [28,29]

Bone Graft Materials

Unlike other tissues, bone has the unique capacity to regenerate itself completely. The major limiting factor is maintenance of space for bone formation. Bone graft materials have been used to facilitate bone formation within a given space by occupying that space and allowing the subsequent bone growth (and graft replacement) to take place. The biologic mechanisms that support the use of bone graft materials are osteoconduction, osteoinduction, and osteogenesis (Table 71-2).

Osteoconduction is the formation of bone by osteoblasts from the margins of **the defect on the** bone graft material. Materials that are osteoconductive serve as a scaffold for bone growth. They do not inhibit bone formation, nor do they induce bone formation. They simply allow the normal formation of bone by osteoblasts into the grafted defect along the surface of the graft material. Osteoconductive bone graft materials facilitate bone formation by bridging the gap between the existing bone and a distant location that otherwise would not be occupied by bone.

Osteoinduction involves new bone formation via stimulation of osteoprogenitors from the defect (or from the vasculature) to differentiate into osteoblasts and begin forming new bone. This induction of the bone-forming process by cells that would otherwise remain inactive occurs via cell mediators that "turn on" these bone forming cells. The most widely studied of these is the family of bone morphogenic proteins (BMPs).

Osteogenesis occurs when living osteoblasts are part of the bone graft as in autogenous bone transplantation. Given an adequate blood supply and cellular viability, these transplanted osteoblasts form new centers of ossification within the graft. Hence in addition to the bone formation from osteoblasts that already exist in **the defect, osteoblasts that have been added as part of the** bone graft also form ossification centers and contribute to the total capacity for bone formation.

Numerous bone graft materials have been used to aid in the reconstruction of bone defects. These range from allografts (derived from the same species) to xenografts (derived from a different species) and alloplast or synthetic graft materials. At a minimum, bone graft materials should be osteoconductive. Bone graft materials that are osteoinductive are believed to be more advantageous than those that are only osteoconductive. Decalcified, freeze-dried bone allograft (DFDBA) is thought to have osteoinductive effects because it retains some of the original BMPs within the donor tissue matrix.62

In contrast to this view, several recent reports have suggested that bone augmentation with DFDBA is not osteoinductive because it does not contain the BMPs necessary to induce bone formation [4,7] Schwartz et al reported that variations in the amount of bone formation induced by DFDBA may be related to the source and processing of the bones.51 In addition to processing

TABLE 71-2

Biologic Properties of Various Bone Graft Materials (Grouped by Source Type)

	Osteoconductive	Osteoinductive	Osteogenic
Alloplast	Yes	No	No
Xenograft	Yes	No	No
Allograft	Yes	Yes/No	No
Autograft	Yes	Yes	Yes

variations, it has been demonstrated that young donor bone results in significantly greater quantities of BMPs retained in the bone allograft matrix as compared with older donor bone .12 Hence the source of donor bone can greatly influence its osteoinductive capacity.

Bone graft materials help maintain space under a barrier membrane to facilitate the formation of bone within a confined space. Perhaps a more important requirement of bone graft materials is that they should facilitate the ingrowth of neovascularization and migration of osteoprogenitors. Because the size of the bone graft particles determine the resultant space available (between particles) for osseous formation, it has been carefully selected according to this concept. The typical size of bone graft particles ranges from 100 to 1000 M,m, which is conducive to the ingrowth of bone. Bone forms in cones called osteons with a central blood supply. The dimension of these cones (100A radius) is determined by the distance that the central vasculature can supply nutrients to cells.

Autogenous Bone Harvesting

As compared with other bone graft materials, autogenous bone is thought to be the best bone graft as it is osteoinductive and osteogenic in addition to being osteoconductive. Intraoral sources of autogenous bone include edentulous spaces, maxillary tuberosity, mandibular ramus, mandibular symphysis, and extraction sites. Bone from a recent extraction site (within 6 to 12 weeks) may have the advantage of increased osteogenic activity as compared with other sites, which are more static and undergoing little or no osteogenesis. The maxillary tuberosity provides a more cellular source of autogenous bone as compared with other sites. However, the trabecular nature of this site provides a lesser quantity of mineralized matrix and the resultant total volume of bone available for grafting is often inadequate. For greater amounts of bone, it is more desirable to harvest bone from the mandibular ramus or symphysis. This bone, which is typically more cortical, can be harvested and used as a block graft or ground or shaved into small fragments and used as a particulate graft.

Despite the fact that the mandibular ramus and symphysis offer good sources of bone for grafting, clinicians are sometimes reluctant to harvest bone from these sites due to an increased risk of morbidity from the surgical procedure. Risks of surgery in the mandibular symphysis region include postoperative bleeding, bruising, wound dehiscence, damage to lower incisors, disfigurement, and injury to nerves. Nerve injury is perhaps the most significant concern because it has the potential to be a long-term, annoying alteration in sensation of the lower lip, chin, anterior teeth, and gingiva for the patient. A more serious risk is the alteration of facial appearance. This is a particular risk when the facial muscles are completely elevated from the bone beyond the inferior border of the mandible. A condition referred to as "witch's chin" can occur when the facial muscles and overlying skin of the chin fall, causing a disfiguring sag of facial tissues after surgery.

Hunt and Jovanovic" presented a retrospective analysis of 48 chin graft harvesting procedures. They emphasized maintaining a 5-mm margin of safety between graft harvest sites and the lower incisors, the inferior border of the chin, and the mental foramen. Using both trephine and custom block harvesting techniques, they reported minimal postoperative complications. In the 48 procedures, postoperative sequelae included bruising of lower face (48/48), bruising of upper neck (6/48), paresthesia of lower lip and incisors (6/48). No patients (0/48) experienced facial disfigurement or muscle prolapse (chin droop). Three of the six patients with paresthesia experienced transient symptoms and recovered completely within 2 months, whereas symptoms persisted longer than 6 months in the other 3 patients. Not surprisingly, the larger harvest defects (trephined 6-rings) resulted in a higher incidence of paresthesia, which was longer lasting than that of the smaller defects (trephined 4-rings). Harvesting bone in a custom-shaped "block" did not result in paresthesia, presumably because these harvest sites were smaller than the 4-ring and 6-ring trephine-harvested sites.

Observation of the following basic principles can minimize the risk of postoperative morbidity:

1. Carefully evaluate the harvest site for potential risks. A critical radiographic evaluation prior to surgery can identify individuals with inferior alveolar nerve branches that extend anterior beyond the mental foramen.
2. Use extreme care in making incisions laterally toward the mental nerve, and dissect the area with blunt instruments to locate the foramen.
3. Do not elevate and reflect muscle attachments beyond the inferior border of the mandible.
4. Limit bone cuts to an area at least 5 mm away from the tooth apices, the inferior border of the mandible, and the mental foramen. Do not extend cuts or harvest bone deeper than 6 mm, and do not include both labial and lingual cortical plates.
5. Suture the wound in layers (muscle and overlying mucosa separately) to prevent postoperative wound separation.

Whenever harvesting autogenous bone, regardless of site or method used, it is important to use techniques that prevent overheating and maintain viability of the bone cells. Exceeding 47° C (116.6° F) is known to cause bone necrosis. Thus use of drills, trephines, or saws to cut bone should always be done with profuse irrigation to keep instruments and bone cooled.

Flap Management for Ridge Augmentation

Soft tissue management is a critical aspect of bone augmentation procedures. Incisions, reflection, and manipulation should be designed to optimize blood supply and wound closure. The design and management of mucoperiosteal flaps must consider the increased dimensions of the ridge after augmentation as well as esthetics and approximation of the wound margins. The surgical procedure needs to be executed with utmost care to preserve the maximum vascularity to the flap and minimize tissue injury.'

Several flap techniques maintain a submerged position of bone grafts and barrier membranes during the entire healing process, including a remote or displaced incision. The advantage of a remote incision is that the wound opening is positioned away from the graft. A conventional crestal incision can be used, even in large supracrestal defects, as long as periosteal releasing incision and coronal advancement of the flap achieve the tension free closure.[31,58] Most reports suggest removing sutures approximately 10 to 14 days after surgery. It is also suggested that no prosthesis be inserted for 2 to 3 weeks after surgery to avoid pressure over the wound during the early healing period.

General concepts for flap management associated with ridge augmentation include the following:

1. Whenever possible, it is desirable to make incisions remote relative to the placement of barrier membranes (e.g., vertical releasing incisions at least one tooth away from the site to be grafted). In the anterior maxilla, keeping vertical incisions remote is also an esthetic advantage.
2. Full mucoperiosteal flap elevation at least 5 mm beyond the edge of the bone defect is desirable.
3. The use of vertical incisions, although often required for surgical access, should be minimized whenever possible.
4. Use of periosteal releasing incision to give the flap elasticity and permit tension-free suturing is essential. This permits complete closure without stress on the wound margins.
5. Avoid postoperative trauma to the surgical site (i.e., no removable appliance should be inserted over the wound for a postoperative period of 2 weeks or more).
6. Wound closure should incorporate a combination of mattress sutures to approximate connective tissues and interrupted sutures to adapt wound edges.

LOCALIZED RIDGE AUGMENTATION

Patients often present for implant planning after tooth loss and alveolar ridge resorption. In these cases, the clinician is obligated to perform advanced augmentation procedures to reconstruct lost bone and place implants in a prosthetically driven position.

Surgical reconstructive procedures for the preparation and placement of dental implants have become more numerous and complex. Depending on the size and morphology of the defect, various augmentation procedures can be used. These procedures have been categorized according to the deficient dimension (i.e., horizontal or vertical). Methods used to augment horizontal as well as vertical bone deficiencies include particulate bone grafts and monocortical block grafts. Barrier membranes can be used along with bone grafts to reconstruct all types of alveolar bone defects. Recently, distraction osteogenesis has been described to regain bone in a vertical direction.

All the proven principles of guided bone regeneration and flap management must be followed to achieve good results. These include generating a blood supply; maintaining a stable, protected space for bone growth; and achieving tension-free flap closure.

Horizontal Bone Augmentation

A deficiency in the horizontal dimension of bone may be minimal, such as a dehiscence or fenestration of an implant surface, or it may be more significant such that the implant would have more than one axial surface exposed while having some bone along the entire vertical length. Dehiscence defects can usually be managed simultaneously with implant placement because most of the implant is covered and stabilized by native bone. If the horizontal deficiency is large and the implant placement would result in significant exposure, it may be better to reconstruct the bone prior to implant placement (staged implant placement).

Although reconstruction of deficient ridges with bone grafts alone (i.e., without barrier membrane) has proved to be effective, variable resorption of the grafted bone has been reported. Preliminary results in a 1- to 3-year study using autografts harvested from the maxillary tuberosity showed an increased ridge width, but resorption of 50% of the graft volume was also noted.[59]

Buser[8] investigated the lateral ridge augmentation procedure using an autograft from the retromolar or symphysis area covered by a membrane in 40 consecutively treated patients and showed that no clinical signs of resorption of the block graft were observed. Emphasis was given to a remote incision technique, perforation of the cortex, stable placement of corticocancellous autografts, precise adaptation and stabilization (with miniscrews) of the e-PTFE membranes, and a tension-free primary soft tissue closure. After 7 to 13 months, the sites were reopened for membrane removal and implant placement. Approximately 38 of 40 patients exhibited excellent ridge augmentation, with two sites showing some soft tissue encapsulation of the grafted bone.

Nevins[44] and Doblin[13] demonstrated case report results that the use of freeze-dried bone allografts with membranes increased the amount of new bone, even in the presence of a membrane exposure. The biopsies showed viable bone cells and visible osteocytes in lacunae, and a 9-month specimen showed no remainder of allograft material. On the other hand, there are some contradictory results using DFDBA and membrane combinations.

Particulate Bone Graft. Advantages of particulate bone grafts (or bone chips) are that the smaller pieces of bone demonstrate more rapid ingrowth of blood vessels (revascularization), larger osteoconduction surface, more exposure of osteoconductive growth factors, and easier biologic remodeling when compared with a bone block. However, particulate grafts often lack a rigid structure and are easier displaced then block grafts.

Harvesting autologous particulated bone grafts can be performed from any edentulous jaw site, either in smaller particle sizes or in larger block size. If the bone has been harvested in block size, a bone mill is necessary to particulate the bone and prepare the bone to be transplanted into the bone defect.

Particulate grafts are indicated in defects with multiple osseous walls or single bone walls and when implants are placed simultaneously with the bone augmentation procedure. If a bone defect does not have sufficient osseous walls to contain the graft and if an implant is placed

simultaneously, a barrier membrane is secured along the periphery with tacks or screws. This bone graft-implant-membrane combination becomes an environment that is stable and supports bone formation.

Monocortical Block Graft. Horizontal alveolar deficiencies can easily be reconstructed with a monocortical block bone graft. The technique uses a cortical block of bone harvested from a remote site and used to increase the width of bone. The block graft taken from an intraoral (e.g., mandibular symphysis or ramus) or extraoral (e.g., iliac crest or tibia) site is fixated to the prepared recipient site with screws. The graft can be separated from overlying soft tissues with a barrier membrane or simply covered with the mucoperiosteal flap. Fixation hardware (i.e., screws and plates) should be removed after an adequate period of healing (approximately 6 months). The disadvantage of this technique is the biologic limitation of revascularizing large bone blocks. It therefore is crucial to have sufficient osteogenic cells in the residual surface of the surrounding bone and to limit this technique to horizontal augmentation and only minimal vertical defects.

Fig. 71-1 shows the use of a monocortical block graft to reconstruct a horizontal deficiency in the posterior right mandible. The patient presented with a loss of the buccal cortical plate of bone after a traumatic extraction of endodontically treated tooth #29. The surgical extraction also resulted in a nonrestorable cut into the mesial root of tooth #30. Recommended treatment included extraction of tooth #30 with monocortical block graft to reconstruct the buccal defect of site #29.

PROCEDURE. After local anesthesia, an incision was made in keratinized tissue along the crest and around the molar tooth (#30) with a vertical releasing incision mesial to the first bicuspid (#28). A full-thickness flap was elevated to expose the alveolar bone. All soft tissues were thoroughly removed from the recipient site prior to bone grafting. After simple forceps delivery of tooth #30, the defect to be grafted was measured to determine the size of block graft to harvest from the mandibular symphysis. Several bleeding points were created using a small round bur.

The autogenous monocortical block graft was harvested from the mandibular symphysis (see Autogenous Bone Harvesting). It was cut to an appropriate size and mortised to intimately fit the recipient site (defect). Once properly positioned, the graft was fixated with two fixation screws (Leibinger, Kalamazoo, MI) that passed through the graft and into the remaining native alveolar bone. A periosteal releasing incision was used to sever the periosteum from anterior to posterior and facilitate coronal advancement of the mucogingival flap.

After 6 months of healing, a full-thickness mucoperiosteal flap was elevated to expose the alveolar bone sites #29 and 30. Minimal resorption of the monocortical block graft is evident. Notice the position of the head of the fixation screws (especially the posterior screw), which are more protruded than the bone (see Fig. 71-1, H, I).

The fixation screws are removed and the sites are prepared in the usual manner for the placement of two screw-type, wide-diameter implants (Implant Innovations, Inc., Palm Beach Gardens, FL). Care is taken to avoid preparing the grafted site too wide or too far labially because the grafted bone may be vulnerable to fracture or resorption (see Fig. 71-1, j).

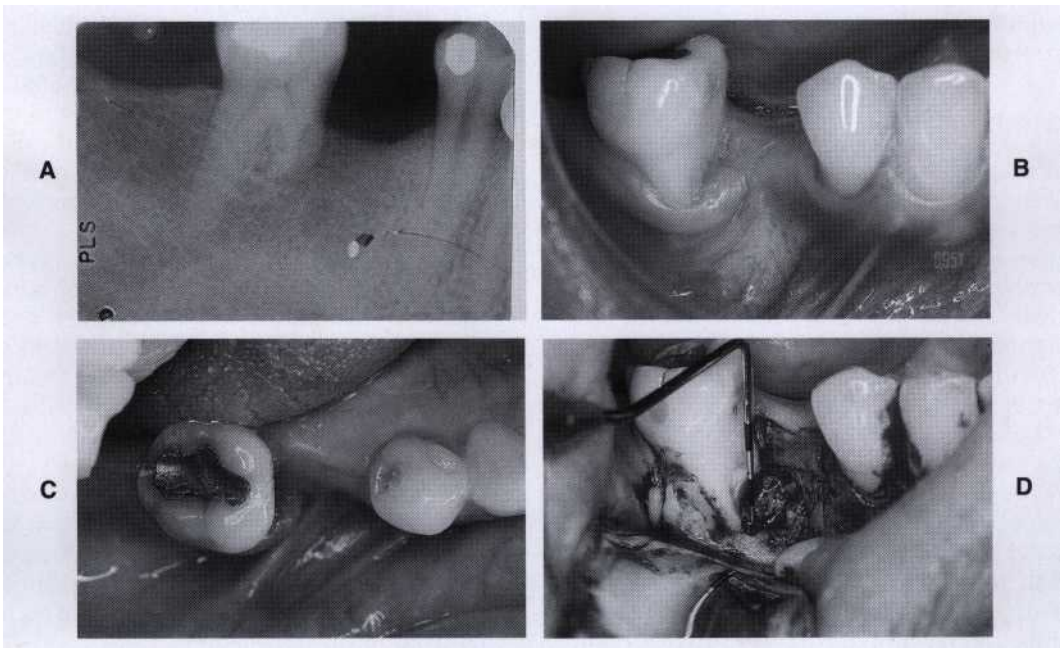

Fig. 71-1 The use of a monocortical block graft to reconstruct a horizontal deficiency in the posterior right mandible. A, Periapical radiograph shows missing tooth #29 and severed mesial root #30. B and C, Labial and occlusal views, respectively, of site reveals deficient alveolar ridge buccal side of #29. D, Full-thickness flap reflection reveals the extent of missing bone in the buccal aspect of site #29 as well a5 the periodontal defect and damaged mesial root #30.

SIMULTANEOUS IMPLANT PLACEMENT AND GUIDED BONE REGENERATION

Large alveolar bone defects need to be augmented prior to implant placement and require a healing period of 6 months or longer. In selected cases, it is possible to perform a bone augmentation procedure simultaneously with the implant placement. It is essential to achieve good implant stability in the existing native bone so that endosseous integration can occur.

A very predictable osseous defect to manage with simultaneous implant placement is the implant dehiscence or fenestration defect. Fenestrations are exposures of the implant's axial surface that do not include the coronal aspect of the implant. Dehiscence defects are those that expose a part of the axial surface including the coronal aspect of the implant while maintaining sufficient bone volume around all remaining implant surfaces. In a dehiscence defect, the implant remains within the confines of the existing bone.

Fenestration and dehiscence defects have been managed with barrier membranes or simply with flap closure. Bone grafts have also been used. The only controlled comparison studies between a membrane treatment and a periosteal flap coverage of exposed implant surfaces in humans demonstrated that the membrane treatment was far superior with regard to bone fill.[10] Another controlled study in humans evidenced better results in the membrane groups; 4 of 6 sites treated with a membrane resulted in 95% to 100% elimination of the dehiscence and total coverage of the threads. In the control sites, only 2 out of 6 sites showed moderate to complete bone fill.[45] All other clinical studies are in the form of case report studies.[40] Fig. 71-2, *M* demonstrates coverage of an implant dehiscence using a barrier membrane. Admittedly, without a biopsy, it cannot be determined whether the tissue covering the implant is bone or firm connective tissue.[25,26]

A 1-year multicenter study evaluating 55 dehisced implants in 45 patients, treated by membrane alone, demonstrated an average bone fill of 82%.[11] The average initial defect size was 4.6 mm. The 1-year follow-up of these implants demonstrated a favorable response to loading. Of the 55 implants a total of 6 failed, corresponding to a cumulative survival rate of 84.7% in the maxilla and 95% in the mandible, which is similar to previously published results.

A clinical report on the use of titanium-reinforced (TR) membranes demonstrated the biologic potential to fill a large protected space in 4 patients. The dehisced implant sites ranged from 5 to 12 mm (mean 8.2 mm). They were covered with a TR membrane alone. Reentry after 7 to 8 months of submerged healing found complete bone coverage of the implants. Radiographic evaluation demonstrated the implants functioning with normal crestal bone support after 1 year.[23]

No clinical comparisons are available in the literature evaluating the placement of bone grafts with or without membranes on dehisced implant surfaces. Most evidence supports the use of graft materials in conjunction with membrane treatment, especially the use of freeze-dried bone allografts (FDBA) in conjunction with GBR. In a study with 40 patients, 110 implants were placed in conjunction with barrier membranes and FDBA grafts; a success rate of 96.8% was achieved with complete bone fill (defined as >90% fill of dehiscence). This study reported an exposure rate of 29% of the membranes, but little effect on the bone regeneration was noted.[47]

Another study evaluated the treatment of dehiscence type bone defects associated with the placement of implants into fresh extraction sockets.[30] Augmentation procedures were conducted with demineralized FDBA particles and e-PTFE membranes. Complete flap closure resulted in complete bone regeneration. Histologic evaluation revealed remnants of the graft material and large areas of vital bone tissue as evidenced by distinct osteocytes. Both woven bone and lamellar bone were observed in direct contact with graft particles. In a 1-year postgrafting biopsy, DFDB particles were still present and osteoblasts were observed engaged in bone formation. Fig. 71-2, *L, M* demonstrates a simultaneous GBR and implant placement in a dehiscence defect.

Supracrestal/Vertical Bone Augmentation

Supracrestal or vertical bone augmentation (Fig. 71-3) presents the greatest challenge in terms of regenerating bone for implant placement. The available evidence related to GBR- associated. and supracrestal implant placement is limited.

Some published studies have evaluated the effect of space creation by a membrane alone or with an autograft. In one clinical study, 5 patients were treated with a supracrestal exposure of 3 to 7 mm (average of 4.67 mm) and showed a clinical bone gain of 0.5 to 4 mm (average of 2.97 mm) after 9 months.[58] The second study evaluated the treatment of an average supracrestal implant exposure of 2.7 mm in a dog study and resulted in a histometric supracrestal bone gain of 0.9 to 4.0 mm with good bone-to-implant contact.[24] The space underneath the membranes in the two studies was filled with new bone 64% and 70%, respectively.

Another experimental dog study evaluated implants with supracrestal implant dehiscence. The membrane resulted in 83% of the defect fill with new bone and a higher interface contact than other graft treatments with or without membrane. The incorporation of bone grafts covered by membranes demonstrated that graft sites without membranes around implants tended to be less well preserved then membrane-covered sites. The membrane treatment preserved the bone graft volume by 70% or greater. The membrane also helped increase bone-implant contact of the incorporated bone graft.[10] All three studies showed that supracrestal bone formation up to 3 mm is predictable using the GBR technique with a membrane-blood clot combination.

Simion[58] and Jovanovic" used a titanium reinforced membrane for vertical bone regeneration around dental implants. No supportive bone substrates were used, except a careful fill of space with a blood clot by perforating the bone surface or injecting it with venous blood. Although the ridge defects varied-one had a wide resorbed bone base and the other a narrow resorbed bone base-significant supracrestal bone regeneration was evident in both studies. The variation in supracrestal bone

regeneration achieved (3.3 mm versus 1.82 mm) in these studies might be explained by the difference in residual bone base at the beginning of the study and the difference in method used to evaluate the results (clinical versus histomorphometric). Recent studies showed that supracrestal bone formation is more predictable using a TR membrane and bone graft filler material. Therefore at present, an advanced surgical reconstruction technique for vertical bone gain is always combined with an autograft material and a nonresorbable TR membrane. (See Fig. 71-3, A-G). A recent 5-year clinical study has demonstrated that vertically augmented bone can be maintained with loaded implant restoration.[67]

Distraction Osteogenesis

This surgical technique has been developed to increase vertical bone height in the deficient jaw site and is in contrast to the more conventional method of bone grafting with or without membranes. Under the proper circumstances, most cells in bone can differentiate into osteogenic or chondrogenic cells needed for repair. The process of generating new bone by stretching, referred to as *distraction osteogenesis,* was introduced by Ilizarov.[18,19]

Based on experimental and clinical studies over 35 years, distraction osteogenesis can provide a surgeon with the possibility of treating extremities, small bones in hands and feet using external fixation devices. Recently, new intraoral devices for vertical bone growth of the alveolar process have been developed and successfully applied before dental implant placement. Other important advantages of distraction osteogenesis are that no second surgical site is needed to harvest bone and the newly created bone has native bone at the crest, which can withstand forces better than fully regenerated bone.

The application for vertical bone augmentation has shown a broad use in the preprosthetic surgical indication with good predictability, although limitations have been encountered to develop horizontal bone growth with this method. A frequent need for secondary bone grafting is seen in the extremely resorbed jaw.

MANAGEMENT OF EXTRACTIONS

Because tooth extraction (or tooth loss) often results in alveolar ridge resorption or collapse, preservation of bone volume at the time of extraction is a desirable goal. A majority of the bone loss after extraction occurs within the first 6 to 24 months.' Therefore when clinicians are afforded the opportunity to intervene at the time of extraction, the preservation of alveolar bone should be initiated. A conservative approach to the management of extraction sites can eliminate or significantly reduce the necessity of advanced bone augmentation procedures.

When extracting a tooth and preparing for implant placement, it is highly desirable to prevent alveolar bone resorption. Experimental animal studies have shown that the use of a barrier membrane enhances the predictability of bone fill in the extraction site and therefore maintains original bone volume when compared with mucoperiosteal flap coverage alone.[6] Clinical studies have also demonstrated the benefits of a regenerative approach to tooth extraction.[35,36,43] These authors found that a nonresorbable barrier membrane resulted in minimal resorption of alveolar ridge size and shape.

Although earlier studies have proposed **the concept** of treating extraction sites without flap closure (i.e., an exposed membrane used to cover the graft), recent studies concluded that complete wound closure over the physical barrier might be associated with greater bone fill.[5,55]

The timing of implant placement relative to the time of extraction has been debated by many clinicians. Depending on the quantity, quality, and support of existing bone as well as the preferences of the clinician and patient, the placement of implants after tooth extraction can be immediate, delayed, or staged. By definition, immediate implant placement occurs at the time of extraction. Delayed implant placement is performed approximately 2 months postextraction to allow for soft tissue healing. Staged implant placement allows for substantial bone healing within the extraction site that typically requires 4 to 6 months or longer.

Immediate Implant Placement

The primary advantage of immediate implant placement is the reduction of the healing time.[34,41,50,63] Because the implant is placed at the time of extraction, the bone-to-implant healing begins immediately with extraction site healing. Another advantage is that the normal bone healing, which generally occurs within the extraction site, takes effect around the implant. This bone-forming activity may enhance the bone-to-implant contact as compared with an implant placed in a less osteogenically active site. Possible disadvantages of immediate implant placement include the need for mucogingival surgeries and bone grafting around the implant.

When a two-stage implant is placed at the time of tooth extraction, the mucogingival flap must be advanced to completely cover the implant (exception = one-stage implants). It may also be necessary to graft bone into the extraction site in areas that do not contact the implant to avoid soft tissue invasion around the implant." A 1-year study of 49 immediate extraction site implants treated by a membrane alone demonstrated a 93.6% bone fill. After 1 year (postloading), the implant success rate was 93.9%.[5]

The placement of 21 transmucosal implants in immediate extraction sites treated with a barrier membrane were tested for the implant success rate and the bone fill. Of 21 transmucosal implants, 20 yielded complete bone fill and coverage of the entire plasma-coated implant surface." More clinical review is needed before it can be **suggested to treat more advanced bone defects with transmucosal** implants. Until then, submerging implants is preferred.[22]

A clinical report on the use of resorbable collagen membranes around extraction site implants demonstrated a variable degree of bone fill in 9 patients.[46] More clinical review of the use of resorbable membranes for GBR is required because evidence is insufficient to properly evaluate the predictability.

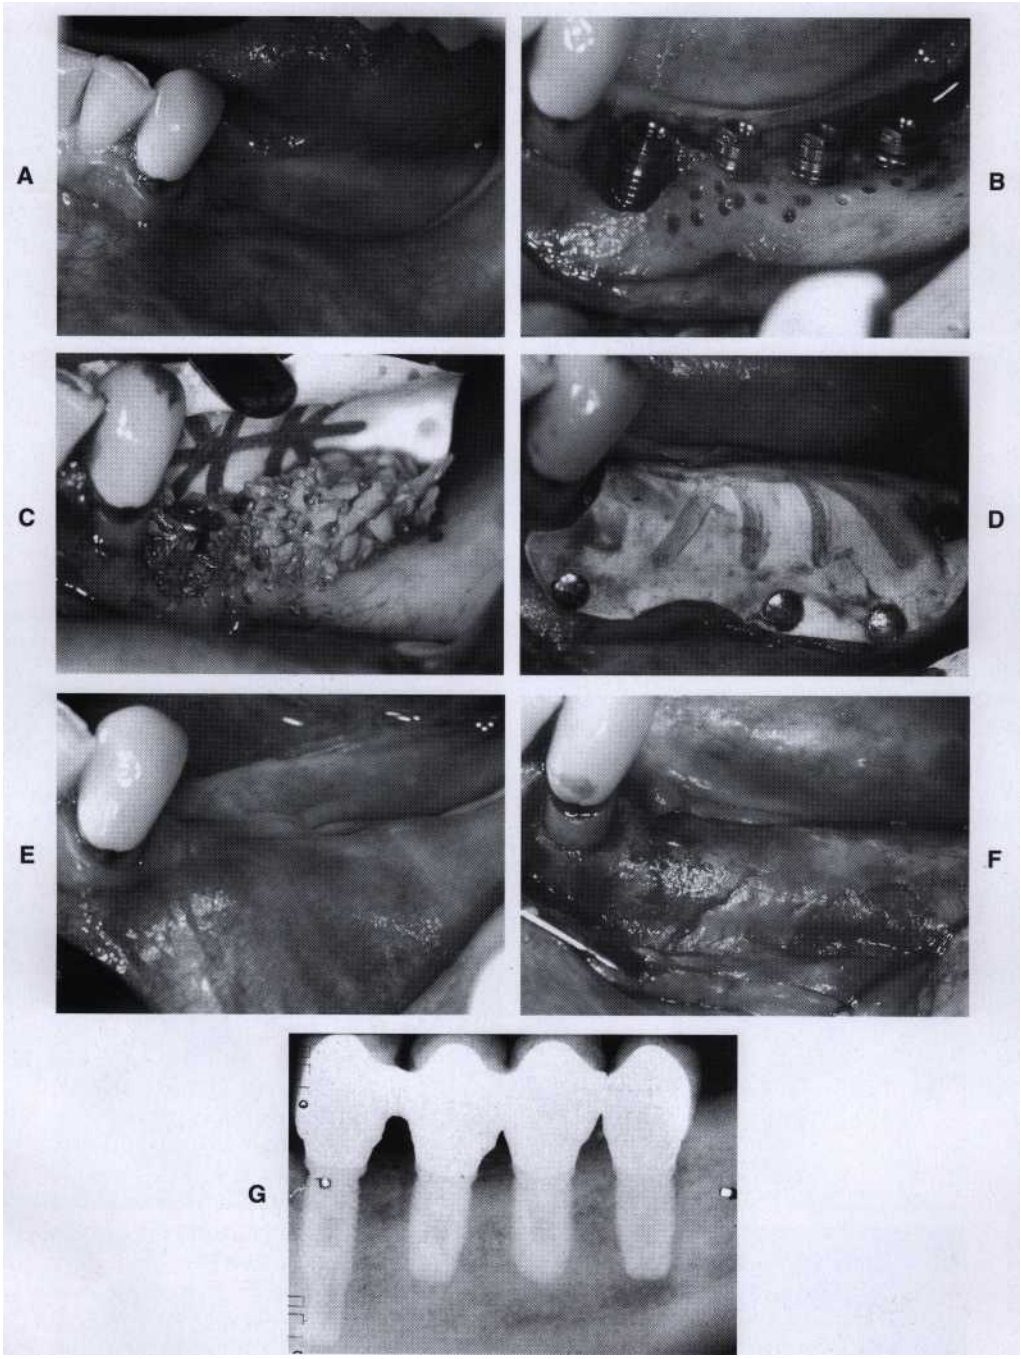

Fig. 71-3 Vertical bone augmentation. A, Partially edentulous patient with a vertically resorbed posterior mandible, with 5 mm from the mandibular canal to the bone crest. Note the normal periodontal level around the anterior teeth. B, After full-thickness flap elevation and implant placement, a supracrestal position of 2 to 4 mm was achieved. The most anterior implant was 15 mm in length (mesial to the mental foramen) and the three posterior implants were 8.5 mm. Note the perforations in the cortical bone to open the marrow spaces and allow for blood supply. C, After an autogenous bone graft was harvested from the ramus and particulated, a nonresorbable, titanium-reinforced e-PTFE membrane (TR-9Y) was trimmed and fixated with two pins on the lingual to act as an envelope for the bone graft. D, The membrane was closed on the buccal and fixated with four pins. Note the safety margin **between the membrane and the tooth and** the mental foramen of a minimum of 2 mm. E, Closure of the surgical site by periosteal release of the buccal and lingual flap. After advancement of the buccal flap and the lingual floor of the mouth, tension-free closure was achieved with a horizontal mattress and interrupted sutures. During an uneventful healing of 7 months, no prostheses was inserted. F, After full-thickness flap elevation and membrane removal, a vertical and horizontal bone gain of more than 5 mm was evident. Note that the vertical augmentation procedure with guided bone regeneration achieved vertical and horizontal bone reconstruction around the previously exposed implant surfaces. G, Radiograph after 1 year of loading shows normal maintenance of bone structures around the implants.

If inadequate bone exists to stabilize the implant, immediate implant placement is not recommended. Finally, there is potential for preexisting infections associated with the tooth to adversely affect the healing and implant success. Acute or subacute infection is a contraindication to immediate implant placement.

In a study of 30 patients, the use of autografts alone in 54 simultaneous extraction site implants was highly effective for implants placed completely within the envelope of bone. The study showed that extraction sites, including those with a buccal dehiscence, could be treated with autografts alone. Because ungrafted sites were not evaluated, the absolute need to graft small defects adjacent to implants was not ascertained by this study.[3] In another study, implants placed in extraction sockets were tested for their potential to regenerate bone with allograft alone, a membrane alone, and a combination treatment. Reentry confirmed 100% thread coverage in all but one implant in the no-wall group treated with DFDB alone.[15]

A clinical study of 5 patients evaluated different treatment modalities for extraction site implants together with bone graft combinations. It was demonstrated that non-spacemaking defects are best treated with a combination of a barrier membrane with an autograft or allograft and achieve better results than a nonreinforced membrane without graft."

Delayed Implant Placement

A delayed implant placement shares some of the advantages afforded by immediate implant placement, namely extraction site preservation, and offers some additional advantages. Unlike immediate implant placement, which is deficient of soft tissue for coverage, the delayed implant placement technique allows time for soft tissue healing.[22] The delayed placement technique still reduces the length of treatment time by several months because it is not necessary to wait for complete bone healing. Furthermore, because bone formation is active within the first few months after tooth extraction, the delayed technique may facilitate more osteogenesis adjacent to the implant. The primary advantage of delayed implant placement is that by allowing for soft tissue healing and closure of the extraction site, mucogingival flap advancement is not necessary. This alleviates the need for additional surgeries to correct mucogingival discrepancies. Delayed implant placement also allows time for resolution of infections that may have been present within the extraction site. As with immediate implant placement, similar limitations of bone support and implant stability exist. The normal osseous healing that occurs within the first 2 months does not significantly affect the anatomy of the alveolar ridge. Hence limitations in bone support after 2 months of healing are similar to those that exist at the time of extraction.

Staged Implant Placement

A staged implant placement allows adequate time for osseous healing. This may be complete osseous healing of an extraction site without a bone graft (if circumferential bone support is good) or with a bone graft. Staged implant placement, by definition, allows for complete hard and soft tissue healing and permits the placement of implants into prosthetically driven positions with adequate coverage by hard and soft tissues." This eliminates the necessity of mucogingival flap advancement, allows for the resolution of preexisting infections, and prevents soft tissue invasion. Furthermore, by using an extended healing period, the grafted bone also has the opportunity to become vascularized. Bone grafts performed simultaneously with implant placement do not share this advantage. The primary disadvantage of staged implant placement is the length of time required for bone healing.

Surgical Technique. Delayed and staged implant placement techniques are demonstrated in one individual using two extraction sites with similar bone morphologies in the anterior maxilla (see Fig. 71-2). Both techniques facilitate the esthetic placement of implants into prosthetically driven positions. They maintain alveolar bone volume, reduce the need for advanced bone augmentation and eliminate the need for subsequent mucogingival surgery. The timing and management of delayed versus staged implant placement techniques vary as described in the following section.

To decide which implant placement method to use, the quantity and location of bone surrounding the tooth should be assessed. Once the patient has been anesthetized, a periodontal probe can be used to "sound" for the level of bone support through the soft tissue. Using this method, the bone levels surrounding the tooth can be mapped. Bone support that surrounds the extraction site can also be evaluated and confirmed after tooth removal by palpation, probing, and direct (internal) visualization.

If the tooth to be extracted has sufficient bone support on all surfaces, then the extraction site can be expected to fill with bone without any additional augmentation procedures except when the labial bone is very thin. A simple extraction followed by a healing period of 4 to 6 months would be sufficient for complete osseous healing. Subsequently, an implant could be placed in the usual manner without the need for bone augmentation. Conversely, if little or no bone exists on the labial surface, it should be anticipated that the site would require bone augmentation to facilitate placement of the implant. In this case, bone grafting at the time of extraction can be used to maintain the alveolar ridge dimensions occupied by the tooth.

Tooth extraction is managed with an atraumatic surgical technique that uses a narrow, flat instrument (Periotome, Hu-Friedy Mfg. Co., Inc., Chicago, IL) directed apically into the sulcus to sever the periodontal ligament and slightly expand the adjacent periodontal tissues. The tooth is elevated and removed with forceps using a gentle, rotational movement. Buccolingual forces are avoided to prevent damaging the integrity of the labial bone. No incisions are made, and care is taken to avoid soft tissue reflection. In this manner, soft tissues maintain their structural anatomy, and the periosteum (blood supply to the bone) remains intact. If the tooth has multiple roots, curved roots, or other anatomic features that

make removal difficult, it may be necessary to cut the tooth using a high-speed drill and remove it in smaller pieces. It is important to cut only tooth structure and avoid cutting (overheating) bone when using high-speed drills. The bone within the extraction site is completely debrided of soft tissue with surgical curettes. After debridement, the extraction site is thoroughly irrigated with sterile saline. At this point, bone level and support is evaluated and a decision is made whether to bone graft the site and when to place the implant, immediate, delayed, or staged.

SINUS ELEVATION AND SINUS BONE GRAFTING

Rehabilitation of the edentulous posterior maxilla with osseointegrated implants often represents a clinical challenge because of the insufficient bone volume resulting from enlargement of the maxillary sinus and crestal bone resorption. In situations where the interarch distance is normal or moderately reduced, grafting of the maxillary sinus is indicated. In this procedure, the lateral wall of the maxillary sinus membrane is elevated prior to grafting of the new sinus-floor cavity. In cases demonstrating sufficient crestal bone height, a sinus lift approach can be taken through the implant osteotomy. Several recent clinical studies and reports have attempted to evaluate the maxillary sinus augmentation procedures using a variety of bone grafting materials such as autogenous bone from iliac crest or the oral cavity, **as well as bone substitutes such as freeze-dried demineralized bone, resorbable and nonresorbable** hydroxyapatite, and xenografts. However, only a few studies have critically evaluated the long-term clinical outcome of this procedure, and most of these have used a small study population.

Short- to long-term clinical studies on the survival of dental implants placed into grafted sinuses demonstrate a similar or even higher survival rate reported in previous studies for implants placed in the maxilla without a sinus augmentation procedure.[21] The results of these studies support the clinical predictability of maxillary sinus augmentation procedures for the rehabilitation of the edentulous posterior maxilla with implant-supported prostheses. It should not be underestimated that the sinus graft is a technique-sensitive procedure, which requires surgical and prosthodontic skills. Complications can include tearing of the sinus membrane, infection of the graft, or loss of implants.

THE ROLE OF GROWTH FACTORS IN BONE AUGMENTATION

Another adjunct to regenerative therapy is osteogenic stimulating substrates to enhance bone formation. One group is the bone morphogenetic proteins (BMPs), belonging to the transforming growth factor R (TGF-/3) superfamily. Of this family, recombinant human bone morphogenetic protein (rhBMP-2) has shown significant signs of bone-enhancing potential.

Recently, studies showed substantial preclinical data of rapid new bone formation using rhBMP-2 in critical size defects. The potential of combining barrier membranes and rhBMP-2 for osteogenesis is evident.

The inductive capacity of recombinant human rhBMP-2 was demonstrated by impregnating a polymer carrier and placing the substrate in critical-sized rat mandibular defects with or without a barrier membrane.[37] The study evaluated 12- and 24-day healing times and showed a bony union of the defects for BMP treated sites. The membrane by itself took up to 6 weeks before full healing was evident. The authors concluded that rhBMP-2 can be used with or without a barrier membrane but that the membrane might function as a space maintainer.

Platelet-Rich Plasma: Growth Factor Enhancement for Bone Grafts

In recent years, a new approach to enhance the vitality of bone grafts has been introduced by using platelet-rich plasma (PRP).[39] PRP is an autologous source of platelet-derived growth factors and transforming growth factors that is obtained by sequestering and concentrating platelets by centrifugation. The patient's own blood is withdrawn and separated into its three basic components. The PRP is the important content, which contains a high mixture of platelets and a concentration of growth factors. This PRP mixture is added to the autologous bone graft and has shown to increase the quality of and reduce the time needed for bone regeneration. Clinical and experimental studies are scarce but suggest that this technique holds promise for large bone defects or bone defects with low osteogenic potential. Extrapolation to the effect PRP might have on other bone filler materials cannot be made at this time.

Complications of Localized Ridge Augmentation

Advanced procedures such as GBR and bone grafting to increase the bone volume in deficient alveolar ridges have been successful and have enabled the placement of implants into prosthetically driven positions.[53] Unfortunately, these advanced procedures carry an increased risk of morbidity and can require secondary surgeries to correct soft tissue changes resulting from the procedure." For example, keratinized tissues that have been advanced to cover an increased volume of bone create unaesthetic and non-load-bearing mucogingival discrepancies. The subsequent corrective surgeries required to correct mucogingival discrepancies add surgical time and complexity to the implant therapy.

Surgical complications are reported for a variety of bone reconstructive techniques." The use of bone grafts from the hip to rehabilitate extremely resorbed maxilla has reported exposure of bone transplants in up to 30% of the cases." The exposure rate usually correlates with an increased loss of transplanted tissue. Fenestration defects have the least risk and immediate extraction sites have the highest risk for membrane exposure.

A recent review of the literature assessed the number and types of complications associated with bone reconstructive procedures for endosseous implants. The review

of literature (published from 1976 to 1994) included 2315 implants in 733 autogenous block, particulate, and various other bone graft materials. Complications reported included bleeding, postoperative infection, bone fracture, nerve dysfunction, perforation of the mucosa, loss of a portion of the bone graft, pain, decubital ulcers, sinusitis, and wound dehiscence. Wound dehiscence seemed to have the most deleterious effect on implant survival.[60] This finding emphasizes the importance of flap management as discussed previously.

Typical findings include less bone fill with an early exposure and membrane removal as compared with retaining the membrane without exposure for 6 to 8 months.[21,11] Buccolingual ridge deficiencies were treated in a prospective study involving 19 patients using e-PTFE membranes and miniscrews as fixation and tenting devices. The group of defects, which healed uneventfully, yielded upon reentry a 90% to 100% bone regeneration compared with the maximal volume of the space defined by the membrane placement. In the exposed membrane group, the percentage of regenerated bone ranged from 0% to 62%. When a late membrane removal was performed (i.e., 3 to 5 months postsurgically), the regeneration varied between 42% and 62%. The authors concluded that the length of membrane healing and size of the defect played a significant role in the amount of new bone formation."

Other authors have reported successful bone fill in situations where the membranes had to be removed because of an early exposure.[44,14] The use of a bone graft material under the membrane might account for the difference in results. This was confirmed in a clinical study evaluating 36 patients with 23 TPS implants and 20 HA-coated implants placed in immediate extraction sites and treated with membrane alone or membrane in combination with DFDB grafts." When the effect of membrane exposure on bone gain was compared with membranes that remained covered, a significant difference was seen between the covered membrane group and the exposed membrane group but no difference with the exposed membrane/DFDB group. A significantly greater fill of the osseous defects at the grafted sites was noted. The authors concluded that the regeneration of bone around the implants appeared most dependent on the anatomy of the bony defect at the time of implant placement.

Although the effect or amount of regenerated bone with regard to membrane exposure is somewhat contradictory, the aim should be to keep the membranes covered during the healing period so that the risk of infection and soft tissue and esthetic problems can be eliminated. Again, the importance of flap management for ridge augmentation procedures should be stressed.

It can be concluded that the selection of a localized ridge augmentation procedure depends on the size and dimension of the osseous defect. In cases of advanced bone resorption, ridge augmentation before implant placement may be a better choice. It seems reasonable to conclude that the predictability for bone formation is better in horizontal ridge augmentation procedures when compared with vertical ridge augmentation. This conclusion was also made for total maxillary and mandibular ridge reconstruction with calvarial bone grafts because the implant survival rate was increased in cases with horizontal grafting when compared with vertical grafting techniques.[14]

LONG-TERM RESULTS OF IMPLANTS PLACED WITH/AFTER BONE AUGMENTATION PROCEDURES

Long-term data (more than 3 years) of **the** outcome of the membrane technique is scarcely available, and the few reports that **have addressed the question** of how regenerated bone behaves under functional loading with dental implants have shown a favorable result. A canine study showed that implants placed in regenerated bone have a normal interaction with the surrounding bone, resulting in direct bone-to-implant contact within 3 months. A loading period of 6 months demonstrated that the regenerated bone is capable of bearing functional load and reacts similarly to nonloaded regenerated bone sites. Regenerated bone sites that did not receive an implant demonstrated bone atrophy beneath the membrane.

One-year clinical follow-up data is available for implants placed in extraction sites with dehiscence or fenestration-type defects grafted with bone using a membrane-technique. All were comparable to normal implant sites.'-11 A multicenter study determining the predictability of implants placed in immediate extraction sockets and augmented by e-PTFE membranes showed an implant survival rate of 93% after 1 year of loading.' Nonstandardized radiographs were evaluated for bone loss after an average loading of 7.5 months.

Dehiscence type defects were analyzed in 2 separate studies. Dahlinl' demonstrated in a multicenter study that implants with regenerated bone withstood loading for 1- to 2-year evaluation periods and demonstrated a cumulative survival rate of 84.7% in the maxilla and 95% in the mandible, which is in line with previously published work with the Branemark implant-type.

Jovanovic[25] treated 19 dehisced implants with a membrane technique and demonstrated a 6- to 12-month loading result of 100% implant survival. Radiographic analysis demonstrated an average of 1.73-mm mesiodistal bone loss. Differences between studies are related to the measurement method because the choice of a reference point can add or subtract 0.6 mm. If subtracted, a total crestal bone level remains of 1.13 mm, which is in line with other long-term studies of implant loading.

Simion et al" demonstrated in a 1- to 5-year clinical follow-up that vertically regenerated bone can be loaded by dental implants successfully and that the periimplant bone structures are maintained similar to implants placed in native, nonregenerated bone.

CONCLUSIONS

Bone augmentation and advanced implant surgery procedures have been described that allow clinicians to reconstruct alveolar bone deficiencies and replace missing teeth with dental implants in a prosthetically driven position with natural appearance and function. The

predictable outcome of these procedures is dependent on several biologic principles that must be followed. Diagnosis, treatment planning, careful execution of the surgical treatment, postoperative follow-up, and appropriate implant loading are all important factors in achieving success.

IMPLANTS IN THE ESTHETIC ZONE

Controlled clinical research in implant prosthodontics showed excellent long-term results achieved after appropriate case selection, good occlusal harmony and oral hygiene, and careful handling of patients' soft and hard tissues. With these results the placement of implants has become one of the most beneficial surgical procedures performed in connection with prosthodontic procedures and treatment modalities. It has also provided a high psychologic impact and improvement of quality of life for completely and partially edentulous patients.

After the first year of implant function, loss of marginal bone is small around most oral implants. However, clinical studies have shown a correlation between insufficient oral hygiene, occlusal overload, and progression of bone loss around dental implants. In general, occlusal loading can affect the prognosis of both implants and prosthetic reconstructions in implant dentistry. The occlusal load may exceed the mechanical or biologic load-bearing capacity of the osseointegrated oral implants or the prosthesis, causing either a mechanical failure or failure in the osseointegration. If this happens, the load can be defined as an overload.

IMPLANT BIOMECHANICS

It is becoming clear that a knowledge of implant biomechanics is essential if implant-supported restorations are to be employed predictably. The load-bearing capacity of implants supporting the restoration must exceed the loads anticipated during function. If the loads applied exceed load-bearing capacity of the implants, implant overload may be the result, and a resorption remodeling response of the bone around the implants is provoked.

Several factors affect the load-bearing capacity of implants (Fig. 72-1), including implant length, the number of implants used, their arrangement, and their angulation in relation to the plane of occlusion .[2, 15] The quality of the bone implant interface (bone anchorage, or bone appositional index) also greatly influences the load-bearing capacity of implant-supported restorations .[21,18,19,22]

The bone appositional index is particularly influential (see Fig. 72-1). For example, bone anchorage of implants in the posterior maxilla is particularly poor compared with the anterior mandible. As one progresses posteriorly in the maxilla, the trabecular bone is less dense, the cortical layer is thinner, and as a result the bone appositional index in the posterior maxilla may be one third to one half

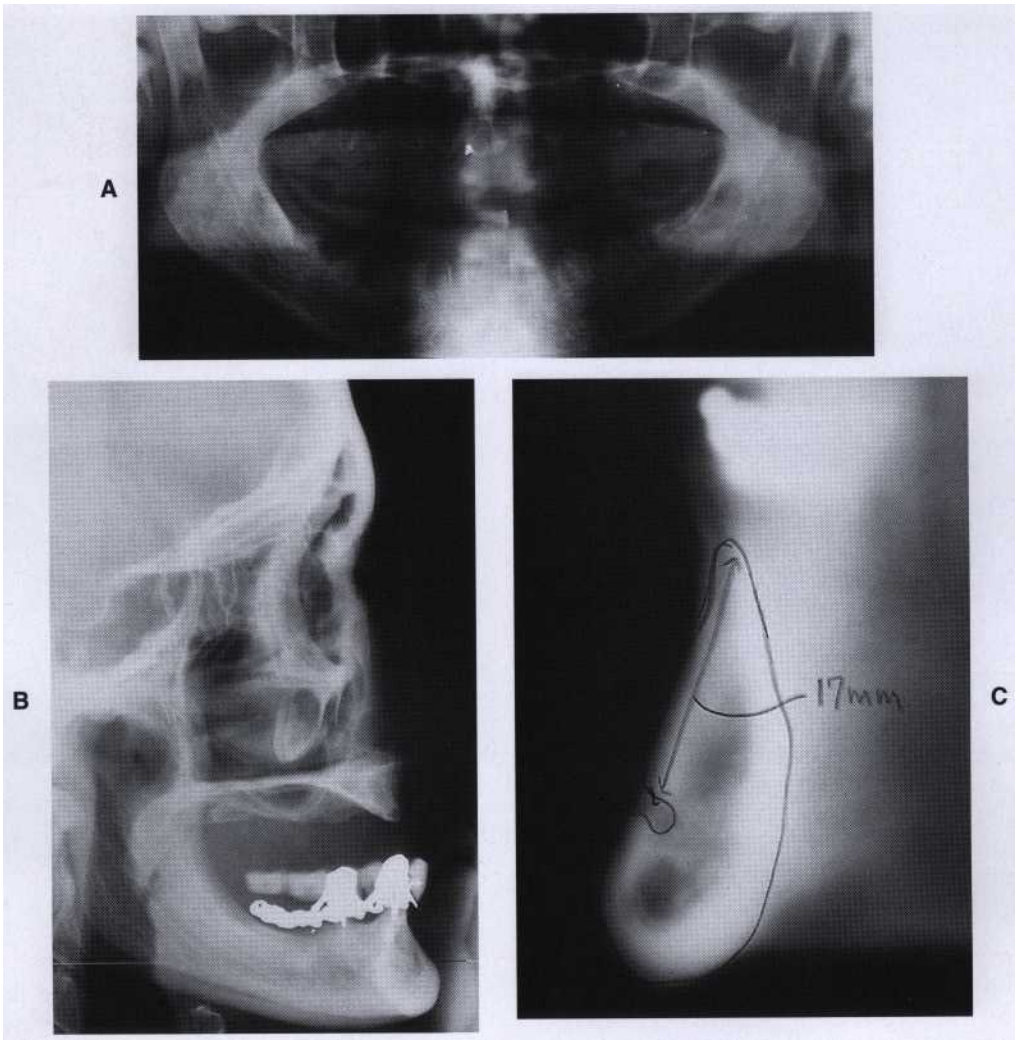

Fig. 72-1 Different radiographic procedures used in implant dentistry. A, Panoramic radiograph. B, Lateral cephalometric radiograph. C, Tomogram of mandibular premolar area.

of that achieved in the anterior mandible. In addition, pneumatization of the maxillary sinus limits the lengths of implants used, further reducing the load-carrying capacity of implants placed in this region.

The number of implants used obviously affects load-bearing capacity (see Fig. 72-1). In the 1980s and early 1990s, many posterior quadrants of the maxilla were restored with one or two implants, and in some patients these implant restorations supported 3 or 4 dental units. In many instances, soon after loading, a distinct pattern of bone loss was observed that led to loss of the implants in many patients. Additional implants significantly improve the biomechanics of these implant-supported fixed partial dentures. Today, when restoring the posterior quadrant of the maxilla, an implant is placed for every tooth restored. There is no unanimous opinion on the number of implants to be used, and extreme positions are championed, such as installing as many implants as possible. However, in general, the tendency at present is to reduce the number of implants.

The angulation of implants (see Fig. 72-1) in relation to the plane of occlusion and the direction of the occlusal load is also an important factor in predicting the success-failure rates of implants used to restore posterior quadrants. In the 1980s, prior to the utilization of the sinus lift and graft, many implants placed in the posterior maxilla exhibited excessive buccal angulations. In addition, many implants placed in the mandible presented with excessive distal angulations. A high percentage of such implants exhibited signs of implant overload (i.e., bone loss around the neck of implants that was progressive and irreversible) after delivery of the prosthesis.

Minor discrepancies in angulation are probably not clinically significant, but if loads are at an angle of 20 degrees or more to the long axis of the implant, load magnification can result, provoking a resorptive remodeling response of the adjacent bone.[2] The combination of short implants in poor-quality bone, where occlusal loads are delivered at angles of 20 degrees or greater along the long axis of the implants, make implants

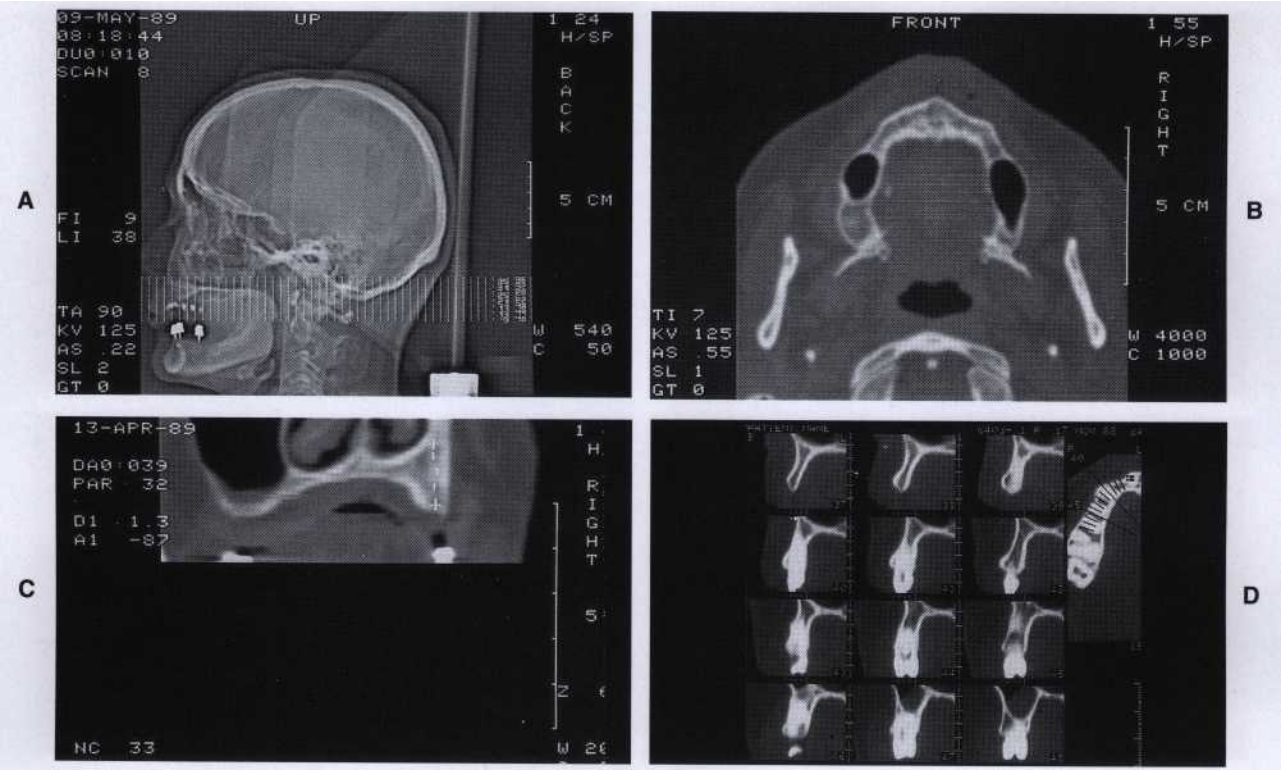

Fig. 72-2 Computed tomographic scans. A, Sagittal view. B, Occlusal view. C, Cross-sectional view. D, Cross-sectional reformatted view.

prone to implant overload, leading to progressive and irreversible bone loss and implant failure.

In clinical situations, the risk of implant overload can be minimized by limiting the width of the occlusal table of the implant-supported fixed partial denture, flattening the cusp angles, avoiding the use of cantilevered restorations, and restoring the anterior guidance provided by the residual anterior dentition. In addition, designing the restoration so that it is independent of the natural dentition simplifies the biomechanics.

EDENTULOUS MAXILLA

Although a conventional denture may be satisfactory for most edentulous maxillas, implants may be desirable in some situations. When a conventional maxillary denture is only marginally stable, the patient may not be aware of the problem when the conventional mandibular denture is even more unstable. If the mandible is restored with a stable implant-assisted overlay denture, the patient becomes aware of the deficiency of the maxillary denture and requests the same type of stability for the maxillary restoration. Another indication for implants in the maxilla may be to offset the potentially destructive effects on the premaxillary area when an edentulous maxilla is opposed by a mandible with natural anterior teeth.

Many patients may feel a psychologic need for either a palateless denture or better retention. The four implant-assisted, palateless overlay denture ideally addresses the needs of most patients (Fig. 72-2). It is usually unsatisfactory to construct a fixed prosthesis in the completely edentulous maxilla unless an unusual amount of alveolar bone is present. The usual resorption pattern of the alveolus places the gingival margin of a fixed restoration too far superiorly, too far palatally, or both. Even if the patient has a low smile line, a lack of lip support just beneath the nose can be unsightly. Most patients are best served with implant-assisted overlay dentures.

EDENTULOUS MANDIBLE

Implant-assisted overlay dentures are most commonly employed. An implant-assisted denture is designed so that most of the masticatory load is borne by the primary denture-support areas (retromolar pad, buccal shelf). A common practice is to place two implants in the anterior mandible with a connecting bar. The denture is retained by two clips over the bar. When an occlusal force is applied posteriorly, the denture rotates around the bar, directing the force into the primary denture support areas (Box 72-1).

Fixed implant-supported prostheses require four to six implants arranged in an appropriate arc of curvature (Fig. 72-3). Many patients prefer this option for psychologic reasons, but the mastication efficiency provided by this prosthesis is little better than that provided by an implant-assisted overlay denture. However, evidence suggests that such fixed restorations tend to stop resorption

of the body of the posterior mandible and in some cases enable regeneration of the bone in this region.

PARTIALLY EDENTULOUS PATIENTS: POSTERIOR QUADRANTS

Anatomic Limitations

Anatomic limitations may prevent placement of implants of adequate length in the posterior quadrants. In the posterior quadrants of the maxilla, the maxillary sinus limits the lengths used, and in the mandible the inferior alveolar nerve limits the lengths of the implants used. In the posterior quadrant of the maxilla, the bone-implant interface or the bone anchorage for osseointegrated implants is compromised because the bone quality is poor. Primary anchorage for an implant placed in this region is provided by the implant engaging the cortical bone of the floor of the sinus and the cortical bone on the alveolar ridge. There is generally very little bone-implant interface along the course of the implant, and if the tip is not properly anchored in the cortical bone in the floor of the sinus, the implant may fail during occlusal loading. The use of implants with rougher surfaces may improve the bone anchorage in poor-quality bone but still may not provide all patients with sufficient anchorage to support unilateral implant-supported fixed partial dentures if the implants are too short.

Because many patients possess insufficient bone in the posterior maxillary quadrant to receive an implant of suitable length, bone augmentation of the alveolar ridge or maxillary sinus has been suggested.[12,22] Free bone grafts taken from the chin, iliac crest, or other locations, often mixed with bone substitutes, are now being used to supplement the existing bone at these sites.[23]

Augmented posterior maxillary sites created by elevating the sinus membrane and placing bone grafts in this region appears to be most successful in supporting implants, particularly if a minimum of 5 mm of residual bone is available over the sinus with which to anchor the neck of the implant. The success rates, however, appear to decrease when less than 5 mm of bone is available over the sinus, presumably because a majority of the site is composed of grafted bone.

In the mandible, the limiting factor with respect to implant placement is the presence of the inferior alveolar nerve. Based on clinical data, the authors feel the minimum length for implants used to restore posterior mandibular quadrants, regardless of implant width, is 10 mm. Implants less than 10 mm should not be used

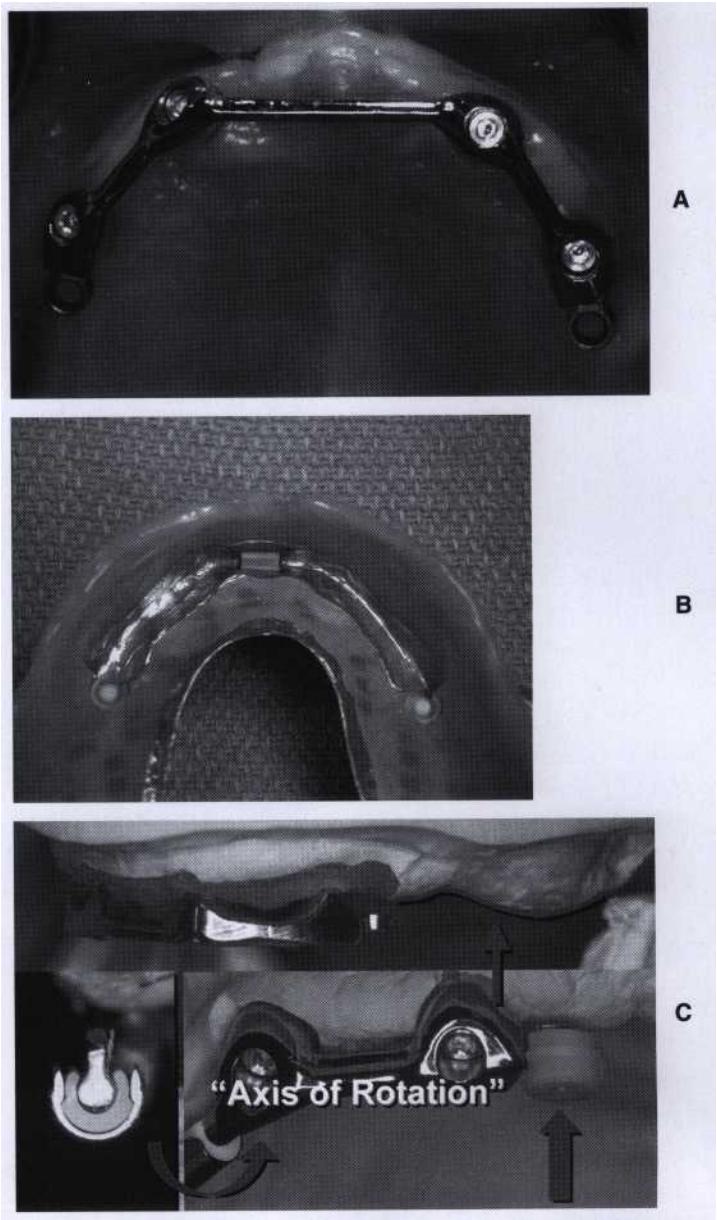

Fig. 72-3 A and B, Four-implant, palateless, overlay assisted design. C, When posterior occlusal forces are applied, the denture rotates around the bar clip anteriorly and resilient attachment (arrow) allows the denture to be compressed to primary denture support areas posteriorly (arrow).

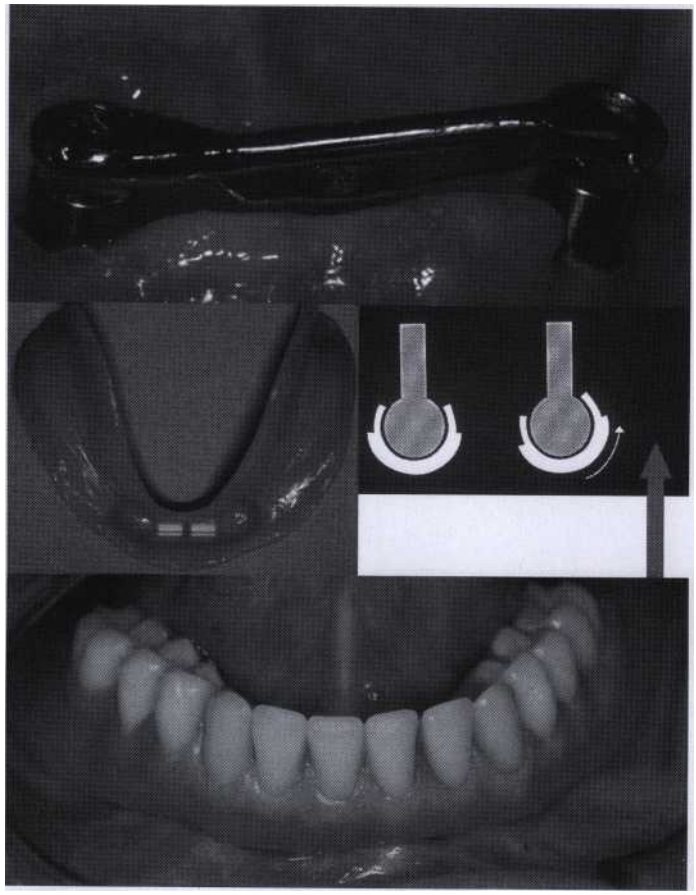

Fig. 72-4 Implant-assisted overlay denture using a bar clip design. When the patient applies occlusal force posteriorly, the overlay denture rotates around the bar and the load is absorbed by primary denture-bearing surfaces posteriorly.

because the bone anchorage of the implant is not sufficient to support posterior occlusal forces. These factors, in combination with the linear configuration of the implants, suggest that 10 mm is the minimal length that should be used for implant supported fixed partial dentures used to restore posterior mandibular quadrants.

When bone for placement of a 10-mm implant is insufficient, some clinicians have recommended that the inferior alveolar nerve be dissected out of its canal and lateralized.[3] Implants can then be used to extend all the way to the inferior border of the mandible, providing bicortical stabilization. The implant success rates obtained with this technique are very high, but unfortunately the risk of injury to the inferior alveolar nerve is significant. In some reports the incidence of permanent nerve injury can be as high as 25%.[4,6] Therefore the authors recommend that this technique not be used. If the patient has a reasonable dentition anteriorly, a distal extension removable partial denture is still a good option. It should be remembered that the mastication efficiency of patients fitted with properly extended and properly designed distal extension removable partial dentures is equivalent to that of patients fitted with implant-supported fixed partial dentures restoring distal extension areas.[14]

Distraction osteogenesis offers a new approach for creating bony sites that possess sufficient width and vertical height. In most instances, however, after completion of distraction osteogenesis, the horizontal dimension of the site must be enhanced with bone grafting. No long-term clinical results of this procedure are available.

Linear Configurations and Implant Overload

When implants are arranged in a linear fashion, the biomechanics with respect to anticipated bone response are quite unfavorable as compared with a configuration where the implants are arranged in a curvilinear fashion with significant anterior-posterior spread, particularly when loads are not applied along the long axis of the implant. In the 1980s, conventional dogma stated that once an implant became "osseointegrated," it did not matter whether occlusal loads were applied axially. However, as more clinical follow-up data and animal research data become available, it is increasingly obvious that in some clinical situations-namely, implant-supported fixed partial dentures restoring posterior quadrants-nonaxial loads can cause sufficient load magnification at the bone-implant interface to lead to bone resorption and eventually a higher rate of implant failure.

Fig. 72-5 Fixed hybrid prosthesis fabricated from denture teeth and acrylic resin with a nonprecious metal support structure.

Brunski proposed the following hypothesis with regard to the biologic mechanisms initiated in bone when an implant was overloaded.' He proposed that excessive occlusal loads lead to microdamage (e.g., fractures, cracks, and delamination) of the bone adjacent to the implant, which provokes a resorptive remodeling response. This results in increased porosity of the affected bone. A vicious cycle ensues in which continued loading leads to more microdamage, porosity, and bone loss until the implant fails (Fig. 72-5).

Nonaxial loads, which cause load magnification, can lead to implant overload, which in turn precipitates a resorptive remodeling response of the bone around the neck of the implants. The bone loss appears to be progressive and can lead to implant failure. Linear implant configurations in the posterior mandible and posterior maxilla are particularly prone to bone loss when loads are not applied axially. Implants should be positioned so that occlusal loads can be directed axially. The response is not universal, however, and is probably dependent on the bone anchorage of the implant, length of the implant, magnitude of the occlusal loads applied to the implants, and whether the implant supported restoration is used for incising or masticating the food bolus. Therefore the authors believe every attempt should be made to surgically position implants in the posterior quadrants so that occlusal forces can be directed axially or along the long axis of the implant. If implants are positioned in such a way, the restoration is very easy and cost effective to fabricate and the implants have a better long-term prognosis.

The use of cantilevered implant-supported restorations in posterior quadrants of the mandible or maxilla is strongly discouraged. Cantilever extensions result in load magnification and can cause overloading of the implant next to the cantilever extension, which in turn may lead to bone loss and implant failure.

When connecting implants to the natural dentition, the authors recommend it be done in a rigid fashion, either with rigid, screw-retained attachments or copings secured with permanent cement (see Fig. 72-5). The case for such rigid connections has been eloquently made by Gulbransen. 7 He showed that if implants are connected to the natural dentition with a rigid system of attachment, the implant failure and complication rates, such as screw loosening, were dramatically reduced. In addition, the well-documented phenomenon of intrusion of the natural tooth abutment associated with the use of semiprecision attachments is prevented.

BOX 72-2

Implant Overload and Bone Resorption: Possible Mechanisms

Excessive occlusal loads
Resultant microdamage (fractures, cracks, and delaminations)
Resorptive remodeling response of bone
Increased porosity secondary to remodeling
Vicious cycle of continued loading, with more microdamage and more porosity until implant fails

Adapted from Brunski J, Puelo D, Nanci A: Biomaterials and biomechanics of oral and maxillofacial implants: Current status and future developments. Int J Oral Maxillofac Imp 2000; 15.

BOX 72-3

Biologic Processes

The following biologic processes need to be completed before an implant is firmly anchored in bone. This process takes 4 months in humans.

- Blood clot
- Angiogenesis
- Osteoprogenitor cell migration
- Woven bone formation
- Deposition of lamellar bone
- Secondary remodeling of woven bone with lamellar

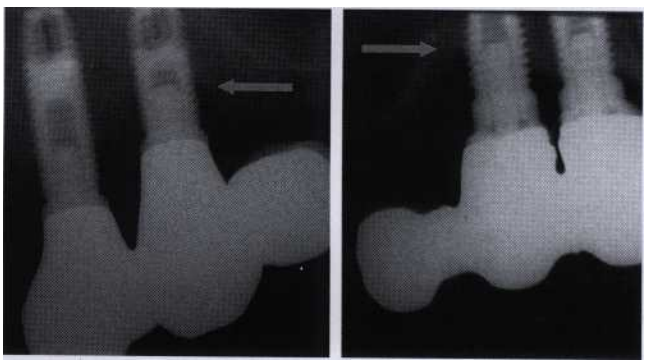

Fig. 72-6 Cantilevers in the posterior quadrants of partially edentulous patients should be discouraged. Note bone loss (arrows).

IMMEDIATE OR EARLY LOADING: POSTERIOR QUADRANTS

Immediate or early loading of osseointegrated implants is generally not recommended when implants are used to restore posterior quadrant defects in partially edentulous patients. When an implant is placed into bone, the initial bone anchorage is not very good and if it is loaded and as a result becomes mobile, it fails to osseointegrate; in other words, a fibrous connective tissue capsule develops around the body of the implant. The biologic processes required to achieve osseointegration takes about 4 months in humans (Box 72-2). Some evidence suggests that implants with acid-etched surfaces resulting in a specific surface morphology may result in the expression of specific genes that promote more rapid healing of the bone around implants.[16,17] However, these animal studies are yet to be confirmed by human follow-up studies. Immediate or early loading may be feasible when implants are placed in good-quality bone (i.e., anterior mandible) and are used to retain implant-assisted overlay dentures. However, when they are placed in posterior quadrants of partially edentulous patients where the bone sites are less dense and all the occlusal loads are born by the implants, immediate or early loading is inadvisable.

In summary, every effort should be made to design implant-supported restorations that are not subject to implant overload. A summary of the strategies are found in Fig. 72-4. If the clinician follows this prescription and also places implants in tooth positions, 1) proper emergence profiles can be developed, 2) space is available interproximately for hygienic access, 3) the clinician has better control over the occlusal anatomy (narrowed occlusal table and flat cusp angles), 4) occlusal loads are delivered axially, and 5) abutment selection is simplified (Fig. 72-6).

SINGLE-TOOTH IMPLANTS IN THE POSTERIOR QUADRANTS

Standard-diameter implants have been used to restore single tooth defects in the posterior quadrants of the maxilla and mandible with mixed results. In the 1980s, clinicians attempted to restore mandibular first molar sites with conventional 3.75- or 4.0-mm diameter implants. Unfortunately, the results were quite disappointing. In some patients, occlusal overload led to loss of bone around the implant, and implant fixtures fractured in other patients. However, these occurrences were rare. The most common problem observed was loosening of the screw retaining the restoration. This is caused by the fact that the diameter of the head of the implant is much smaller than the size of the occlusal surface. Tipping of the restoration during function eventually leads to stretching and loosening of the screw securing the crown to the implant fixture. The buccal-lingual width of the crown can be controlled and the dimension kept to a minimum. However, clinicians do not have control over the mesiodistal dimension because this space must be filled. When the bolus of food becomes positioned on the mesial side of the crown, tipping forces are generated that eventually lead to loosening of the screw retaining the crown. The use of wide-diameter implants resolves the screw-loosening complication (Box 72-4). If the first molar is lost and suitable abutments are available on both sides, a conventional, three-unit, fixed partial denture is still the preferred option. This restoration is cost

BOX 72-4

Strategies to Avoid Implant Overload

The following strategies are used to avoid implant overload in the posterior quadrants of partially edentulous patients. When these conditions cannot be met, removable partial dentures are recommended.

- Place implants perpendicular to the occlusal plane. (Note that the occlusal plane is not flat [i.e., curve of Wilson, curve of Spee].)
- In mandibular extension defects, when in doubt, always add a third implant.
- In maxillary extension defects, use at least three implants.
- Avoid the use of cantilevers in linear configurations.
- If you are required to attach to the natural dentition, do so with a rigid attachment system.
- Control occlusal factors (i.e., cusp angles and width of occlusal table) and restore anterior guidance if required.
- Avoid the use of short implants (less than 10 mm).

effective and quite predictable. In distal extension areas restoring one molar tooth, the authors recommend that two conventionally sized implants be placed close together. This restoration is biomechanically sound and can be designed to allow adequate hygiene access.

Single implants can be used with a high rate of success in the mandibular and bicuspid area. The bone implant interface achieved in this area is good and the size of the occlusal surface is generally small. Likewise, the success rate in the maxillary bicuspid region has been good. However, the authors recommend the use of implants 13 mm in length or longer to restore these sites because the bone-implant interface is not ideal in these regions.

IMPLANTS IN THE ESTHETIC ZONE

Implants placed in the anterior quadrants of partially edentulous patients enjoy a high success rate and high satisfaction rate with patients. In the anterior region, the forces and bending moments acting on the implant-supported replacement are normally less and the bone volume is greater than in the posterior region. Therefore it may be possible to reduce the number of implants in the anterior region to a few longer implants, such as replacing four incisors with two implants and a four-unit fixed prostheses. The bone sites are generally favorable in quality and quantity, although there may be deficiencies in labial lingual and apicocoronal dimension in the maxilla in patients. These areas, however, can be predictably augmented with autogenous bone grafts with or without barrier membranes." The quality of the esthetic result is dependent on restoration of bone and soft tissue contours and proper implant positioning (Fig. 72-7). The rule of thumb has been to place the implant in the tooth

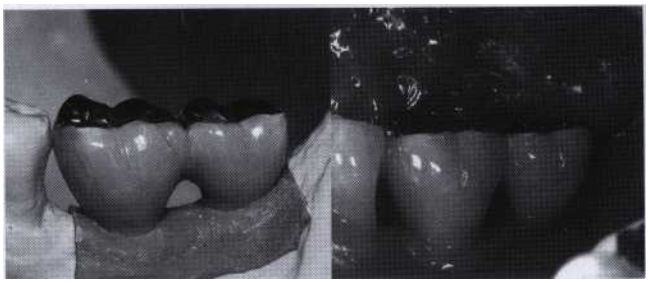

Fig. 72-7 Guidelines for restoring posterior quadrants. Embrasures must be large enough for proxy brush access, occlusal table must be narrowed, posterior cusp angles flattened, proper emergence profiles developed, and anterior guidance restored.

position in a mesiodistal, buccolingual, and apicocoronal position. A number of reviews recommend placing implants after esthetic three-dimensional considerations in the anterior region. This is called *prosthetically driven implant placement* and may be preceded by prosthetically driven site development. If the neighboring teeth demonstrate intact periodontal tissue support, the implant head is placed about 2 to 3 mm below the anticipated buccal gingival margin. The implant-supported restoration should contour the soft tissue and emerge with a profile in the same dimensions as the natural tooth and with physiologic contours.

MAINTENANCE

Despite the long-term predictability of osseointegrated implants,[1,3,11] biologic, biomechanical, and esthetic complications can occur in a small percentage of cases. Pathologic changes of the periimplant tissues can be placed in the general category of *periimplant disease.*[31] Inflammatory changes, which are confined to the soft tissue surrounding an implant, are diagnosed as *periimplant mucositis.*[31] Progressive periimplant bone loss in conjunction with a soft tissue inflammatory lesion is termed *periimplantitis.*[31] Periimplantitis begins at the coronal portion of the implant, while the more apical portion of the implant maintains an osseointegrated status.[24,30,34,55] This means that the implant is not clinically mobile until the late stages when bone loss has progressed to involve the complete implant surface. Technical failures can occur in a small percentage of cases in the form of implant, abutment, and screw fractures and loosening of fixation screws. Esthetic complications may occur in patients with high esthetic expectations and less than optimal implant placement and restorative treatment results.

The invaluable help of Dr. Karl Donath, University of Hamburg, Department of Oral Pathology, Germany, with the histologic aspects of this chapter is gratefully acknowledged.

INCIDENCE

Few studies have reported the frequency of occurrence of periimplant disease.[16,21,52,57,58,63,64] Most long-term studies present an average of the marginal bone loss around implants, and therefore individual implant sites with periimplant disease are not reported.[1] It is important to note that mean crestal bone around an implant decreases 0.9 to 1.6 mm during the first year of implant function. In the follow-up period, mean annual rates of bone loss decrease to 0.05 to 0.13 mm.[1,3]

Recent clinical data showed that after a period of implant function, bone loss around implants can develop and even progress to levels at which the implant is at risk for failure. Implant designs and surface characteristics can influence the amount of periimplant marginal bone loss.[22,48] Under experimental periimplantitis conditions, the character of the implant surface influenced the amount of periimplant tissue breakdown.[22]

Titanium plasma-sprayed (TPS)-coated implants (TPS-screw) in a clinical retrospective study demonstrated

periimplant bone loss exceeding 4 mm in 4% to 15% and probing depth exceeding 5 mm in 5% to 20% of the implants.[12]

Machined titanium implants (Branemark) showed in a 2-year follow-up study on maxillary overdentures that 6% had a partial marginal radiolucency, but the amount of bone loss in millimeters was not reported.[5]

TPS International Team for Oral Implantology (ITI)-implants demonstrated a mean radiographic change in periimplant bone levels of less than 1.1 mm in the first year of function.[64] However, the percentages of implant sites with bone level changes of more than 0.5 mm between years 1 and 2 was 7% and bone level changes of more then 1 mm were 4%.

Hydroxyapatite (HA)-coated implants showed a significant number of implants experiencing moderate (1 to 3 mm) bone loss, whereas a smaller number of implants demonstrated severe bone loss. Further data is necessary because case reports have been published demonstrating an alarming amount of bone loss. Thus the overall frequency of periimplantitis appears to be in the range of 5% to 10%.

Implants with a smooth coronal titanium neck and nonsplinted maxillary implants have shown increased

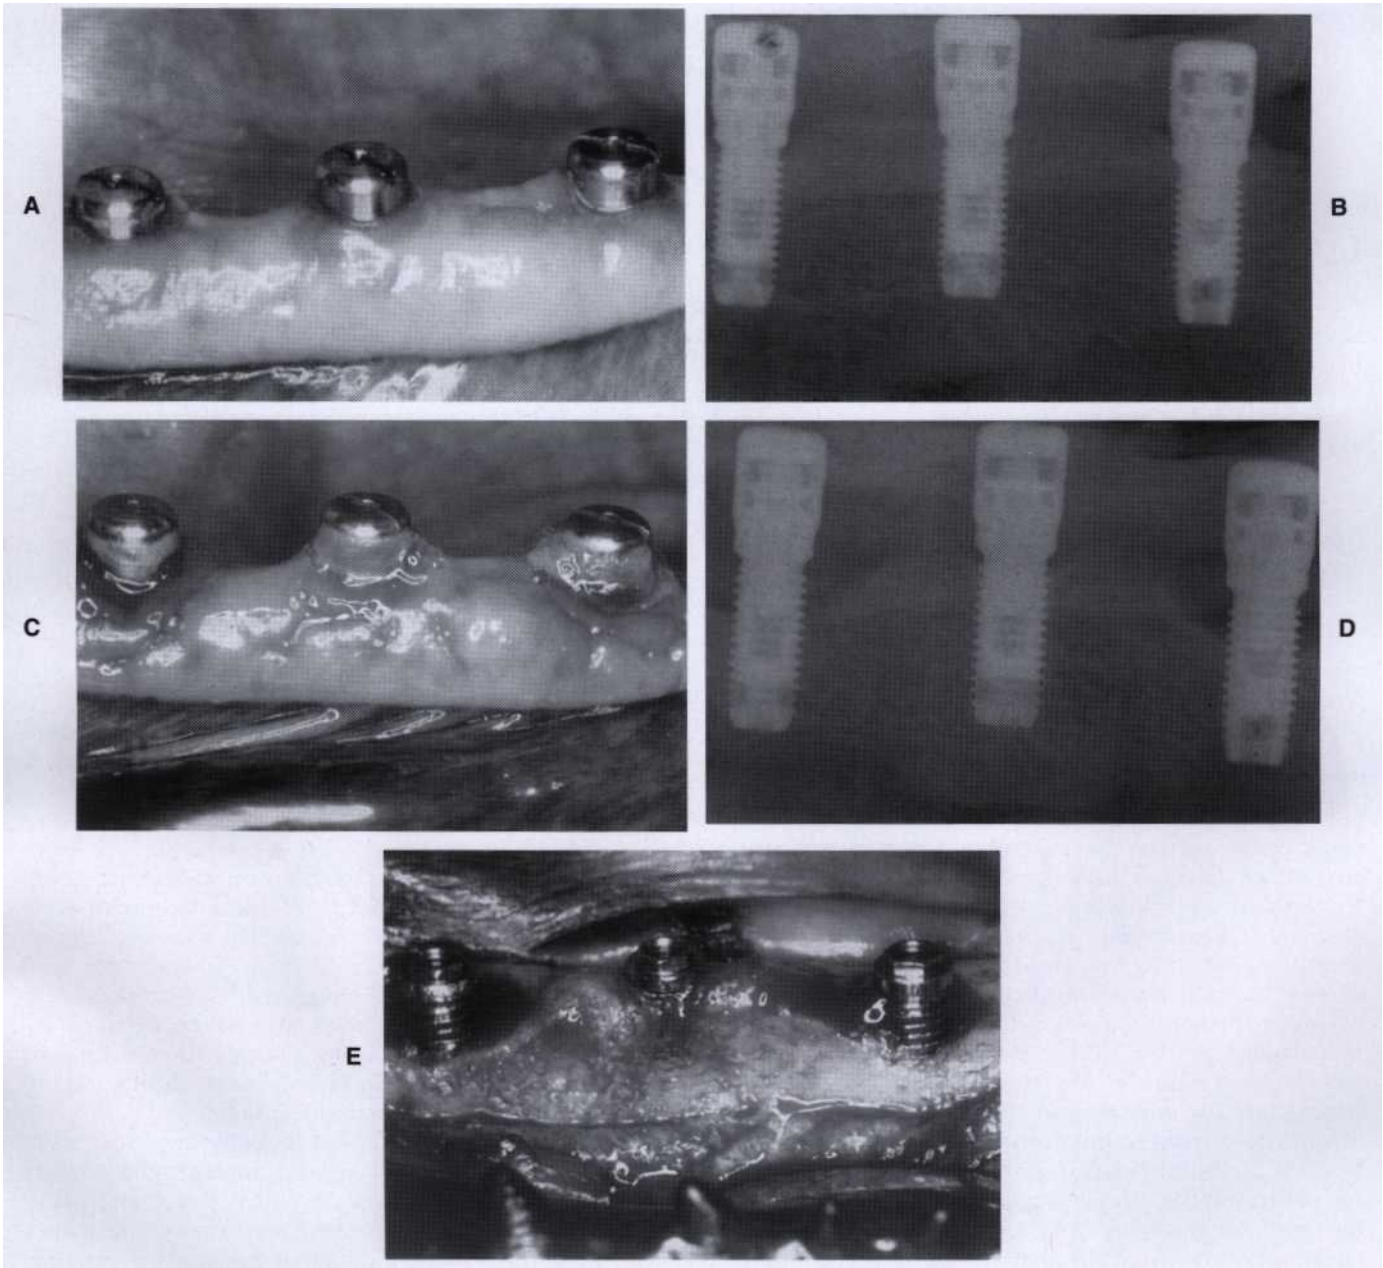

Fig. 73-1 Experimental periimplantitis in beagle dogs. Clinical picture (A) and radiograph (B) of three Branemark implants in place, 6 months after abutment connection. C to E, Six months after placement of a ligature to induce plaque accumulation in implants at left and at right; the middle implant represents a non-ligated control. C, Clinical picture showing inflammatory changes. D, Radiograph depicting the resultant bone loss. E, Actual bone loss shown after raising a flap.

periimplant bone loss during the functional phase.[48] This bone loss is attributed to the nonfunctional characteristic of smooth or polished titanium, which does not maintain bone integration during the loading period. Nonsplinted implants are at risk for overloading, especially in the maxilla and in sites with high stress zones and few implants.

Soft tissue complications such as periimplant mucositis and hyperplasia were noted in 21% to 28% of the jaws during the first period of clinical experience with osseointegration" but decreased to a low degree in recent years. The improvement was attributed to improved oral hygiene methods and changes in prosthetic designs.

Depending on the severity of the periimplant bone loss, morphology of the bone defect, and implant surface, there is the potential to arrest the progression of the disease process, and in selected cases, to regenerate the lost bone tissue.

Patients with a history of periodontitis may represent a group of individuals with an elevated risk of developing periimplantitis. This view is based on the evident susceptibility to periodontitis, and the potential for transmission of periodontal pathogens from teeth to implants.[39]

ETIOLOGY

The two major etiologic factors associated with resorption of crestal perhmplant bone tissue are bacterial infection and biomechanical factors associated with an overloaded implant site."

Bacterial Infection

If plaque accumulates on the implant surface, the subepithelial connective tissue becomes infiltrated by large number of inflammatory cells and the epithelium appears ulcerated and loosely adherent. When the plaque front continues to migrate apically, the clinical and radiographic signs of tissue destruction are seen around both implants and teeth (Fig. 73-1); however, the size of the soft tissue inflammatory lesion and the bone loss is larger around implants. In addition, the implant lesions extend into the supracrestal connective tissue and approximate/populate the bone marrow (Fig. 73-2) while the lesions associated with teeth do not. These studies suggest that plaque-associated soft tissue inflammation around implants may have more serious implications than marginal inflammation around teeth with a periodontal ligament (Fig. 73-3). One reason for the increased inflammation around an implant might be the low-vascularity soft tissue band and the difference in collagen/fibroblast ratio of gingival tissue, which affects the defense mechanisms around an implant as compared with those seen in tissues around teeth with a periodontal ligament. In addition, different implant surface characteristics influence the amount of periimplant tissue breakdown and inflammation; specifically, HA-coated implants seem to have increased bone loss when compared with titanium implants (Fig. 73-4).[16,21,22]

Subgingival bacterial flora associated with clinically inflamed implant sites is quite different to that seen around "healthy" implants. These microbial shifts are very similar to those occurring around natural teeth, and

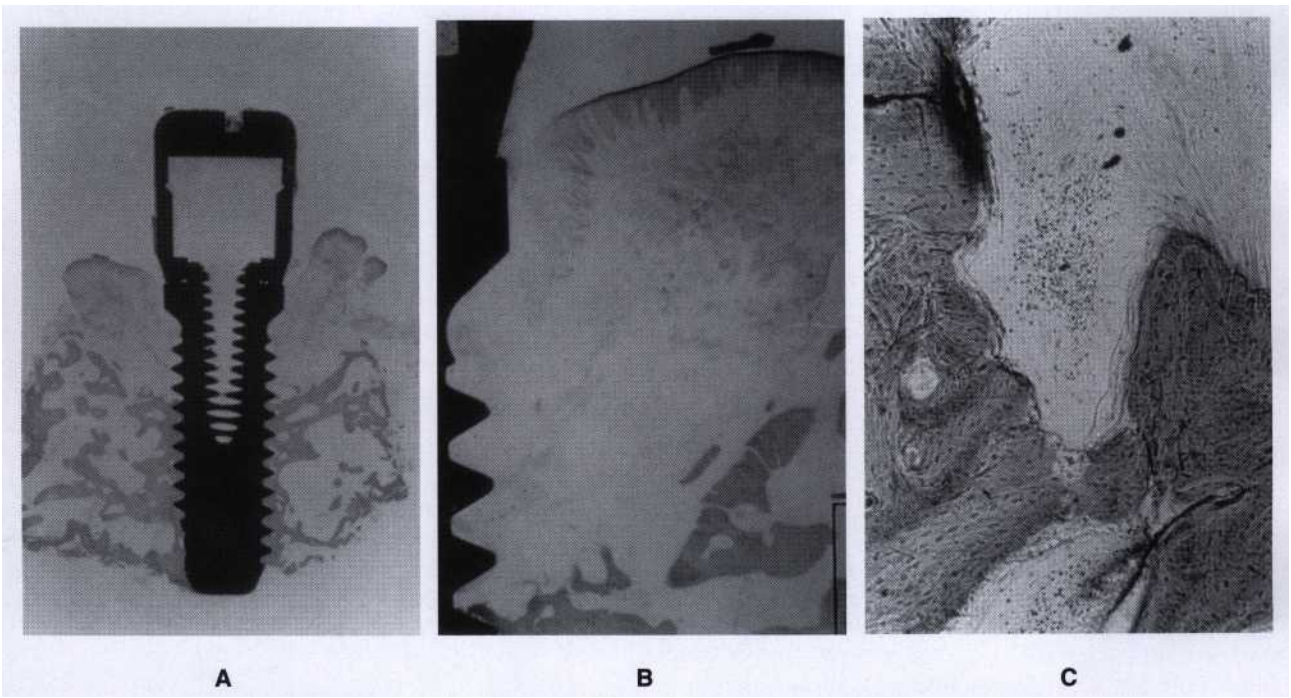

Fig. 73-2 Microscopic view of experimental periimplantitis in a beagle dog. A, Low-power view of the implant in situ, showing vertical bone loss. Note that osseointegration persists in deeper portions of the implant. B, Higher-power view of the area of bone loss next to the implant. C, Higher-power view showing extension of inflammation into bone.

no bacterial flora in chronic periodontitis and periimplantitis seem to have great similarities. [7,23,33,40,42,50]

It is possible that these organisms are the direct cause of the periimplant breakdown, but proof is not available. Nevertheless, a subepithelial inflammatory response occurs and undoubtedly plays a role in continuing the inflammatory changes that cause this breakdown to progress.[24,28,30,55] A marked difference has been documented between the bacterial morphotypes of the totally edentulous and the partially edentulous mouth.[4,46] The so-called periodontal pathogens were decreased in the implant sulci of the totally edentulous mouth. This might indicate a higher susceptibility for periimplantitis in the partially edentulous mouth.

Biomechanical Factors

Experimental and clinical evidence supports the concept that excessive biomechanical forces may lead to high stress or microfractures in the coronal bone-to-implant contact and thus lead to loss of osseointegration around the neck of the implant. [17,34,48,53,61] Although overload is clinically difficult to define and measure, the role of overloading is likely to increase in four clinical situations:

1. The implant is placed in poor quality bone.
2. The implant's position or the total amount of implants placed does not favor ideal load transmission over the implant surface.
3. The patient has a pattern of heavy occlusal function associated with parafunction.
4. The prosthetic superstructure does not fit the implants precisely.

It is important to note that the cause for periimplant crestal bone loss can be multifactorial and that both bacterial infection and biomechanical factors can be contributing factors. Each factor should be identified and eliminated before treatment of the implant site is initiated. Other etiologic factors such as traumatic surgical techniques, smoking, inadequate amount of host bone resulting in an exposed implant surface at the time of placement, and a compromised host response can act as co-factors in the development of periimplant disease.

TECHNICAL IMPLANT FAILURES

In clinical reality, fatigue of implant materials, weakness in prosthetic design and dimensions, and other factors may result in implant fractures. [1,6] Balshi listed three categories of causes that may explain implant fractures: design and material, nonpassive fit of the prosthetic framework, and physiologic or biomechanical overload.[6]

Fractures may occur in **a few cases** out of thousands of patients treated with oral implants and cannot completely be avoided. The occurrence of implant fractures can be kept to a minimum through the use of quality controlled implant designs and the consideration of physical principles and biomechanical characteristics of various materials and prosthesis design. Patients with bruxism seem to be at higher risk for such events and therefore need to be screened and informed accordingly.[5,6]

Abutment Loosening and Fracture

Screw loosening has been reported to occur quite frequently in screw-retained fixed partial dentures. Screw-

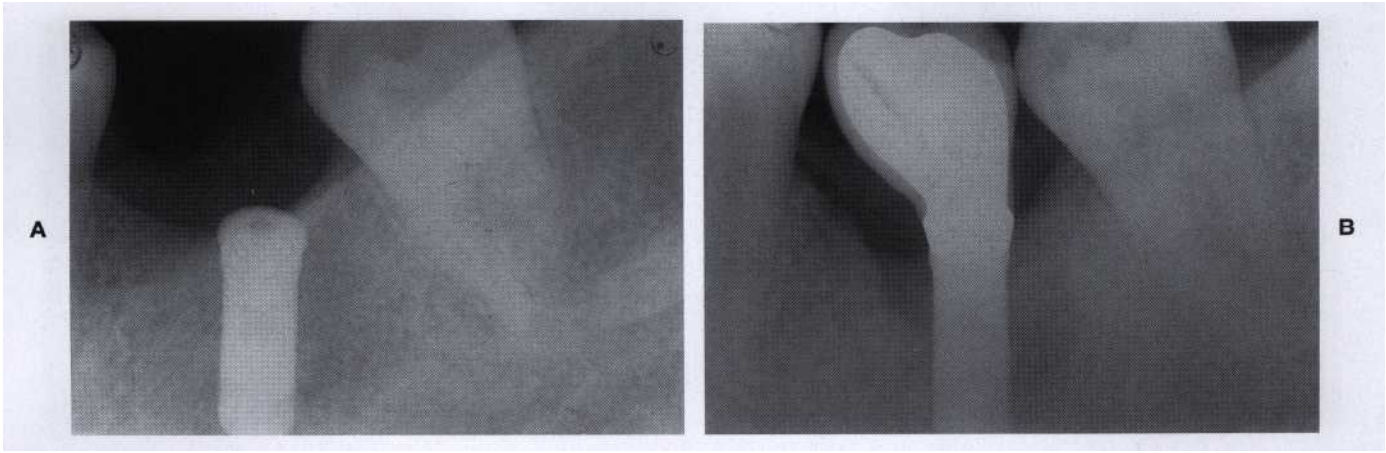

Fig. 73-4 Rapid destruction of bone after placement of an implant. A, Normal supporting tissues after placement of the implant. B, Advanced bone loss 12 months later.

retained single crowns may also be prone to technical complications. Reports have shown anywhere from 6% to 49% screw loosening at the first annual check-up.[20,41] Newer abutment designs and higher torque levels used to insert abutment screws have helped reduce the rate of screw loosenings.

Abutment screw fractures are less frequent but remain clinical hazards that are not always easily resolved. If the fractured abutment is buried within the internal threads of the implant, it may be impossible to retrieve the screw. Such an implant may then be left buried beneath the mucosa. In some instances, screw retrieval sets can be used successfully to salvage implants with deep broken fragments.

It is important to note that any of the previously mentioned technical implant failures are caused by stress and should be addressed at an early stage of onset.

Esthetic Complications

Implant placement in the esthetic zone requires precise three-dimensional tissue reconstruction and ideal implant placement. This reconstructive procedure enables the restorative dentist to develop a natural emergence profile of the implant crown. If the amount of available bone does not allow for ideal implant placement and the implant is positioned too apical, buccal, or interproximal, a prosthetic profile will be developed with an esthetic dimensions. The same is true if a bone reconstruction procedure shows a compromised result and the implant is still placed but in an inappropriate position.

If crown form, dimension, shape, and gingival harmony around the implants are not ideal, the patients consider the implants/restorations as complications because the result does not represent a natural profile. Often these implants need to be removed, the case reevaluated, and if possible, retreated.

Appropriate treatment planning and execution keeps esthetic complications to a minimum, although it should be noted that anterior implant work is very technique sensitive and time consuming.

DIAGNOSIS OF PERIIMPLANT TISSUE BREAKDOWN

A number of clinical parameters used to evaluate periodontal conditions have also been used to assess periimplant conditions. These parameters include the evaluation of oral hygiene, periimplant marginal tissues, and bone-implant interface.

Successful implants generally allow probe penetration of approximately 3 to 4 mm, and the location of the periimplant bone level can be expected to be about 1 mm apical to the position of the probe tip.

The long-term success of dental implants depends on the continued health of periimplant hard and soft tissues and an appropriate force distribution to the implants.[44,s1] Soft tissue health should be established by obtaining a high level of patient compliance for plaque removal and having a prosthesis design that follows perioprosthetic guidelines.

The rationale to prefer attached, masticatory mucosa surrounding an implant, especially in the partially edentulous mouth, is based on the different microbial composition between the partially and totally edentulous mouth, the risk for bacterial seeding from adjacent periodontal pockets, the weak soft tissue adherence around the perigingival area of an implant, and the increased inflammatory response around implants undergoing bacterial infection.[4,8,12,24,34,46]

Radiographs reveal the periimplant bone status as well as the marginal bone level. Periapical intraoral radiographs should be obtained because panoramic radiographs have a lower discrimination power. Baseline radiographs should be taken at functional loading (i.e., insertion of the prosthesis). Direct digital imaging may have the potential to replace conventional radiology.

Biomechanical forces on implants are influenced by an adequate number of implants, favorable implant positions for load distribution, and the establishment of an appropriate occlusion.[51,53]

To diagnose a compromised implant site, soft tissue measurements using manual or automated probes have

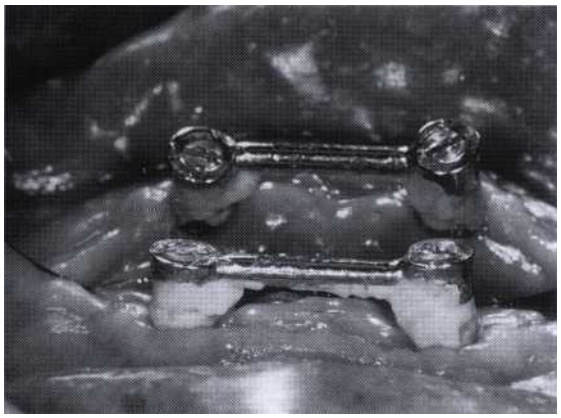

Fig. 73-5 Plaque and debris accumulation around implants, with resultant inflammation.

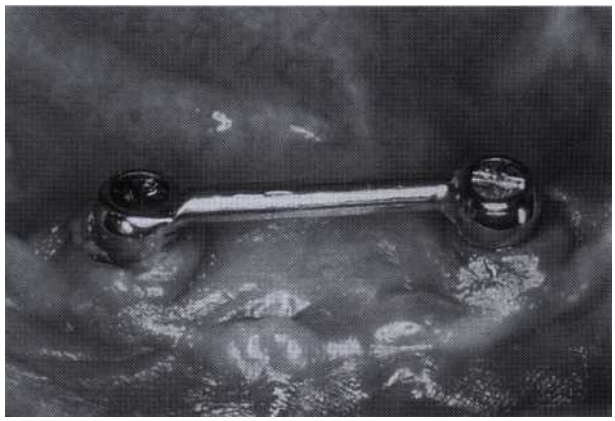

Fig. 73-6 Periimplant disease, resulting in soft tissue swelling and inflammation.

been suggested. Although some reports say that probing is contraindicated, careful monitoring of probing depth and clinical attachment level over time seems useful in detecting changes of the periimplant tissue.[13,52,61,62] Radiographic procedures to assess perimplant bone level have been shown to be useful. Standardized radiography, both with and without computerized analysis, have been documented in a number of studies (see Fig. 73-4).[1,9,11,24,52]

Aside from pocket formation and radiographic bone destruction, suppuration, calculus build-up (Fig. 73-5), swelling (Fig. 73-6), color changes, and bleeding upon gentle probing have been documented as signs of periimplant disease.[40,44]

Mobility has been extensively described to detect early and late failures after loading of the implants with the superstructure.[1,44,48] However, mobility should only be used as an absolute diagnostic information for lack of osseointegration. The current electronic diagnostic tools for measuring mobility are not sensitive enough to detect mobility changes in osseointegrated implants undergoing marginal bone loss.

Microbial monitoring is useful in evaluating the periimplant health condition and the microbial composition of a periimplantitis site. This information then can potentially be used to determine the etiology of the breakdown and select a specific antibiotic regimen.[7,38,44]

REMOVAL OF FAILED IMPLANTS

In cases in which osseointegration has been reduced severely and bone loss has extended into the apical half of the implant, or in which the implant demonstrates mobility, implant removal should be considered (Box 73-1).[3,43] After the implants are removed, the ridge defects can be reconstructed to their original level using bone graft and membrane techniques. This treatment usually enables the clinician to place new implants in a previously compromised situation.

INITIAL PHASE OF PERIIMPLANTITIS TREATMENT

Occlusal Therapy

When excessive forces are considered the main etiologic factor for periimplant bone loss, treatment involves an analysis of the fit of the prosthesis, the number and position of the implants, and an occlusal evaluation. Prostheses design changes, improvement of implant number and position, and occlusal equilibration can contribute to arrest the progression of periimplant tissue breakdown.

Antiinfective Therapy

The nonsurgical treatment of periimplant bacterial infection involves the local removal of plaque deposits with plastic instruments and polishing of all accessible surfaces with pumice59; subgingival irrigation of all periimplant pockets with 0.12% chlorhexidine; systemic antimicrobial therapy for 10 consecutive days; and improved patient compliance with oral hygiene until a healthy periimplant site is established.[38,62] As in the treatment of periodontal disease, this initial phase of therapy may be sufficient to reestablish gingival health or may need to be followed by a surgical approach (Box 73-2).

The implant surface is contaminated with soft tissue cells, bacteria, and bacterial byproducts.[24,29,34] Bacterial adherence is enhanced by the microirregularities of implant surfaces,[47] and as long as the contamination is present, wound healing is compromised. Therefore if regeneration of new bone and reosseointegration is to occur, the defect must first be debrided and the contaminated implant surface prepared. *Reosseointegration* can be defined as the growth of new bone in direct contact to the previously contaminated implant surface without an intervening band of organized connective tissue.[25]

For implant surface preparation, mechanical devices and chemotherapeutics have been evaluated in vitro and in vivo.[14,45] Conventional hand and ultrasonic instru-

BOX 73-1

Indications for Implant Removal

- Severe periimplant bone loss (>50% of implant length)
- Bone loss involving implant vents or holes
- Unfavorable advanced bone defect (one wall)
- Rapid, severe bone destruction (within 1 year of loading)
- Nonsurgical or surgical therapy ineffective
- Esthetic area precluding implant surface exposure

BOX 73-2

Indications for Nonsurgical Therapy

- Mucosal inflammation detected by clinical signs
- Radiographic bone level stable

ments are not suitable for the preparation and detoxification of the implant surface. Mechanical instrumentation may damage the implant surface if performed with metal instruments harder than titanium.[39] The method of choice involves the use of a high-pressure air powder abrasive (mixture of sodium bicarbonate and sterile water). This method removes microbial deposits completely from titanium surfaces, does not change the surface topography significantly, and does not adversely affect cell adhesion. There have been some warnings for the potential of air-emphysema when using high pressure air spray instrumentation in the surgical site." Clinical case reports have shown successful treatment of periimplant disease with a protocol for detoxification using an air-powder abrasive.[26,35]

Preparation of the implant surface has also been achieved by applying chemotherapeutic agents. Different agents[15,65,66] have been evaluated for this purpose, and it has been reported that the use of a super saturated solution of citric acid for 30 to 60 seconds has the highest potential for removal of endotoxins from both HA- and titanium-implant surfaces. Clinical case reports have also shown the succesful treatment of periimplant disease using only chemotherapeutic agents as a detoxification protocol.[32-37]

Irradiation with a soft laser for elimination of bacteria associated with periimplantitis has also shown promising results in the destruction of bacterial cells.[22]

SURGICAL TECHNIQUES FOR TREATMENT OF PERIIMPLANTITIS

Once the inflammatory process in the periimplant tissues is under control, an attempt may be made to improve or reestablish osseointegration.

The surgical techniques presently advocated to control periimplant lesions are modified from techniques used to treat bone defects around teeth. The type and size of bone defect has to be identified before deciding on the appropriate treatment modality. Therefore probing and sounding of the defects is done using local anesthesia, and radiographs are evaluated so that the surgical treatment plan is finalized immediately prior to beginning the procedure. This forms the basis to determine whether the implant will be removed or a resective type of surgery or a regenerative procedure will be used. The resective therapy is used to reduce pockets, correct negative osseous architecture and rough implant surfaces, and increase the area of keratinized gingiva if needed. The regenerative therapy is also used to reduce pockets but with the ultimate goal of regeneration of lost bone tissue.

As in the treatment of certain types of periodontitis, systemic antibiotics have been advocated as a supportive regimen during the treatment phase of periimplant disease.[26,12,38] This may be especially important due to the close proximity of the inflammatory lesion to the implant and the bone marrow (see Fig. 73-2, C).[24,42] Antibiotics frequently used without sensitivity testing are doxycycline and metronidazole.[26,32,38] If bacterial sensitivity testing is done, the antibiotic regimen is determined by the laboratory result.

Morphology of Osseous Defects

The pattern of bone destruction caused by periimplant disease varies and in general depends on the amount of bone present at the time of implant placement and the length and severity of the pathologic insult. The bone defects can be divided into four main groups.

Group I demonstrates moderate horizontal bone loss with a minimal intrabony component. This group of implants is usually covered by a thin buccal and lingual/palatal bone crest at time of placement and is at an early stage of periimplant breakdown.

Group II presents moderate to severe horizontal bone loss with a minimal intrabony component. This group of implants is an advanced condition of the implants in Group I.

Group III demonstrates minimal to moderate horizontal bone loss with an advanced circumferential intrabony lesion. These implants are initially covered by a thin coronal bone crest with a wider apical bone base. Frequently the pattern of bone loss has a symmetric feature, with a circular trough of uniform width and depth occurring around the circumference of the implant.

Group IV presents more complicated implant defects with moderate horizontal bone loss with an advanced circumferential intrabony lesion; additionally, the buccal and/or lingual plate has been lost (Fig. 73-7). These implants usually demonstrated a thin bone plate at the time of implant placement, which resorbed under the pathologic conditions.

Implant Surface in the Defect Area. The surface of the implant is a source of controversy and might play a role in the choice of treatment. HA-coated

implants have clinical and histologic evidence that resorption of the surface by inflammatory phagocytosis is present under the influence of marginal bacterial inflammation (Fig. 73-8).[21,22,29] The treated and detoxified periimplantitis-affected sites show continued phagocytosis of the HA surface.[22] Until further experimental and clinical data are available, a careful and conservative approach should be employed when treating HA-coated implants affected by periimplant disease.

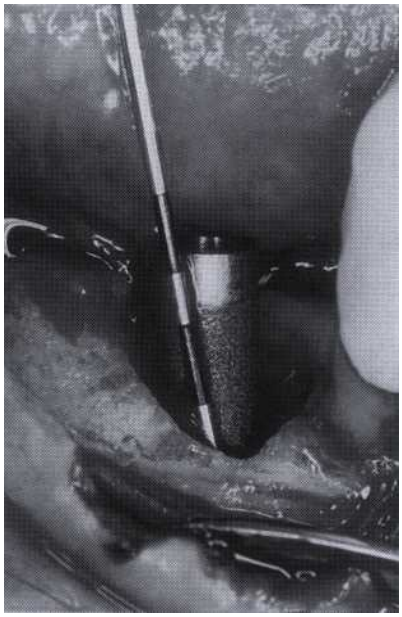

Fig. 73-7 Advanced type IV bone loss around implants.

Titanium implants show little to no resorption of the surface.[24,34] As long as the inflammatory lesion around a titanium implant can be arrested, surgical treatment of selected cases seems indicated.

Periimplant Resective Therapy

The type of osseous defect should be identified before deciding on the treatment modality (Box 73-3). Apically positioned flap techniques and osseous resective therapy are used to correct horizontal bone loss and moderate vertical (<_3 mm) bone defects and reduce overall pocket depth (Fig. 73-9).[27,35,60]

Full-thickness or split-thickness flap management are used to access the surgical area. With the flap raised, degranulation of the osseous defect is performed. Care should be taken to avoid contact between the implant and metal instruments. An implant surface can now be prepared with chemicals and air abrasives. Implant surface preparation is performed by applying the air spray of the air-powder abrasive for a maximum of 60 seconds on the implant surface, followed by copious irrigation with saline solution. Then the application of supersaturated citric acid is applied for 30 seconds, followed again by irrigation with saline solution.

Surface Polishing/Implantoplasty. The long-term goal of the surgical treatment of periimplant breakdown is to arrest the progression of the disease and achieve a maintainable site for the patient. For this purpose, all implant surfaces that are smooth and clean coronal to the bone level are preferred. Therefore surfaces with threads or roughened topography, such as HA, are indicated for alterations with high-speed diamond

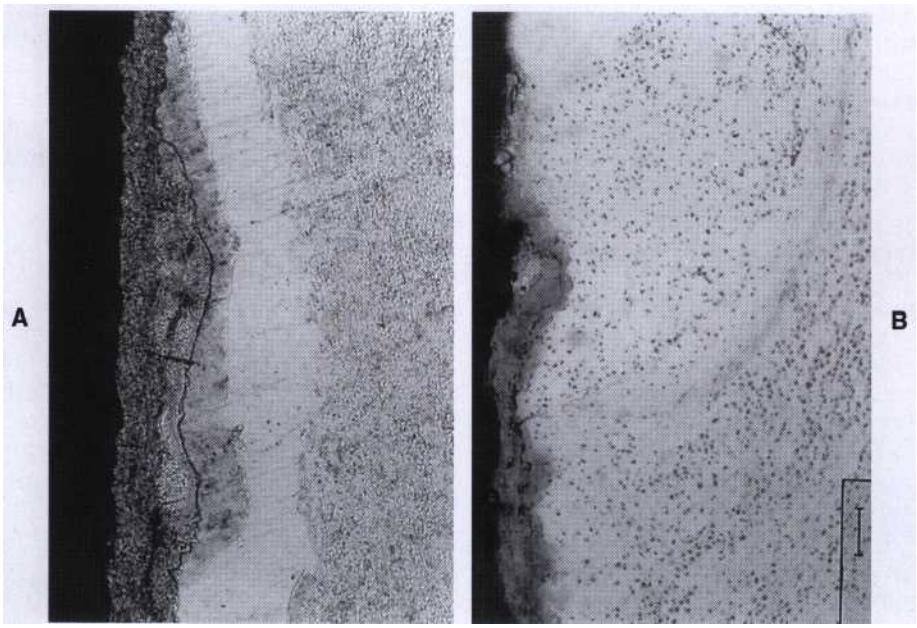

Fig. 73-8 Light microscopic view of resorption of the surface of a HA-coated implant surrounded by inflammatory cells (Toluidine blue stain). A, Early stage of calculus buildup on HA surface, showing dense inflammatory infiltrate. B, Late stage of inflammation around HA surface, resulting in partial resorption.

burs and polishers to produce a smooth continuous surface (see Fig. 73-9, B).[27,35] Copious irrigation for cooling purposes is used while the implant topography is modified. Surface modifications are performed only during a resective type of surgery and not during a regenerative procedure, where the metal particles could interfere with the regeneration of bone tissue. If a rough implant surface or moderate bone defect still exists after a bone regeneration procedure, a reentry surgical procedure after a minimal healing time of 6 months can be performed. During this second surgical intervention, a resective approach with a modification of the implant surface can be applied. Periimplant bone defects with predominately horizontal or one-wall topographies treated with surgical resective techniques result in healthy shallow pockets postsurgery.[62]

Periimplant Regenerative Therapy

An increasing number of reports have shown successful treatment of periimplant bone defects around functioning dental implants.[2,26,27,32,37] To accomplish regeneration of lost bone tissue and reosseointegration, guided bone regeneration (GBR) and bone graft techniques have been suggested.[27,37] In several experimental and clinical studies, the GBR principle using a nonresorbable expanded polytetrafluoroethylene membrane has been used for healing of bone defects seen at the time of implant placement[13,25] and around failing implants.[22,26,32]

Regeneration of bone seems to be enhanced if the area is isolated from the oral environment. Therefore it is recommended to remove the implant prosthesis 4 to 8 weeks prior to the regenerative surgical procedure to allow optimal compliance with oral hygiene procedures and the soft tissue to collapse and heal over the implant site with a newly attached cover screw in place. Thus at the time of regenerative surgery, a more intact soft tissue flap can be helpful to seal off the periimplant tissues during the healing period. A crestal incision is then used for the flap design.

If it is not possible to remove the prosthesis beforehand, a sulcular incision is used to raise a full-thickness flap and evaluate the surgical site. With the flap raised, degranulation of the osseous defect is performed with curettes while extreme care is taken not to contaminate the implant surface.

The surgical therapy includes implant surface preparation by air-powder abrasive for 30 to 60 seconds and the application of an oversaturated citric acid solution for 30 to 60 seconds. Consecutively, an elaborate rinse of the surgical area is performed with saline solution. To achieve increased access of osteogenic cells to the defect, the bone surface is prepared by roughening and penetrations with small round burs.

A membrane is then trimmed to extend 3 to 4 mm beyond the margins of the bone defect and secured with fixation screws. The flap is closed primarily over the site with mattress and interrupted sutures. Care is taken not to have any tension on the flap and therefore periosteal release can be used to advance the flap. Postoperatively the patients are instructed to rinse twice daily for 2 weeks with 0.12% chlorhexidine solution, and a systemic antibiotic is prescribed.[28] The sutures are removed after 14 days. The membrane is left undisturbed, if a submerged condition is maintained, for at least 4 to 6 months (Box 73-4). At that time the membrane is removed and the abutment secured (Color Fig. 73-1). If the membrane becomes exposed before this time, chlorhexidine application is continued to control infection of the healing tissues over the defect. If exudation is present, immediate removal of the membrane is advised. Otherwise, exposed membranes are usually removed 4 weeks after the perforation occurs.

BOX 73-3

Indications for Resective Therapy

- Moderate to severe horizontal bone loss
- One- and two-wall bone defects
- Implant position in unesthetic area

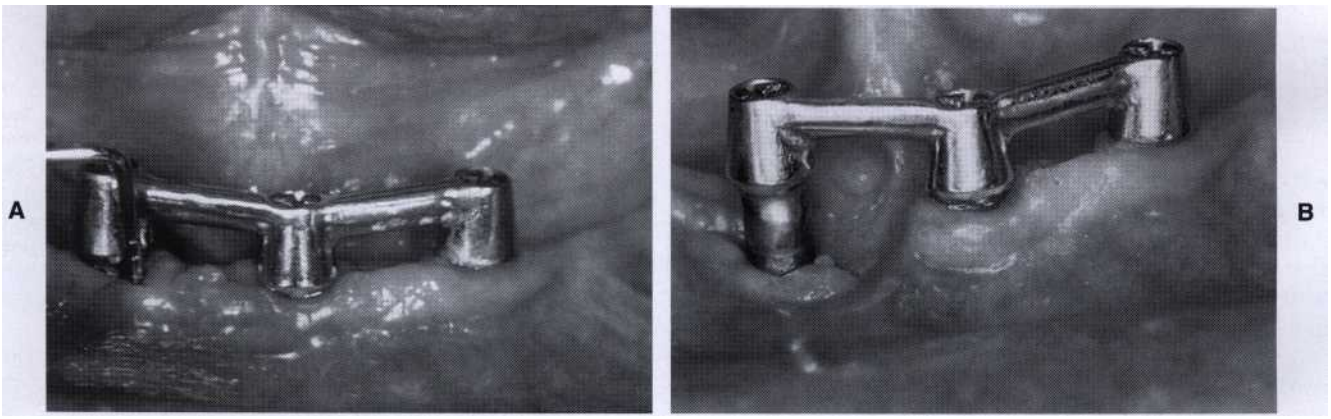

Fig. 73-9 Treatment of pedimplantitis by resective surgical therapy and implantoplasty. A, Before treatment. B, After treatment.

BOX 73-4

Indications for Submerged Regenerative Therapy

- Implant allowing complete closure with flap
- Moderate to severe circumferential intrabony defects
- Two- and three-wall bone defects
- Detoxification of implant surface possible

BOX 73-5

Indications for Pergingival Regenerative Therapy

- One-stage implant or nonretrievable prostheses
- Moderate to severe circumferential intrabony defects
- Three-wall bone defects
- Detoxification of implant surface possible

When one-stage implants are treated or the prosthesis has to be maintained in place, a pergingival GBR therapy is applied (Box 73-5). The membrane is perforated with a 3-mm hole and slid over the implant. The membrane should ensure complete coverage and isolation of the vertical bone defect. The flap is then sutured closely to the implant neck.

With a pergingival healing environment present, the removal of membranes has to occur 6 to 8 weeks after surgery. This is necessary due to the accumulation of plaque on the membrane and the potential risk of membrane and periimplant infection. Postoperative maintenance care is the same as for the submerged GBR therapy.

Various *bone graft materials* can be used in conjunction with GBR therapies. Graft materials such as HA demineralized freeze-dried bone, and autogenous bone have been suggested as support for the membrane.

Demineralized freeze-dried bone and HA have been used as a supporting graft material for the membrane therapy, but with inconclusive results." ," The allograft bone undergoes patterns of incorporation similar to those of autografts, but the incorporation tends to be slower and less complete.

Until more supportive results for allografts or synthetic graft materials are demonstrated, the use of intraoral autogenous bone grafts are preferred. These bone grafts have been extensively evaluated in the surgical literature and have shown their potential to be revascularized and eventually to be replaced by the patient's own bone. Furthermore, the bone grafts stabilize the blood clot, support the membrane, and above all, totally exclude disease transmission. The removal of the bone graft brings minimal morbidity to the intraoral donor site, and the surgical cost is minimal. However, remodeling occurs slowly and, depending on the size and quality of the graft, revascularization may require up to 1 year.

A recent study evaluated the use of recombinant human bone morphogenetic protein (rhBMP-2) in experimental periimplantitis sites. Within the newly formed bone, reosseointegration averaged 40% in rhBMP-2 defects as compared with control defects. [18]

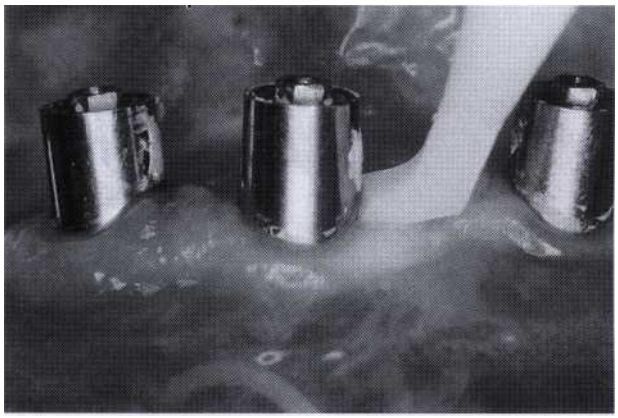

Fig. 73-10 Professional plaque removal around implants as part of maintenance care.

Although incomplete surface decontamination seems to be the major obstacle for growth of bone on previously exposed implants, the biologic requirements for direct regrowth of bone still need investigation.

MAINTENANCE

After surgical intervention, all patients are placed on a close recall schedule (Fig. 73-10). It is advised to schedule maintenance visits at least every 3 months. This allows for monitoring of plaque levels, soft tissue inflammation, and changes in the level of the bone. The importance of the maintenance procedures should never be underestimated by either the patient or the therapist.

Preparation of the Periodontium for Restorative Dentistry

Henry H. Takei, Robert A. Azzi, and Thomas J. Han

CHAPTER OUTLINE

PHASE[THERAPY
PERIODONTAL SURGERY
Restorative Considerations in Periodontal Surgery
Preprosthetic Periodontal Surgery

Active periodontal disease must be treated and controlled prior to any restorative dentistry. If restorative dentistry is performed on teeth where the periodontal prognosis is not determined and disease not treated, the loss of the restored tooth can occur. Restorative dentistry must be performed on a periodontium free of inflammation and pockets, without any mucogingival involvement, and with the contour and shape of the periodontium corrected for a good functional and esthetic restorative result. Implant dentistry also requires site development and preparation, not only for bone where it may be lacking but also for the augmentation of gingival soft tissues. The following are reasons why periodontal disease must be eliminated prior to restorative dentistry:

1. To locate and determine the gingival margins of restorations properly, the position of the healthy and stable gingival margin must be established prior to tooth preparation. Margins of restorations covered by inflamed gingiva shrinks after periodontal treatment.
2. The position of teeth is frequently altered in periodontal disease. Resolution of inflammation and regeneration of periodontal ligament fibers after treatment cause the teeth to move again, often back to their original position. Restorations designed for teeth before the periodontium is treated may produce injurious tensions and pressures on the treated periodontium.
3. Inflammation of the periodontium impairs the capacity of abutment teeth to meet the functional demands made on them. Restorations constructed to provide beneficial functional stimulation to a healthy periodontium become a destructive influence when superimposed on existing periodontal disease, shortening the life of the teeth and the restoration.
4. Partial prostheses constructed on casts made from impressions of diseased gingiva and edentulous mucosa do not fit properly when periodontal health is restored. When the inflammation is eliminated, the contour of the gingiva and adjacent mucosa is altered. Shrinkage creates spaces beneath the pontics of fixed bridges and the saddle areas of removable prostheses. Resultant plaque accumulation leads to inflammation of the mucosa and gingiva of the abutment teeth.

5. Discomfort from tooth mobility interferes with mastication and function. Periodontal treatment can reduce mobility with the elimination of edema in the periodontal ligament and regeneration of bone.

Furthermore, the aims of periodontal treatment are not limited to elimination of periodontal pockets and restoration of gingival health. *Treatment should also create the gingivomucosal environment and osseous topography necessary for the proper function of single-tooth restorations and fixed and removable partial prostheses.*

In patients with mutilated dentitions and extensive periodontal disease, the sequence of treatment can be modified as follows:

I. "Hopeless" teeth are extracted, followed by construction of a temporary partial denture. Temporary crowns are prepared with provisional margins.
2. Periodontal therapy is performed.
3. Approximately 2 months after periodontal treatment, when gingival health is restored and the location of the gingival sulcus is established, the preparations are modified to relocate the margins in proper relation to the healthy gingival sulcus, and final restorations are constructed.

Current periodontal and restorative therapy must also address the esthetic demands of the patient. A stable, healthy gingival margin and adequate exposure of the clinical crown is mandatory prior to crown preparation. This is necessary to prevent the exposure of the crown margin and root surface after the crown is placed. If there is not adequate clinical crown exposure for the retention of the crown, the margin of the crown may be placed in the junctional epithelium and the connective tissue attachment, resulting in gingival inflammation and subsequent bone loss. These situations require crown lengthening surgery. Fixed bridges in the anterior areas requires pontic placement on edentulous ridges that are not resorbed to avoid unesthetic pontics. Ridge augmentation would be necessary. Therefore the goal of these procedures is not treatment of a periodontal condition but instead preparation of the mouth for the ensuing esthetic, restorative, or prosthetic therapy. These surgical techniques are called *preprosthetic periodontal surgery* and include procedures such as crown lengthening and ridge augmentation. This chapter discusses Phase I therapy to control and treat the inflammatory phase of periodontal disease prior to restorative treatment and preprosthetic periodontal surgery.

PHASE I THERAPY

The specific goal of Phase I therapy is the control of active dental disease (see Chapters 47 and 48). Therefore when this phase of therapy is completed, patients should be in a state of dental health with active caries no longer present and active destruction of the periodontium under control. This results in elimination of the acute inflammatory response associated with periodontal destruction. Thus the status of the gingival tissues should be such that further restorative procedures of a more complex nature can be carried out without detrimental effects from unhealthy gingiva.

Obtaining control of periodontal inflammation during Phase I therapy results in restorations of a much higher quality than would be obtained if restoration were carried out in an environment of gingival inflammation. The presence of an acute inflammatory response in the gingiva causes ulceration of the epithelium that lines the gingival pocket and an increase in vascularity and edema of the tissues immediately beneath this epithelium. There is a possibility of continual bleeding and exudation of inflammatory tissue fluid into the gingival crevice and into the environ ment of restorative dental procedures. Therefore it is of utmost importance that all areas of the gingiva showing hemorrhage and significant amounts of inflammatory exudates be brought to an improved state of health before any restorative procedures other than emergency control of dental caries are carried out.

The removal of etiologic factors causing gingival inflammation results in a return to a healthy gingival state within 1 or 2 weeks. Thus plaque control, calculus removal, and the correction of any inadequate dental restorations in the gingival environment should be important initial procedures.

PERIODONTAL SURGERY

Restorative Considerations in Periodontal Surgery

Periodontal surgery is necessary in some patients. These periodontal surgical procedures should be carried out with due regard for the restorative needs of the patient. Therefore the final level of the periodontium should allow good access to all restorative marginal regions, and any necessary increase in clinical crown length should be obtained by postsurgical positioning of the periodontal tissues. If restorative procedures necessitate the resolution of mucogingival inadequacies, the appropriate surgical procedure should be completed before restorative therapy is begun.

Routine periodontal surgery procedures aimed at the correction of periodontal and mucogingival defects are described in previous chapters. Some of these surgical procedures may be modified because of the restorative or prosthetic needs of the patient. In addition, the goal of some procedures is not treatment of a periodontal condition, but preparation of the mouth for the ensuing restorative or prosthetic therapy.

Preprosthetic Periodontal Surgery

Management of Mucogingival Problems. It often is necessary to carry out a free soft tissue autograft in the patient who has a mucogingival defect associated with gingival inflammation and requires a dental restoration in the immediate environment of the gingiva (Fig. 74-1). The procedure for this free soft tissue autograft is presented in Chapter 66. Periodontal plastic surgery should be carried out at least 2 months before placement of the dental restorations. This allows time for mature tissue to form in the gingival margin so that restorative procedures do not cause a return of clinical inflammation. Augmentation of keratinized gingiva provides stability of the free gingival margin and surrounding gingival tissues

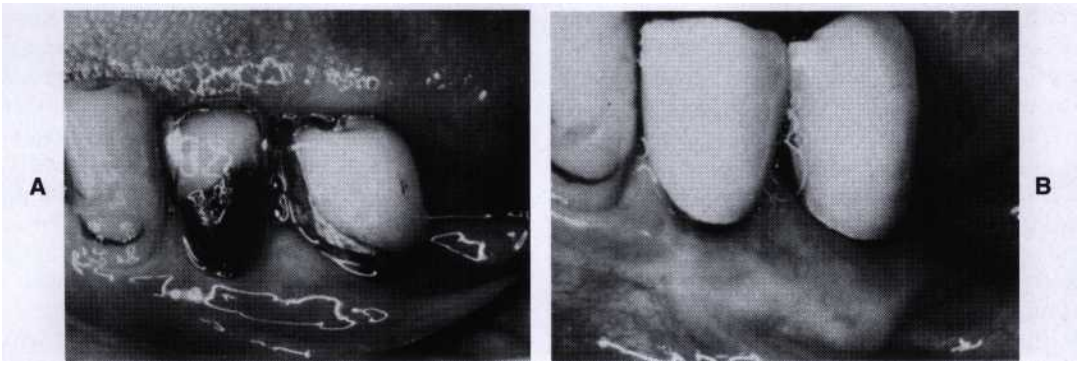

Fig. 74-1 Mucogingival problems. A, Preoperative mucogingival problem. The gingiva in the region where a crown margin is to be placed is inadequate. The presence of a plaque-enhancing margin necessitates the development of an adequate band of gingiva. B, Postoperative soft tissue autograft, 6 months after mucogingival surgery and placement of restoration. Note the adequate band of gingiva.

so that the dental restoration can be placed in an environment in which gingival health can be maintained.

Crown-Lengthening Procedures. In situations in which a tooth has a short clinical crown deemed inadequate for the retention of a required cast restoration, it is necessary to increase the size of the clinical crown using periodontal surgical procedures. These crown-lengthening procedures enable the dentist performing the restoration to develop an adequate area for crown retention without extending the crown margins deep into the periodontal tissues, referred to as the *biologic width.'* As discussed in Chapter *75,* the term *biologic width is* used to describe the junctional epithelium and connective tissue that attach to the root surface. Studies have indicated that the average lengths of the connective tissue attachment and junctional epithelium are *1.07* and *0.97* mm, respectively.' Therefore the average length of the biologic width is about *2* mm (Fig. *74-2).* The healthy gingival sulcus coronal to the junctional epithelium, which is not attached to the tooth surface, has an average depth of *0.69* mm. The biologic width usually remains constant. If the restorative margin is placed into this area, the crestal bone will be lost to reestablish the biologic width. The other consequence of margin placement into this area is gingival inflammation and pocket formation. A detailed discussion of biologic width and margin placement is presented in Chapter *75.* The surgical procedure to expose adequate clinical crown to prevent the placement of the crown margin into the area of the biologic width is termed *crown-lengthening surgery*. A gingivectomy technique can be used to eliminate the tissue that forms the pocket or sulcus wall; such tissue may be overgrown (gingival pocket) and may interfere with the intended restorative procedures. This technique does not lengthen the clinical crown and therefore is not considered true crown-lengthening surgery. By definition, the clinical crown is that portion of the tooth coronal to the alveolar crest. Therefore the bone margin must be removed to lengthen it. This is accomplished with an apically positioned flap and osteoectomy (Color Fig. *74-1),* which means that tooth-supporting bone is removed. The removal of bone is usually not necessary around the entire circumference of the tooth but, if undertaken, should be done with great caution. *It is essential that there be at least 3 mm between the most apical extension of the restoration margin and the alveolar bone crest.* This space allows sufficient room for the supracrestal collagen fibers that are part of the periodontal support mechanism, as well as providing a gingival crevice of *2* to 3 mm. If this guideline is used, the margin of the crown is finally positioned at its correct level, approximately halfway down the gingival crevice. Chapter *75* presents the clinical evaluation and determination of methods used for assessing the biologic width. Failure to allow sufficient space between the crown margin and the alveolar crest height means that the finished restoration is positioned deep in the periodontal tissues and results in increased inflammation and pocket formation.

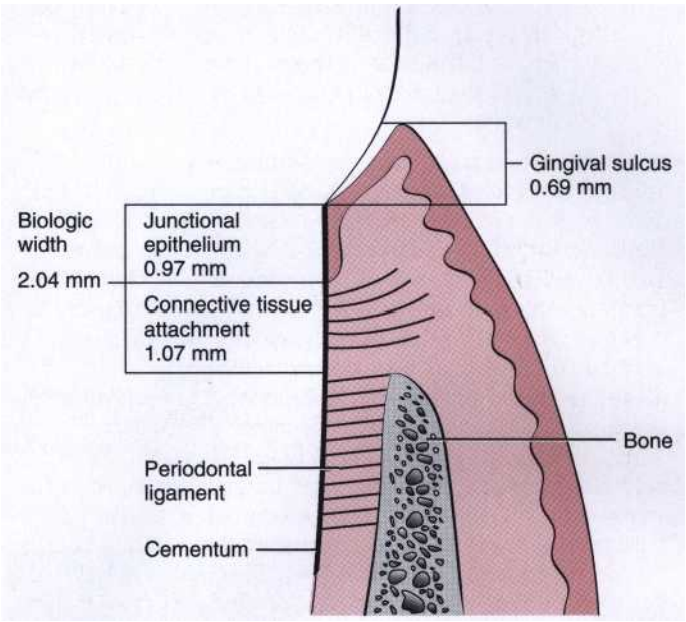

Fig. 74-2 The dentogingival junction. Note the area of biologic width composed of junctional epithelium and connective tissue attachment.

Color Fig. 74-1 presents crown-lengthening surgery of the maxillary anterior area. Extensive loss of tooth structure has occurred, and crown-lengthening surgery is necessary prior to crown preparation. This area not only requires crown lengthening but also proper symmetry and shape of the gingival tissues for esthetic objectives. Because the gingival tissue outline follows that of the underlying bone, the removal of the bone must achieve an esthetic symmetry. A surgical template constructed prior to surgery helps determine the amount of bone removal and the contour that must be incorporated to achieve a good esthetic symmetry. Chapter 62 addresses this technique. Chisels are used to sculpt the outline of the bone removal. For proper esthetic symmetry, the height of the central incisors and the cuspids are equal and apical to the lateral incisors. The flap to expose the bone is initially full thickness at the crestal area but converted to a split thickness flap so that the flap may be positioned apically during closure. Holding sutures are used to position the flap, and closing sutures are placed at the papilla for flap closure. The final result (see Color Fig. 74-1, j) was both functionally and esthetically acceptable to the patient.

Ridge Augmentation Procedures. These procedures are aimed at correcting the excessive loss of alveolar bone that sometimes occurs in the anterior region as

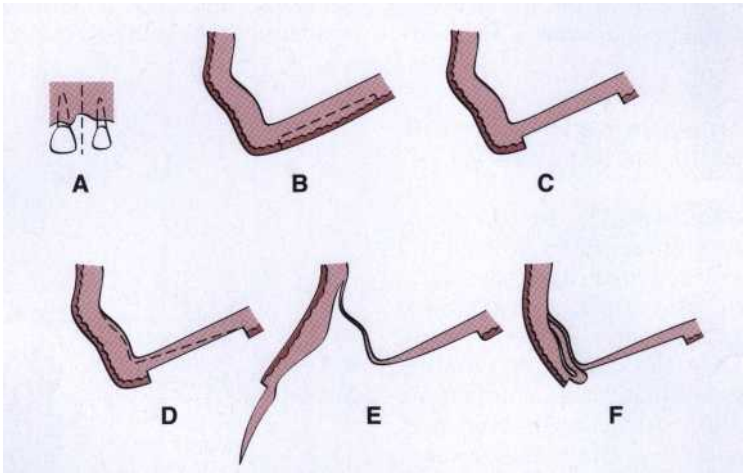

Fig. 74-3 The roll technique for ridge augmentation. A and B, The epithelial surface is removed on the palatal surface. C, The split-thickness flap is directed toward the facial aspect. D, The split thickness flap is reflected. E and F, The portion of the split thickness flap with the epithelium removed is folded to augment the

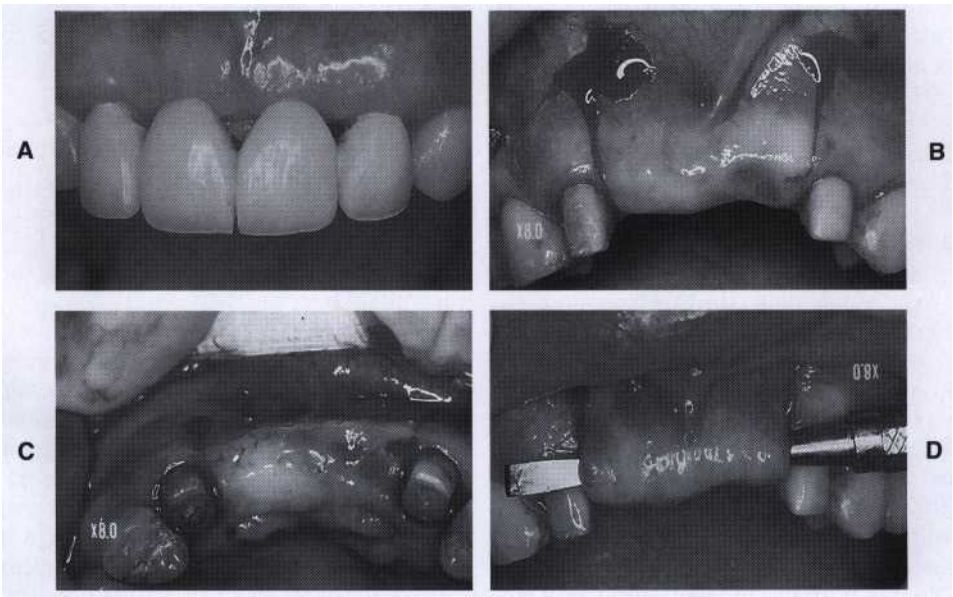

Fig. 74-4 Vertical and horizontal ridge augmentation using the connective tissue tunnel technique. A, Preoperative view of the maxillary anterior area. Note the deficient ridge. B, Vertical incisions at both ends of the deficient ridge after the bridge is removed. C, The vertical incision is extended to the palatal areas to augment vertically. D, A split thickness tunnel is created at the recipient site.

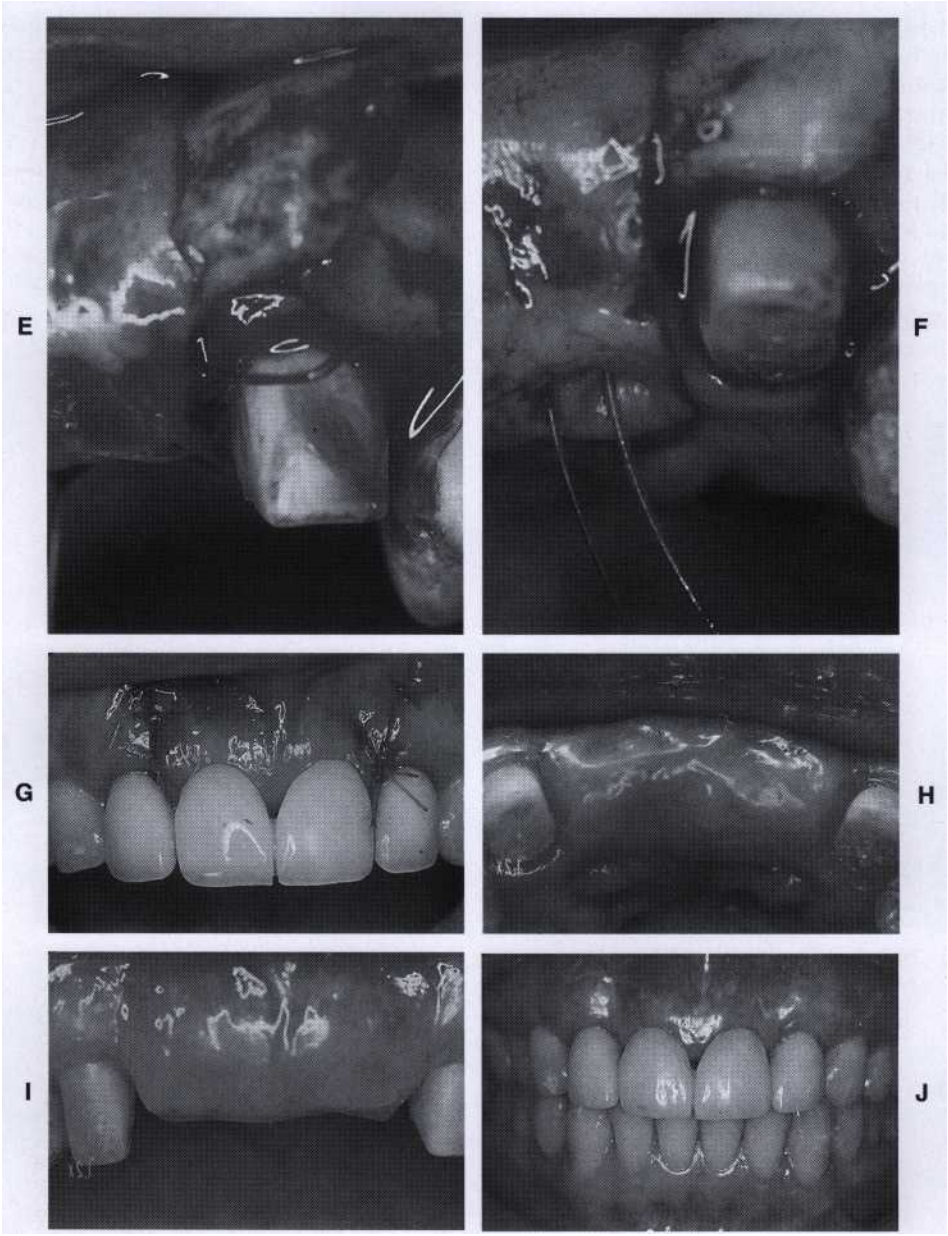

Fig. 74-4, cont'd E, Two separate subepithelial connective tissues are inserted into the tunnel at both ends. F, Sutures placed from the palatal surface are used to position the connective tissue in the tunnel. G, The recipient site is sutured. H, Four months postoperative. Horizontal augmentation. 1, Four months postoperative. Vertical augmentation. 1, **The final result with the fixed restoration in place.**

a consequence of advanced periodontal disease, advanced periapical bone loss, traumatic tooth extractions, and external trauma. This excessive bone loss may create a difficult esthetic problem and complicate the prosthetic reconstruction.

In fixed prosthetic replacement, the large space may result in either a long pontic or a space between the apical end of the pontic and the resorbed ridge. These osseous defects may occur in a coronoapical or buccolingual direction. In many situations, it can occur in both directions simultaneously.

Several surgical procedures have been developed to correct these ridge discrepancies. The roll technique was reported by Abrams to manage moderate tissue loss in the buccolingual direction. Fig. 74-3 illustrates this surgical procedure. Initially, the epithelium on the palatal side of the defect is removed (see Fig. 74-3, A). After a split-thickness incision, the flap denuded of the epithelial covering is rolled beneath the buccal split flap. The rolled portion of the palatal split flap augments the ridge in a buccal direction. Ridge defects that are more extensive can be augmented using subepithelial connective donor tissue from the palate, which is placed in pouches or tunnels created at the recipient site. Fig. 74-4 illustrates a case using connective tissue donor graft placed in a tunnel. Vertical incisors at the two ends of the defect and a

tunnel made in both the horizontal and vertical directions create a recipient site that provides excellent blood supply to the donor tissue. This tissue is positioned with gut sutures from the palatal side. The vertical augmentation achieved by this surgery provides an excellent soft tissue environment for an esthetic fixed restoration (see Fig. 74-4, j). Larger defects may require bone grafts in the form of a monocortical block using fixation screws or particulate bone grafts held in place with a titanium-supported membrane. These procedures are discussed in Chapter 66.

OCCLUSAL CONSIDERATIONS

SPECIAL CONSIDERATIONS
- **Restoration of Root-Resected Teeth**
- **Splinting**
- **Anterior Esthetic Surgery**

The relationship between periodontal health and the restoration of teeth is intimate and inseparable. For restorations to survive long term, the periodontium must remain healthy so that the teeth are maintained. For the periodontium to remain healthy, restorations must be critically managed in several areas so that they are in harmony with their surrounding periodontal tissues. To maintain or enhance the patient's esthetic appearance, the tooth/tissue interface must present a healthy natural appearance, with gingival tissues framing the restored teeth in a harmonious manner. This chapter reviews the key areas of restorative management necessary to optimize periodontal health and therefore the esthetics and function of restorations.

BIOLOGIC CONSIDERATIONS

Margin Placement and Biologic Width

Restorative clinicians must understand the role of biologic width in preserving healthy gingival tissues and controlling the gingival form around restorations. They must also apply this information in the positioning of restoration margins, especially in the esthetic zone where a primary treatment goal is to mask the junction of the margin with the tooth. A clinician is presented with three options for margin placement: supragingival, equigingival (even with the tissue), and subgingival locations.[10] The supragingival margin has the least impact on the periodontium. Classically, this margin location has been applied in nonesthetic areas due to the marked contrast in color and opacity of traditional restorative materials against the tooth. With the advent of more translucent restorative materials, adhesive dentistry, and resin cements, the ability to place supragingival margins in esthetic areas is now a reality (Figs. 75-1 and 75-2). Therefore whenever possible, these restorations should be chosen not just for their esthetic advantages but for their favorable periodontal impact as well. The use of equigingival margins traditionally was not desirable because they were thought to retain more plaque than supragingival or subgingival margins and therefore result

Fig. 75-1 With the advent of adhesive dentistry and ultrathin ceramic veneers, it now is possible to prepare restorations equigingival without visible margins. The preparations for six porcelain veneers with the margins placed at the level of tissue are shown.

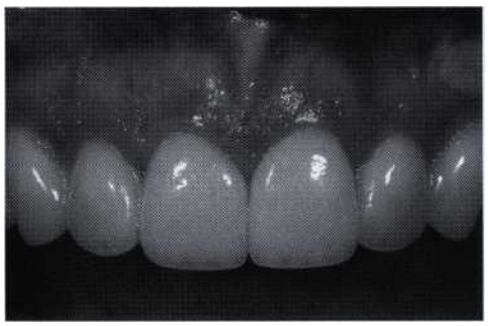

Fig. 75-2 The completed veneers. Note the invisible gingival finish line, even though the margin has not been carried below tissue.

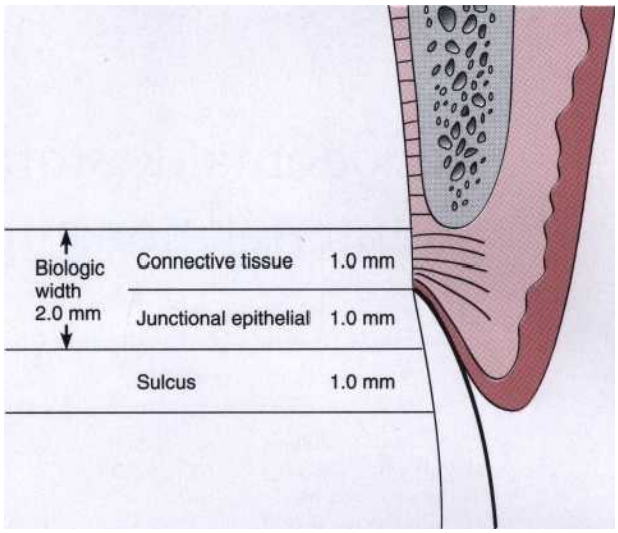

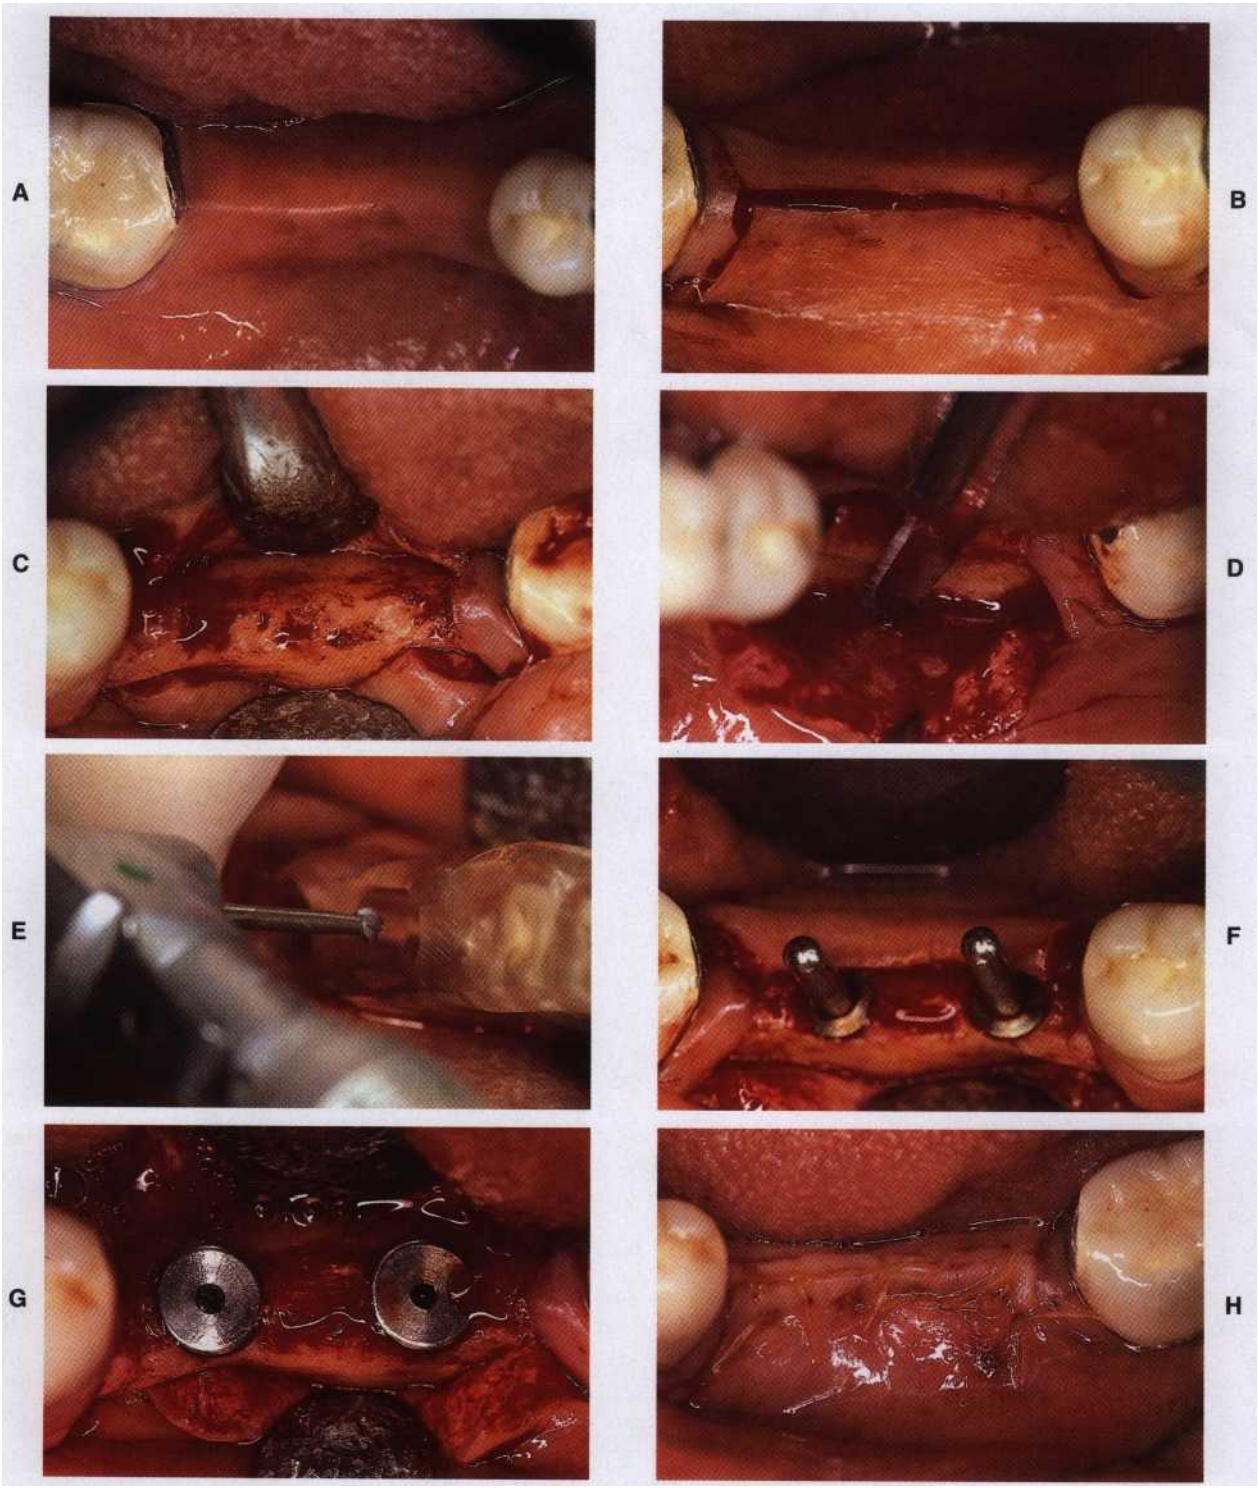

Fig. 75-3 Average human biologic width: Connective tissue attachment 1 mm in height; epithelial attachment 1 mm in height; sulcus depth of approximately 1 mm. The combined connective tissue attachment and epithelial attachment or biologic width equals 2 mm.

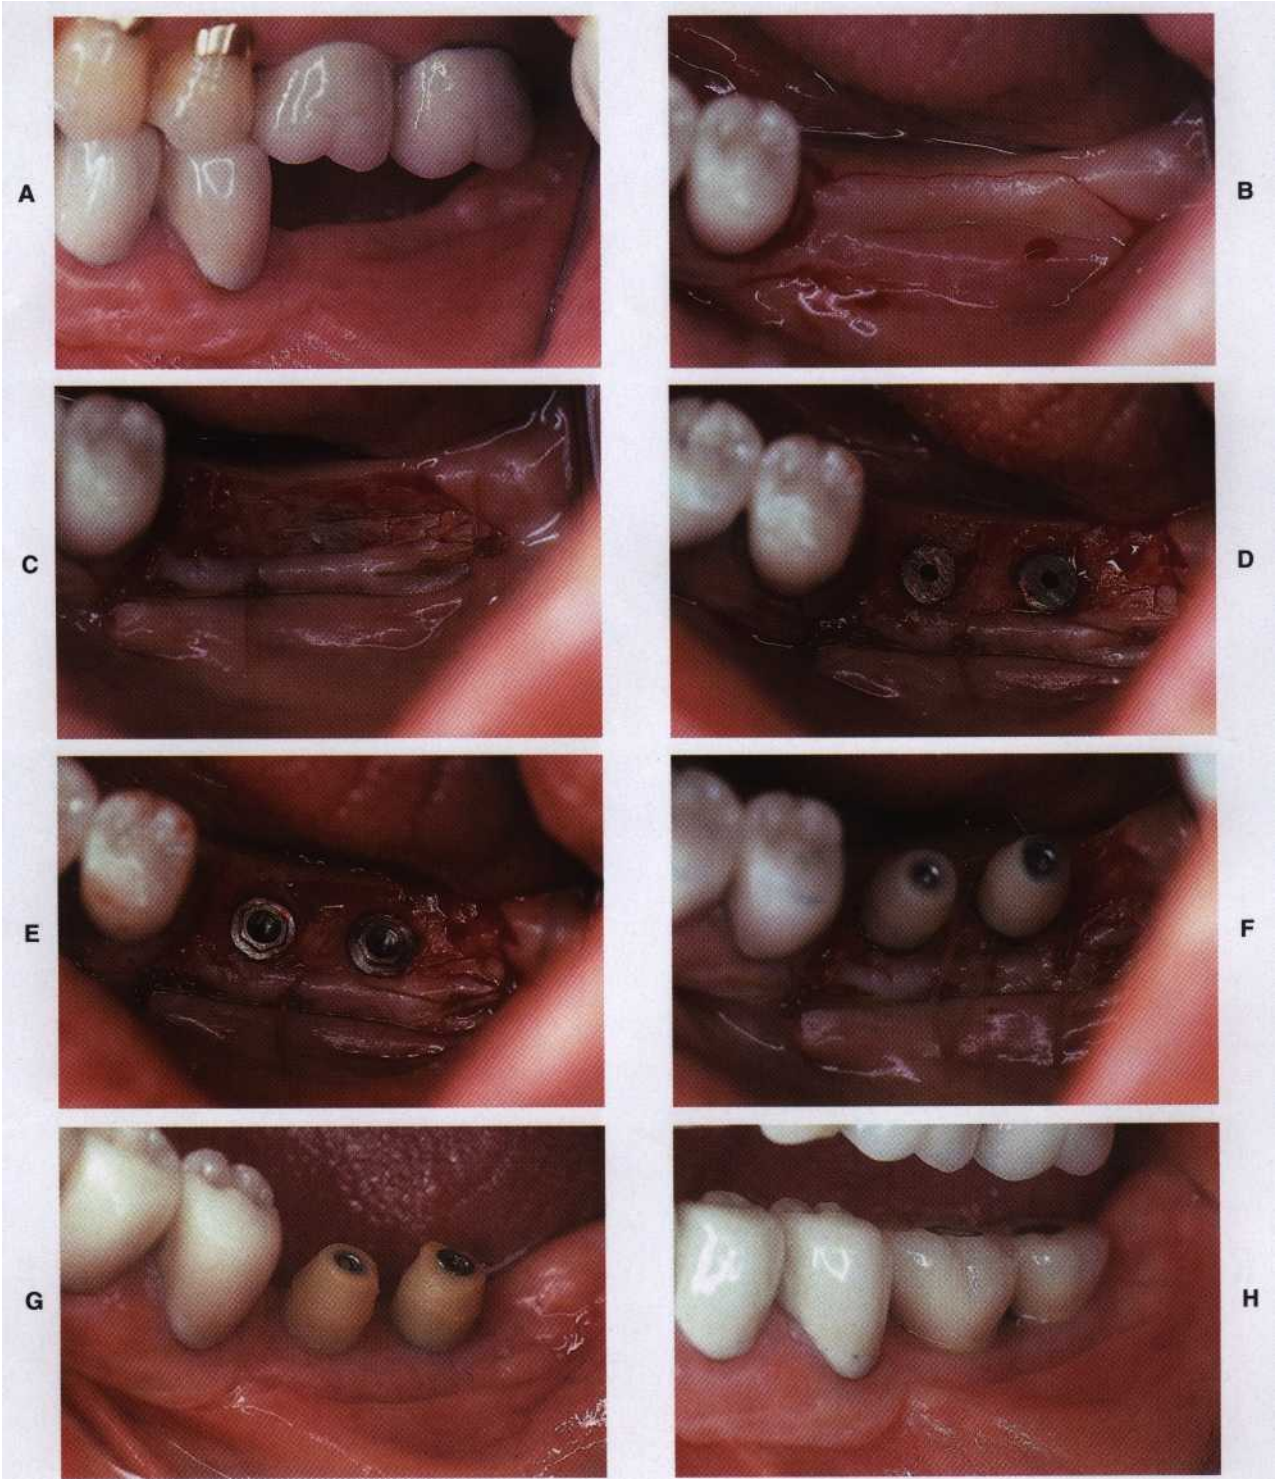
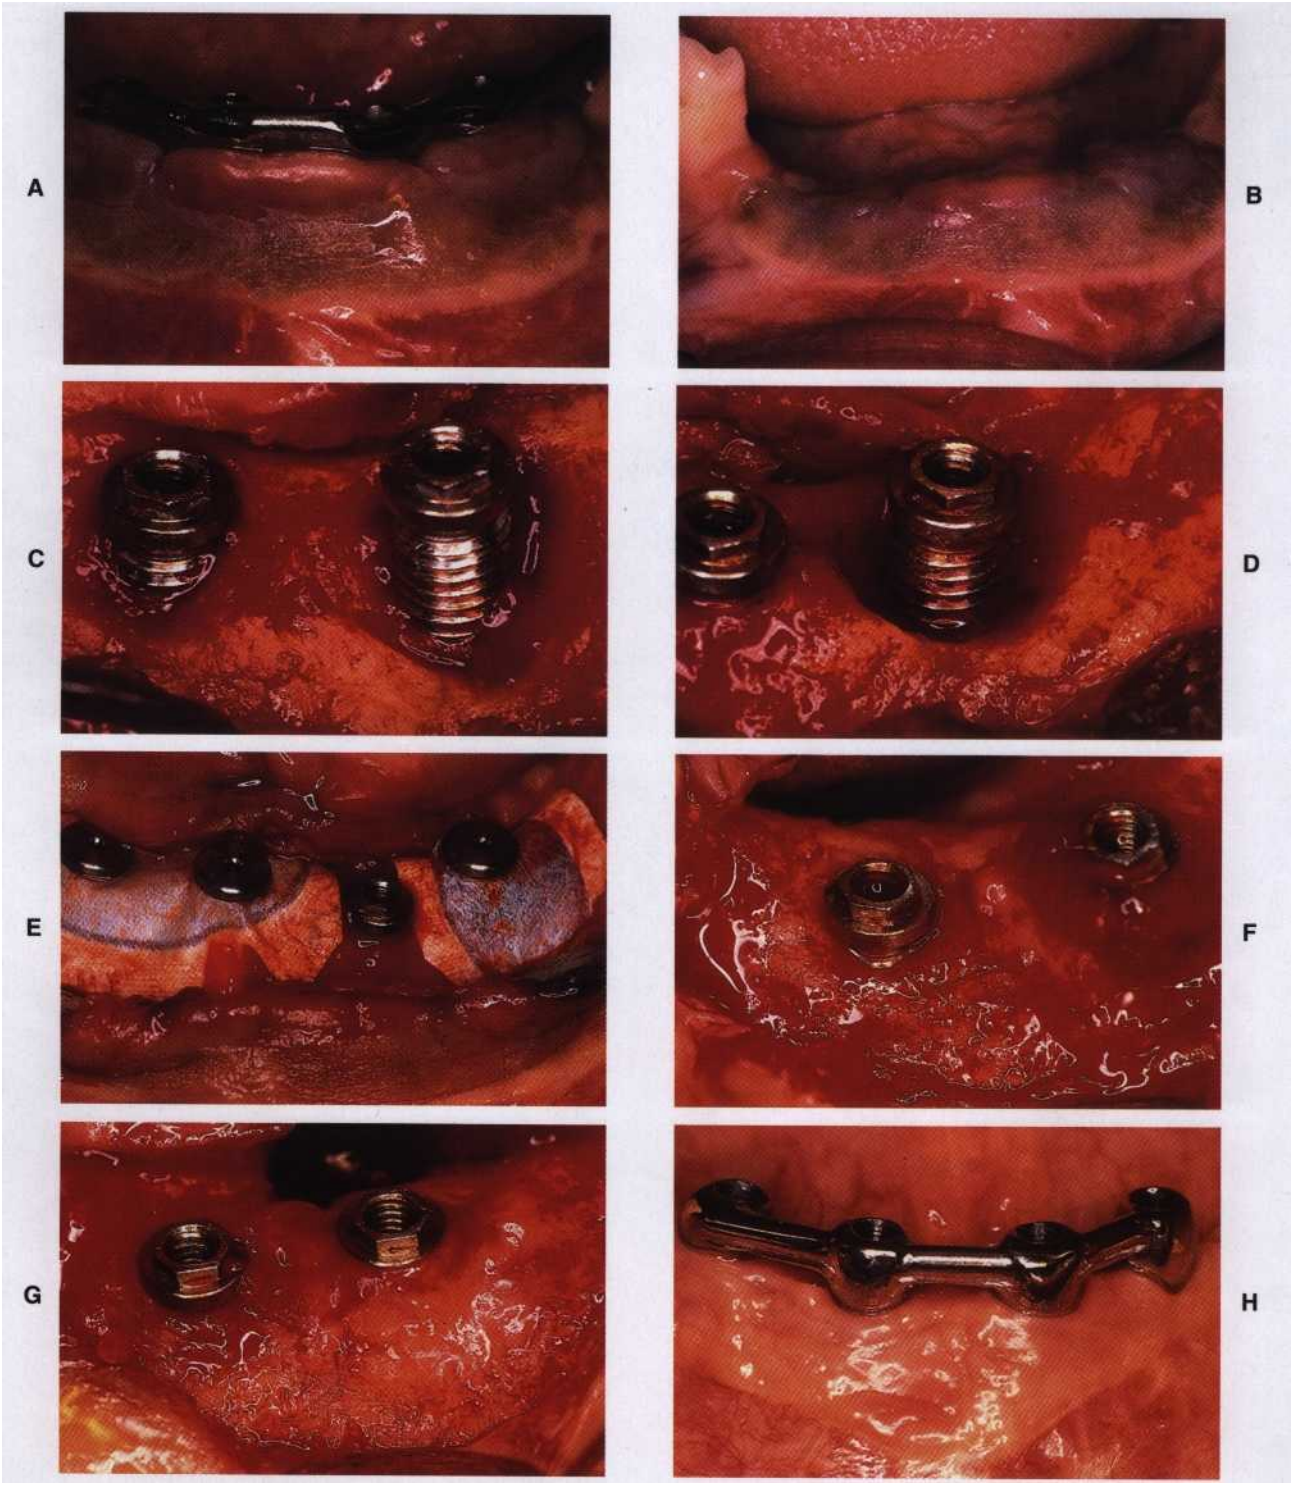
in greater gingival inflammation. There was also the concern that any minor gingival recession would create an unsightly margin display. These concerns are not valid today, not only because the restoration margins can be esthetically blended with the tooth but also because restorations can be finished easily to provide a smooth, polished interface at the gingival margin. From a periodontal viewpoint, both supragingival and equigingival margins are well tolerated. The greatest biologic risk occurs when placing subgingival margins." These margins are not as accessible as supragingival or equigingival margins for finishing procedures, and in addition, if the margin is placed too far below the gingival tissue crest, it violates the gingival attachment apparatus.

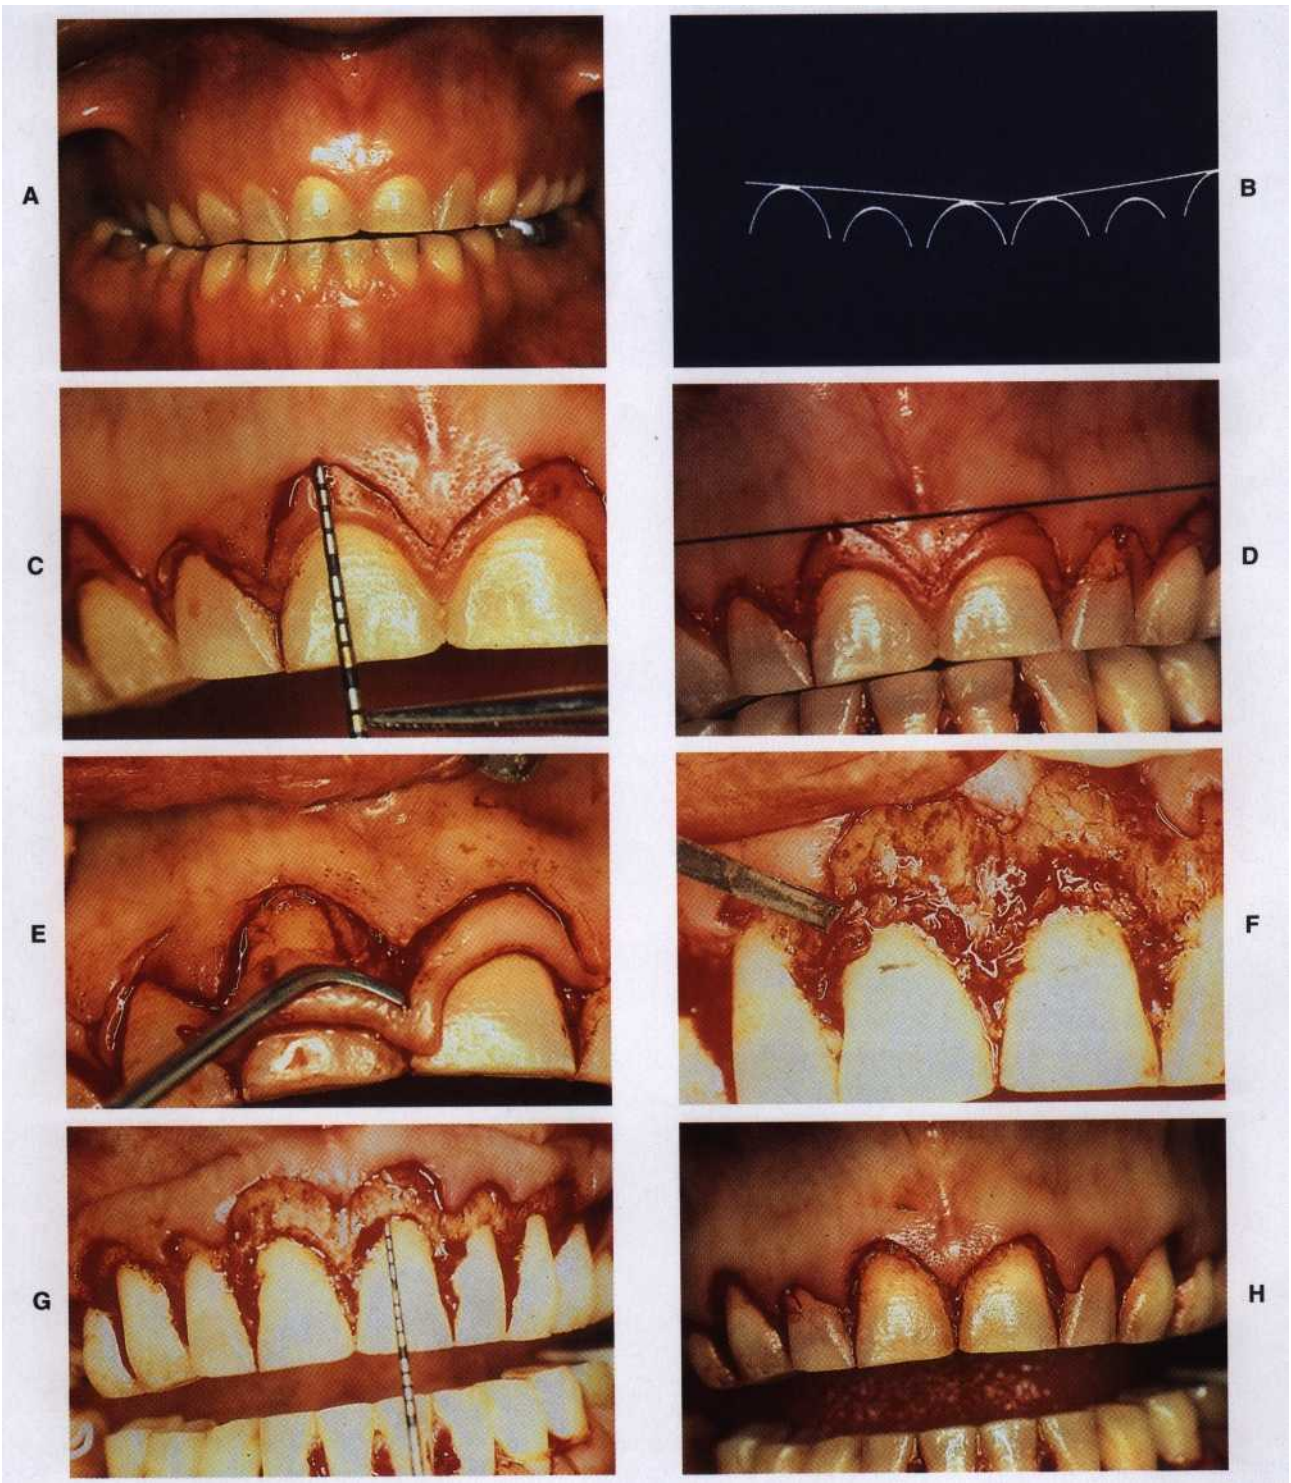


The dimension of space that the healthy gingival tissues occupy above the alveolar bone is now identified as the biologic *width.* Most authors credit Gargiulo, Wentz, and Orban's study on cadavers with establishing the dimensions of space required by the gingival tissues." They found that in the average human, the connective tissue attachment occupies 1.07 mm of space above the crest of the alveolar bone and that the junctional epithelium below the base of the gingival sulcus occupies another 0.97 mm of space above the connective tissue attachment. The combination of these two measurements constitutes the biologic width (Fig. 75-3). Clinically, this information is applied to diagnose biologic width violations when the restoration margin is placed 2 mm or less away from the alveolar bone and the gingival tissues are inflamed with no other etiologic factors evident.

Restorative considerations frequently dictate the placement of restoration margins beneath the gingival tissue crest. Restorations may need to be extended gingivally to create adequate resistance and retentive form in the preparation, to make significant contour alterations because of caries or other tooth deficiencies, or to mask the tooth/restoration interface by locating it subgingivally. When the restoration margin is placed too far below the gingival tissue crest, it impinges on the gingival attachment apparatus and creates a violation of biologic width.[49] Two different responses can be observed from the involved gingival tissues (Fig. 75-4). One possibility is that bone loss of an unpredictable nature and gingival tissue recession occur as the body attempts to recreate room between the alveolar bone and the margin to allow space for tissue reattachment. This is more likely to occur in areas where the alveolar bone surrounding the tooth is very thin. Trauma from restorative procedures can play a major role in causing this fragile tissue to recede. Other factors also have been presented in the literature as influencing the likelihood of recession. These variables include whether the gingiva is thick and fibrotic or thin and fragile and whether the periodontium is highly scalloped or flat in its gingival form. It has been found that highly scalloped thin gingiva is more prone to recession than a flat periodontium with thick fibrous tissue.[48]



The more common finding with deep margin placement is that the bone level appears to remain unchanged, but gingival inflammation develops and persists. To restore gingival tissue health, it is necessary to clinically establish space between the alveolar bone and the margin.



Color Fig. 70-1 First-stage surgery. A, A partial edentulous ridge. A presurgical and prosthodontic treatment has been completed. B, Mesial and vertical incisions are connected by a crestal incision. Notice that bands of gingival collars remain adjacent to teeth. C, Minimal flap reflection is used to expose the alveolar bone. Sometimes a ridge modification is necessary to provide a flap recipient bed. D, A buccal flap is partially dissected at the apical portion to provide a flap extension. This is a very critical step to ensure a tension-free closure of the flap after the implant placement. E, It is important to use the surgical stent to determine the mesial-distal, buccal-lingual, and proper angulation of the implant placement. F, Frequent use of the guide pins ensures the parallelism of the implant placement. G, After the placement of two Nobelpharma implants, the cover screws are placed. The cover screws should be flush with the rest of the ridge to minimize the chance of exposure. This is especially important if a partial denture is to be worn during the healing phase. H, Suturing completed. Both regular interrupted and inverted mattress sutures are used intermittently to ensure tension-free, tight closure of the flaps.

Color Fig. 70-2 Second-stage surgery. A, Two endosseous implants were placed 4 months previously and are ready to be exposed. Notice the narrow band of keratinized tissue. B, Two vertical incisions are connected by crestal incision. If facial keratinized tissue is insufficient, it is necessary to locate the crestal more lingually so that there is a minimum of 2 to 3 mm of keratinized band. C, A buccal partial-thickness flap is sutured to the periosteum apical to the emerging implants. D, Gingival tissue coronal to the cover screws is excised using the gingivectomy technique. E, The cover screws are removed and the heads of the implants are cleared. F, Abutments are placed. Visual inspection ensures intimate contact between the abutments and the implants. G, Two- to three-week healing after second-stage surgery. H, Four months after the final restoration. Notice the healthy band of keratinized attached gingiva around the implants.

Color Fig. 73-1 Reconstructive treatment of periimplantitis. A, Four osseointegrated implants used for retention of an overdenture in an edentulous lower jaw. Moderate to severe periimplantitis, with soft tissue hyperplasia and deep pockets around all implants. There was radiographic evidence of progressive bone loss around three of the four implants. B, A submerged regenerative therapy was initiated by removal of the abutments 6 months before surgery, and a 1-week period of systemic antibiotic coverage was instituted. Note the improved soft tissue appearance. C and D, Elevated flap, showing bone loss around three of the four implants. The defects consisted of horizontal bone loss and shallow-to-deep circumferential vertical defects around the implants. The defects were carefully degranulated by hand, and the implant surfaces were detoxified with supersaturated citric acid and an air abrasive for 30 to 60 seconds and then flushed with sterile water. Bone surfaces were roughened and penetrated with small, round burs. E, Two membranes placed over the periimplant bone defects, allowing a blood clot to form underneath. Note the close adaptation of the membranes to the periphery of the bone defects, acting as a tent over the defects. F and G, After an uneventful healing period of 4 months, the surgical sites are exposed and the membranes removed. Note the osseous regeneration in the minimal soft tissue retraction around all implants.

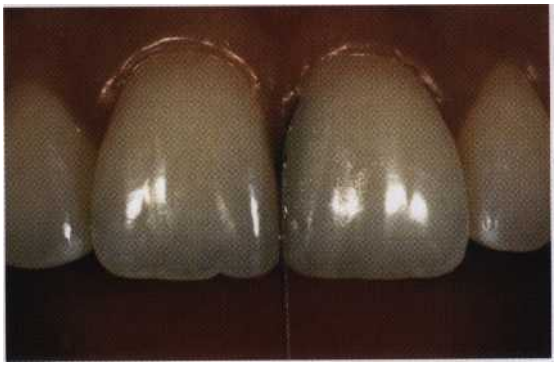
Color Fig. 74-1 Crown lengthening of the maxillary anterior dentition. A, Before treatment. Note the short clinical crown that is inadequate for full crown restorations. The facial gingival symmetry is also uneven. The gingival margin of the two lateral incisors is apical to the two cuspids and even with the two central incisors. B, The ideal gingival symmetry. The apical gingival margins for the two central incisors and cuspids are even and apical to that of the lateral incisors. C, Measurement taken for crown lengthening. D, The incision for the flap, following the ideal symmetry. E, Removal of tissue prior to flap reflection. F, Bone removal with a chisel, following ideal symmetry and measurement. G, Measurement taken after bone removal. H, The flap positioned for suturing.

Continued

Color Fig. 74-1, cont'd 1, Healing after 3 months. The crown is ready for restorations. J, The final restoration. Note the ideal symmetry.

Color Fig. 75-1 Depth from the attachment to the level of the margin is greater than 3 mm. This patient had an altered eruption pattern and a sulcus of more than 3 mm at the time these restorations were placed.

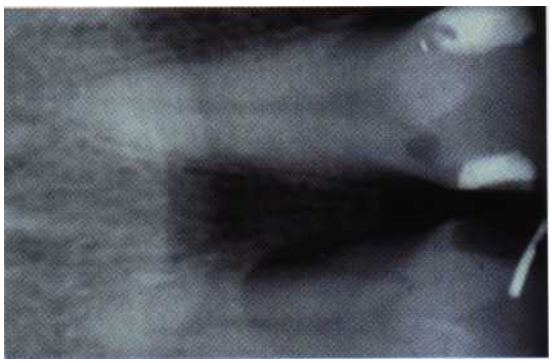
Color Fig. 75-2 Two options were available to appropriately manage treatment: 1) place the original margins half the depth of the sulcus, in which case the recession that occurred would not have exposed them; or 2) perform a gingivectomy, creating a 1- to 1.5-mm sulcus. This was the option chosen when the restorations were redone. The margins were then placed 0.5 mm below tissue after the gingivectomy.



Color Fig. 75-3 At 6 weeks after the gingivectomy and preparation of the teeth. Note the tissue level and that the tissue is rebounding coronally over the margins. This is a common finding when a pure gingivectomy is done.

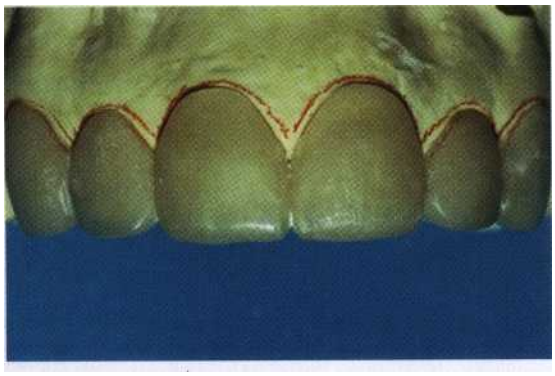
Color Fig. 75-4 A 4-year recall photograph after placement of the final restorations. Note the tissue level has been maintained with a sulcus depth of 2 mm on the facial.

Color Fig. 75-5 This patient has parallel roots, has recently completed orthodontics, and is unhappy with the open gingival embrasure between her centrals. An evaluation of papillary heights finds them all at an equal level. This can only mean that the open embrasure is the result of an overly tapered tooth form.



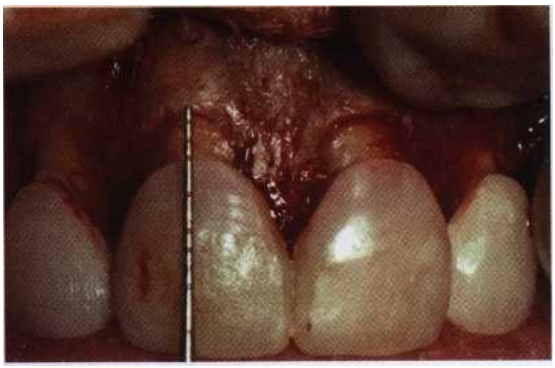
Color Fig. 75-6 One method of correctly altering tooth form. A metal matrix band has been shaped to the desired tooth form and placed 1 to 1.5 mm below the tip of the papilla. Restorative material then was added to the tooth against the matrix band, forming the new mesial surface of the left central incisor.

Color Fig. 75-7 A 1-year recall photograph after restoring the mesial surfaces of the right and the left central incisors, moving the contact to the tip of the papilla and carrying the restorations 1 to 1.5 mm below the papilla, blending them into the tooth and making an easily cleaned area.



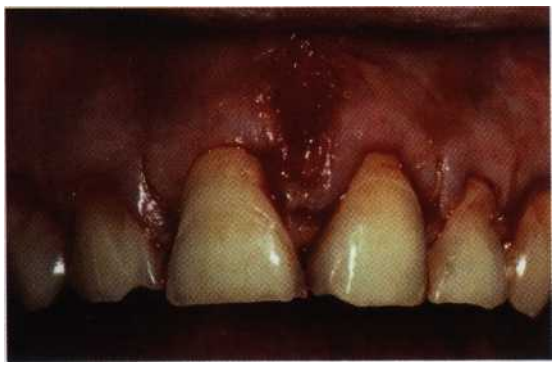
Color Fig. 75-8 A patient who will have the right central incisor extracted due to periodontal disease. The patient is choosing to have a fixed partial denture rather than an implant as the method of replacement. An ovate pontic will be used to maintain the papillary form after the removal of this central incisor.

Color Fig. 75-9 Note radiographically the presence of the palatal well due to a deep palatal groove on this right central incisor. Two attempted periodontal surgeries have failed to correct this, and it still probes 10 mm with suppuration.



Color Fig. 75-10 Because the patient desired to alter the esthetics of her remaining anterior teeth, all the anterior teeth were prepared before removal of the right central incisor.

Color Fig. 75-18 A composite resin surgical guide is fabricated on this stone model, extending to the line drawn. This guide can be taken to the mouth for try-in and verification by the patient.



Color Fig. 75-19 A photograph taken the day the surgical guide was tried in. The patient approved the new length of the maxillary anterior teeth and the form created by altering the soft tissue profile.

Color Fig. 75-20 By placing the surgical guide during the surgery, it is possible to recognize where the bone needs to be placed. The surgical guide represents the desired final free gingival margin position and can be used as a reference for osseous recontouring. This patient had an average biologic width of 2 mm. Allowing an additional 1 mm for sulcus depth, the desired distance between the bone and free gingival margin will be 3 mm. With this knowledge, the periodontist can use the guide and remove bone until it is 3 mm from the position of the guide on each tooth.

Color Fig. 75-21 The surgical guide is also useful during suturing. Because the guide represents the desired free gingival margin position, it is possible to suture to the level of the guide, knowing that the surgery has now recreated biologic width and a 1-mm sulcus. This shortens the amount of time necessary for healing and eliminates the need to wait for tissue rebound prior to restorative dentistry.

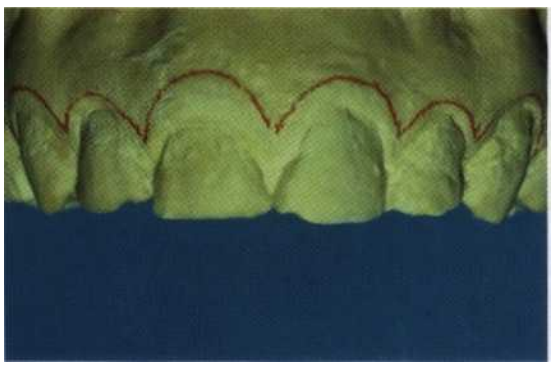
Color Fig. 75-22 The soft tissue profile as seen the day of surgery with the guide removed. Note that in this patient, the interproximal papillae were not changed because the interproximal papilla form and height were deemed acceptable.

Color Fig. 75-23 A photograph taken 4 years after placement of the final restorations. Note the excellent soft tissue health and the attainment of the desired free gingival margin and papillary form.

Color Fig. 75-11 The key to maintenance of the interproximal papilla is that the ovate pontic extend 2.5 mm into the extraction site on the day of extraction. This will maintain gingival embrasure form and therefore maintain interproximal papilla height.

Color Fig. 75-12 Note that when the provisional is seated on the day of extraction, 2.5 mm of temporary extend upward into the extraction socket. Also note the open gingival embrasures present to allow space for the papilla to rebound coronally.

Color Fig. 75-13 9 months after placement of the provisional restoration. At 4 weeks after placement, the pontic was shortened to extend 1.5 mm into the extraction site to facilitate oral hygiene. Note maintenance of papillary form and free gingival margin height, predictable in this patient because she has excellent interproximal and facial bone.



Color Fig. 75-14 The ovate pontic after removal of the provisional and prior to final impressions. Note that papillary form has been maintained because of the ovate pontic maintaining gingival embrasure volume.

Color Fig. 75-15 A 2-year recall photograph of the final fixed prosthesis. Note how the final ovate pontic also has maintained papillary form.

Color Fig. 75-16 A patient who is unhappy with the appearance of her maxillary teeth and the discrepancies of tissue height and tooth form.

Color Fig. 75-17 To create a surgical guide, a stone model is modified by drawing the desired soft tissue profile with a red wax pencil.

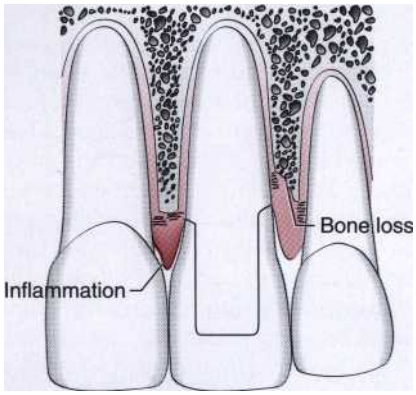


Fig. 75-4 Ramifications of a biologic width violation if a restorative margin is placed within the zone of the attachment. On the mesial of the left central, bone has not been lost, but gingival inflammation occurs. On the distal of the left central, bone loss has occurred and a normal biologic width has been reestablished.

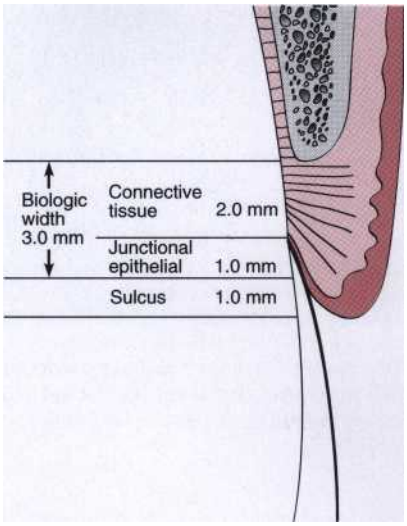

Fig. 75-5 Possible variations exist in biologic width. Connective tissue attachments and epithelial attachments may be variable. In this example the connective tissue attachment is 2 mm in height, the epithelial attachment 1 mm in height, and the sulcus depth 1 mm, for a combined total tissue height above bone of 4 mm. However, the biologic width is 3 mm. This is just one variation that can occur from the average depicted in Fig. 75-3.

This can be accomplished either by surgery to alter the bone level or by orthodontic extrusion to move the restoration margin farther away from the bone level.

Evaluation of Biologic Width

Radiographic interpretation can identify interproximal violations of biologic width. However, with the more common locations on the mesiofacial and distofacial line angles of teeth, radiographs are not diagnostic because of tooth superimposition. If a patient experiences tissue discomfort when the restoration margin levels are being assessed with a periodontal probe, it is a good indication that the margin extends into the attachment and that a biologic width violation has occurred. A more positive assessment can be made clinically by measuring the distance between the bone and the restoration margin using a periodontal probe. The probe is pushed through the anaesthetized attachment tissues from the sulcus to the underlying bone. If this distance is less than 2 mm at one or more locations, a diagnosis of biologic width violation can be confirmed. This assessment is **completed circumferentially around the tooth to evaluate the extent of the problem.** However, biologic width violations can occur in some patients in whom the margins are located more than 2 mm above the alveolar bone level .[23] In 1994, Vacek et al also investigated the biologic width phenomenon." Although their average width finding of 2 mm was the same as that previously presented by Gargiulo et al, they also reported a range of different, patient-specific biologic widths. They reported biologic widths as narrow as 0.75 mm in some individuals, whereas others had biologic widths as tall as 4.3 mm (Fig. 75-5). This information dictates that specific biologic width assessment should be performed for each patient to determine whether they need additional biologic width in excess of 2 mm for restorations to be in harmony with their gingival tissues. The biologic, or attachment, width can be identified for each individual patient by probing under anesthesia to the bone level (referred to as "sounding to bone") and subtracting the sulcus depth from the resulting measurement. This measurement must be performed on teeth with healthy gingival tissues and should be repeated on more than one tooth to ensure an accurate assessment. The technique allows the variations in sulcus depths found in individual patients to be assessed and factored into the diagnostic evaluation. The information obtained is then used to definitively diagnose biologic width violations, the extent of correction needed, and the parameters for placement of future restorations.

Correction of Biologic Width Violations

Biologic width violations can be corrected by either surgically removing bone away from proximity to the restoration margin or orthodontically extruding the tooth and thus moving the margin away from the bone. Surgery is the more rapid of the two treatment options. It is also preferred if the resulting crown lengthening will create a more pleasing tooth length. In these situations, the bone should be moved away from the margin by **the measured distance of the ideal** biologic width for that patient, with an additional 0.5 mm of bone removed as a safety zone.

Gingival recession is a potential risk after removal of bone.' If interproximal bone is removed, there is a high likelihood of papillary recession and the creation of an unesthetic triangle of space below the interproximal contacts. If the biologic width violation is on the interproximal, or if the violation is across the facial surface and the gingival tissue level is correct, then orthodontic

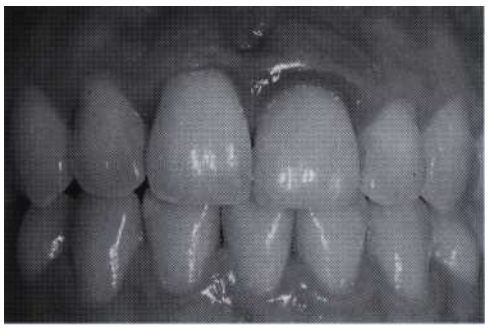

Fig. 75-6 The left central incisor was fractured in an accident 12 months ago and restored at that time. The patient is unhappy with the appearance of the tissue surrounding the restoration.

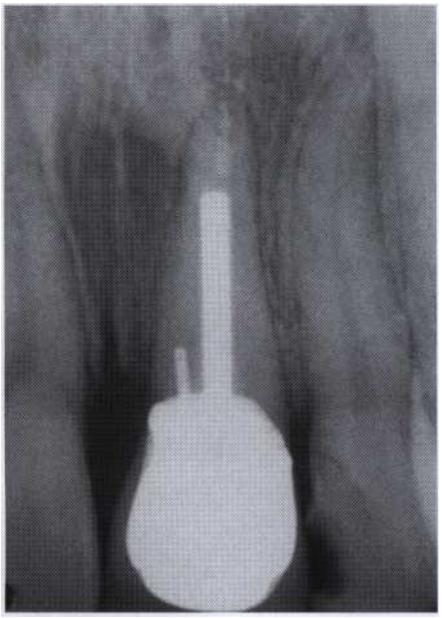

Fig. 75-7 A radiograph reveals a biologic width violation on the mesial surface interproximally. Removal of interproximal bone would create an esthetic deformity. This patient is better treated with orthodontic extrusion.

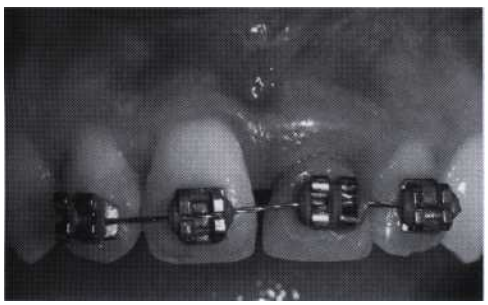

Fig. 75-8 After orthodontic eruption. The tooth has been erupted 3 mm to move the bone and gingiva coronally 3 mm on the left central. It is now possible to surgically reposition the bone to the correct level and position the gingiva to the correct level, reestablishing normal biologic width.

extrusion is indicated (Figs. 75-6 to 75-9).[28] The extrusion can be performed in two ways. By applying low orthodontic extrusion force, the tooth is erupted slowly, bringing the alveolar bone and gingival tissue with it. The tooth is extruded until the bone level has been carried coronal to the ideal level by the amount that needs to be removed surgically to correct the attachment violation. The tooth is stabilized in this new position and then treated with surgery to correct the bone and gingival tissue levels. Another option is to carry out rapid orthodontic extrusion whereby the tooth is **erupted the desired** amount over several weeks.[32] During this period, a supercrestal fiberotomy is performed weekly in an effort to prevent the tissue and bone from following the tooth. The tooth is then stabilized for at least *12* weeks to confirm the position of the tissue and bone, and any coronal creep can be corrected surgically.

Margin Placement Guidelines

When determining where to place restorative margins relative to the periodontal attachment, it is recommended that the patient's existing sulcus depth be used as a guideline in assessing the biologic width requirement for that patient. The base of the sulcus can be viewed as the top of the attachment, and therefore variations in attachment height are accounted for by assuring that the margin is placed in the sulcus and not in the attachment.[4,37,38,57] The variations in sulcular probing depth are then used to predict how deeply the margin can safely be placed below the gingival crest. With shallow probing depths (1 to 1.5 mm), extending the preparation more than 0.5 mm subgingivally will risk violating the attachment. This assumes that the periodontal probe penetrates an average of 0.5 mm into the epithelial attachment in healthy gingiva. With shallow probing depths, future recession is unlikely because the free gingival margin is located close to the top of the attachment. Deeper sulcular probing depths provide more freedom in locating restoration margins farther below the gingival crest. However, in most circumstances, the deeper the gingival sulcus, the greater the risk of gingival

Fig. 75-9 A 1-year recall photograph after orthodontic extrusion, osseous surgery, and placement of a new restoration. Note the excellent tissue health after the re-establishment of biologic width.

recession. The first step in using sulcus depth as a guide in margin placement is to manage gingival health. Once the tissue is healthy, the following three rules can be used to place intracrevicular margins.

1. If the sulcus probes 1.5 mm or less, place the restoration margin 0.5 mm below the gingival tissue crest. This is especially important on the facial aspect and prevents a biologic width violation in a patient who is at high risk in that regard.
2. If the sulcus probes more than 1.5 mm, place the margin one half the depth of the sulcus below the tissue crest. This places the margin far enough below tissue so that it still is covered if the patient is at higher risk of recession.
3. If a sulcus greater than 2 mm is found, especially on the facial aspect of the tooth, then evaluate to see whether a gingivectomy could be performed to lengthen the teeth and create a 1.5-mm sulcus. Then the patient can be treated using Rule 1.

The rationale for Rule 3 is that deep margin placement is more difficult and the stability of the free gingival margin is less predictable when a deep sulcus exists. Reducing the sulcus depth created a more predictable situation in which to place an intracrevicular margin. It is not guaranteed that the tissue will remain at the corrected level, however, because some gingival rebound can occur after gingivectomy. However, it ensures that the restorative margins are not exposed and visible in the patient's mouth (Fig. 75-10 and Color Figs. 75-1 to 75-4).

Clinical Procedures in Margin Placement

The placement of supragingival or equigingival margins is simple because they require no tissue manipulation. With regard to overall tooth preparation, the amount reduced incisally or occlusally, facially, lingually, and interproximally will be dictated by the choice of restorative materials. Prior to extending subgingivally, the preparation should be completed to the free gingival margin facially and interproximally. This allows the margin of the tooth preparation to be used as a reference for subgingival extension once the tissue is retracted (Fig. 75-11).

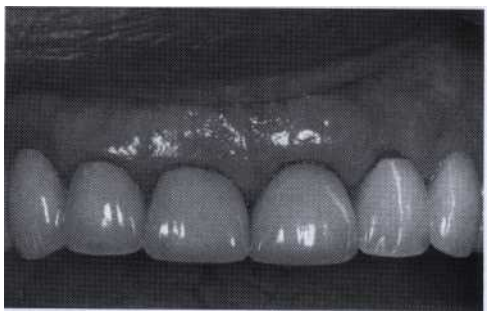

Fig. 75-10 A 78-year-old woman presents with the maxillary anterior restorations placed 6 months earlier. She is unhappy with the exposed margins and notes that the margins were covered the day the restorations were placed.

Tissue Retraction

Once the supragingival portion of the preparation is completed, it is necessary to extend below the tissue.[6,24] The preparation margin must now be extended to the appropriate depth in the sulcus, applying the guidelines presented previously. In this process, the tissue must be protected from abrasion, which will cause hemorrhage and can adversely affect the stability of the tissue level around the tooth. Access to the margin is also required for the final impression, and a clean, fluid controlled environment is desired. Tissue management is achieved with gingival retraction cords, using the appropriate size to achieve the displacement required. Thin, fragile gingival tissues and shallow sulcus situations usually dictate that smaller diameter cords be chosen to achieve the desired tissue displacement.

For a Rule 1 margin, the cord should be placed so that the top of the cord is located in the sulcus at the level where the final margin will be established, which will be 0.5 mm below the previously prepared margin (Fig. 75-12). On the interproximal aspects of the tooth, the cord will usually be 1 to 1.5 mm below the tissue height because the interproximal sulcus is often 2.5 to 3 mm in depth. With this initial cord in place, the preparation is extended to the top of the cord, with the bur angled to the tooth so that it will not abrade the tissue (Fig. 75-13). This process protects the tissue, creates the correct axial reduction, and establishes the margin at the desired subgingival level. To create space and allow access for a final impression, it is now necessary to pack a second retraction cord. The second cord is pushed so that it displaces the first cord apically and sits between the margin and the tissue (Fig. 75-14). For the final impression, the top cord only is removed, leaving the margins visible and accessible to be recorded with the impression material (Fig. 75-15). The initial cord remains in place in the sulcus until the provisional restoration is completed.

As an alternative to additional retraction cords, electrosurgery can be used to remove any overlying tissue in

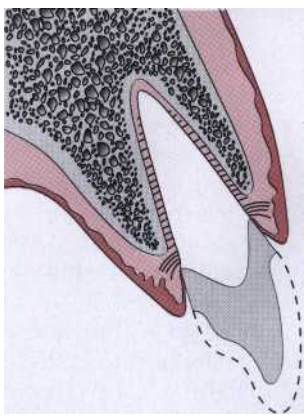

Fig. 75-11 To provide a reference position for margin placement after tissue retraction, the margin of the tooth preparation is initially established level with the free gingival margin.

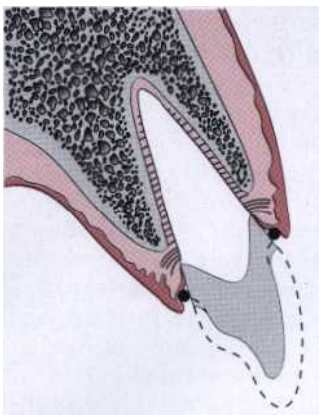

Fig. 75-12 The second step in margin placement is to place a single layer of deflection cord below the previously prepared margin to the desired final margin level. Here, a single cord has been placed 0.5 mm below the previously prepared margin.

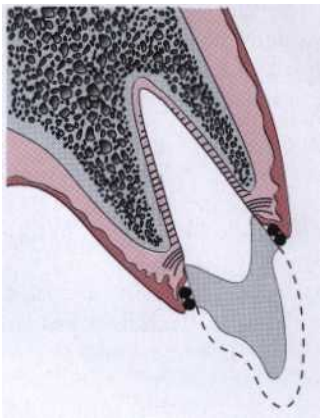

Fig. 75-14 To provide space for impression material, a second impression cord is now placed on top of the first deflection cord. This impression cord is placed so that it is between the margin of the preparation and the gingiva to create adequate space for impression material after removal of the cord.

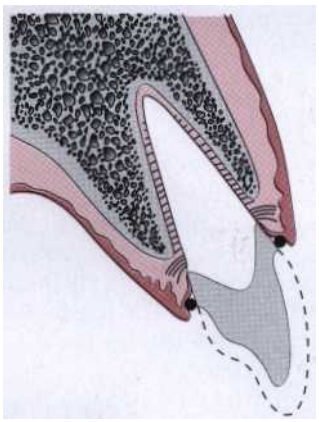

Fig. 75-13 The margin of the preparation is now extended apically to the top of the retraction cord; this represents the correct placement of the margin below the previously nonreflected free gingival margin.

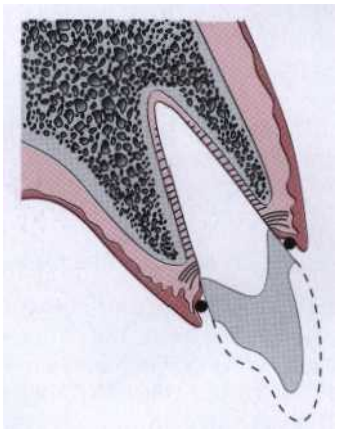

Fig. 75-15 The ideal situation after removal of the impression cord. The deflection cord is still in place maintaining the open sulcus but has been displaced apically another .05 mm by the placement of the impression cord, exposing tooth structure apical to the margin so that it can be captured in the impression.

the retraction process. A fine wire-tip electrode is held parallel to the tooth and against the margin in the sulcus and moved through the overhanging tissue, opening up the margin and the retraction cord to visual access (Figs. 75-16 to 75-19). The electrosurgery tip sits on top of the retraction cord in place in the sulcus. This controls the vertical position of the tip and results in the removal of the least tissue needed for access.

For Rule 2 situations where the sulcus is deeper, two larger diameter cords are used to deflect the tissue prior to extending the margin apically (Figs. 75-20 to 75-22). The top of the second cord is placed to identify the final margin location at the correct distance below the previously prepared margin, which was at the gingival tissue crest level. The margin is lowered to the top of the second cord (Fig. 75-23) and then a third cord is placed in preparation for the impression (Figs. 75-24 and 75-25). In the deep sulcus patient where the margin may be 1.5 to 2 mm below the tissue crest, electrosurgery is often necessary to remove overhanging tissue. To avoid altering the gingival tissue height, it is important to hold the electrosurgery tip parallel to the preparation (Fig. 75-26).

Provisional Restorations

Three critical areas must be effectively managed to produce a favorable biologic response to provisional restorations .3-7s The marginal fit, contour, and surface finish of the interim restorations must be appropriate to maintain the health and position of the gingival tissues during the time interval until the final restorations are delivered. Provisional restorations that are poorly adapted at the

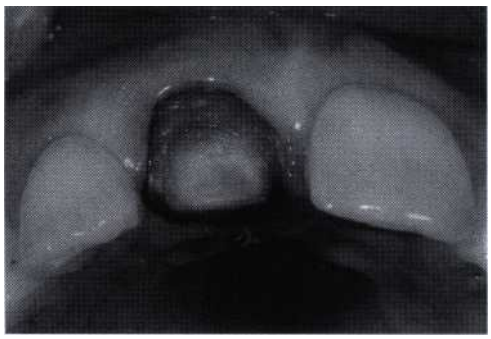

Fig. 75-16 The deflection cord and the impression cord are in place. The **soft tissue is falling over the margins of the preparation. In this situation, if the impression cord were removed, the impression would not capture** the margins in the areas where the tissue is overhanging.

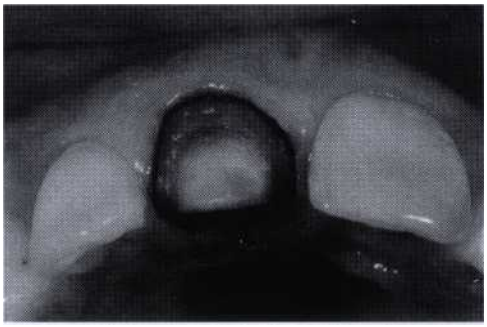

Fig. 75-17 The overhanging tissue has been removed and space created for the impression material with electrosurgery. Note that the deflection cord and the impression cord are still in place. The impression cord is now visible completely around the tooth, allowing **easy access for the impression material to the margin after removal of the impression cord.**

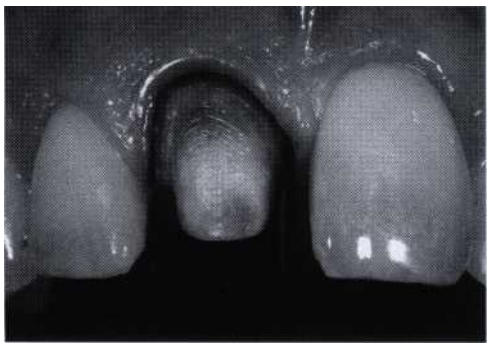

Fig. 75-18 With **electrosurgery, the fine wire electrode tip** is held **parallel to the tooth preparation and rests on the cord as the tip is** moved around the tooth.

Fig. 75-19 **After removal of the impression cord, an adequate space is created for the impression material, with no soft tissue overhanging the margins to trap or tear the impression material. Note the first or deflection cord is still in place.**

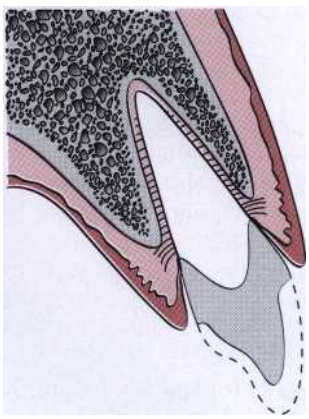

Fig. 75-20 The **first step in margin placement for the patient with altered eruption or a deep sulcus is to prepare to the existing free gingival margin, just as in** the Rule 1 patient.

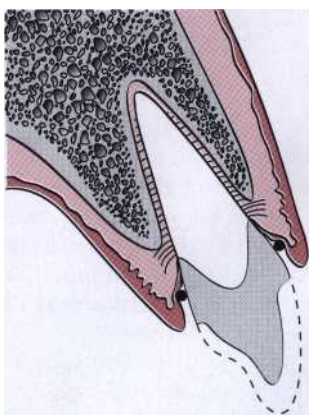

Fig. 75-21 **The second step for the patient with altered eruption is to place the deflection cord.** Note that the placement of a single deflection cord does not provide adequate deflection of the tissue to allow the margin to be carried below tissue without abrading the gingiva with the bur.

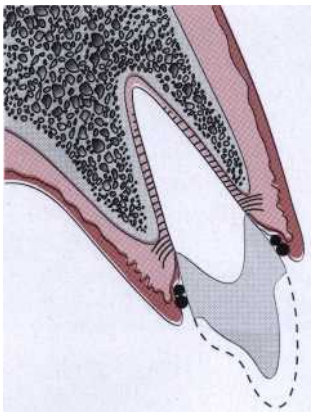

Fig. 75-22 The third step for the patient with altered eruption and a deep sulcus is to place a second, larger-diameter deflection cord on top of the first deflection cord. Combined, these two cords allow adequate deflection to open up the sulcus so that the margin can be carried below tissue without abrading the gingiva.

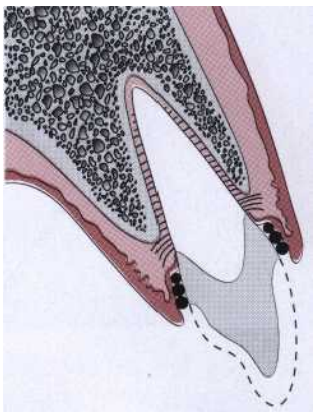

Fig. 75-24 After the extension of the margin to the top of the deflection cord, a third layer of cord is applied that will act as the impression cord. This impression cord should be placed so that it fits between the free gingival margin and the margin of the preparation. Its placement will also apically displace the previously two placed deflection cords.

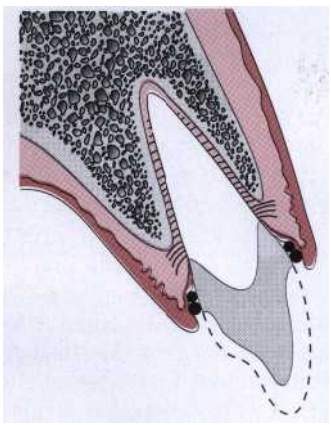

Fig. 75-23 The preparation is now extended to the top of the second deflection cord, finalizing margin location.

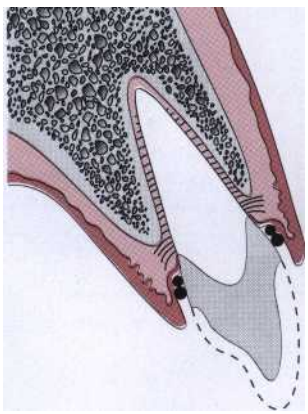

Fig. 75-25 Removal of the impression cord creates an adequate space for the impression material to capture the margin and 0.5 mm of tooth structure below the margin where the impression cord had displaced the first two cords.

margins, are overcontoured or undercontoured, and have rough or porous surfaces can cause inflammation, overgrowth, or recession of gingival tissues. The outcome can be unpredictable and lead to unfavorable changes in the tissue architecture that can compromise the success of the final restoration.

Marginal Fit

Marginal fit has clearly been implicated in producing an inflammatory response in the periodontium. It has been shown that the level of gingival inflammation can increase, corresponding with the level of marginal opening." Margins that are significantly open (several tenths of a millimeter) are capable of harboring large numbers of bacteria and may be responsible for the inflammatory response seen. However, the quality of marginal finish and the margin location relative to the attachment are far more critical to the periodontium than is the difference between a 20 ~tm fit versus a 100 b,m fit. [44,47,60]

Crown Contour

Restoration contour has been described as extremely important to the maintenance of periodontal health.", [16] Ideal contour provides access for hygiene and has the fullness to create the desired gingival form and a pleasing visual tooth contour in esthetic areas. Evidence from hu-

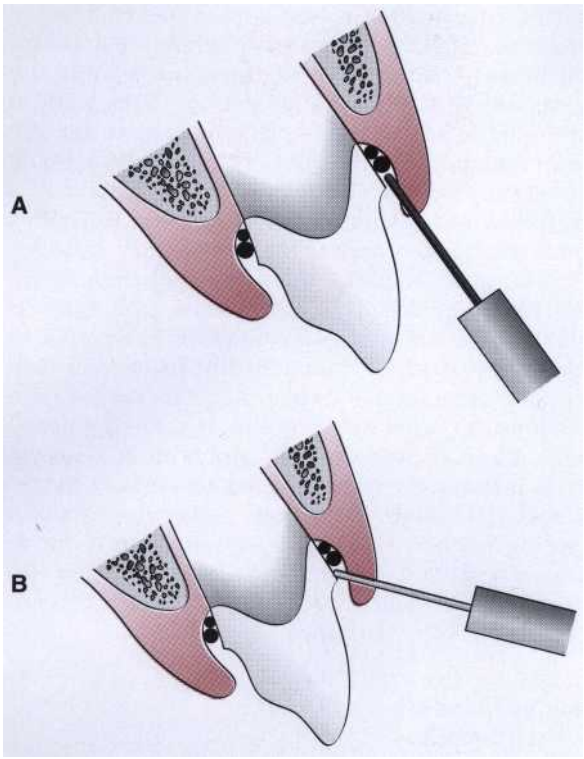

Fig. 75-26 If it is necessary to use electrosurgery, either in the normal or altered eruption patient, the correct inclination of the electrosurgery tip is important. (A) illustrates the electrosurgery tip being held parallel to the preparation and resting on the previously placed retraction cord. This removes a minimal amount of tissue, and the presence of the retraction cord protects the attachment from the electrosurgery. (B) represents the incorrect inclination of the electrosurgery tip. The tip is leaning away from the preparation. This inclination results in excess tissue removal.

man and animal studies clearly demonstrates a relationship between overcontouring and gingival inflammation; however, at the same time, undercontouring produces no adverse periodontal effect. The most frequent cause of overcontoured restorations is inadequate tooth preparation by the dentist, which forces the technician to produce a bulky restoration to provide room for the restorative material. In areas of the mouth where esthetics are not critical, a flatter contour is always acceptable.

Subgingival Debris

Leaving debris below the tissue during restorative procedures can create an adverse periodontal response. The cause can be the retraction cord, impression material, provisional material, or either temporary or permanent cement.[56] The diagnosis of debris as the cause of gingival inflammation can be confirmed by examination of the sulcus surrounding the restoration with an explorer, removal of any foreign bodies, and monitoring of the tissue response. It may be necessary to provide tissue anesthesia for patient comfort during the procedure.

Hypersensitivity to Dental Materials

Inflammatory gingival responses have been reported related to the use of nonprecious alloys in dental restorations." Typically, the responses have occurred to alloys containing nickel, although the frequency of these occurrences has been debated. Hypersensitivity responses to precious alloys are extremely rare, and these alloys provide an easy solution to the problems encountered with the nonprecious alloys. More importantly, tissues respond more to the differences in surface roughness of the material rather than the composition of the material. The rougher the surface of the restoration subgingivally, the greater the plaque accumulation and gingival inflammation. In clinical research, porcelain, highly polished gold, and highly polished resin all show similar plaque accumulation. Regardless of the restorative material selected, a smooth surface is essential on all materials subgingivally.

ESTHETIC CONSIDERATIONS IN GINGIVAL TISSUE MANAGEMENT

Interproximal Embrasure Form

The interproximal embrasure created by restorations and the form of the interdental papilla have a unique and intimate relationship. The ideal interproximal embrasure should house the gingival papilla without impinging on it and also extend the interproximal tooth contact to the top of the papilla so that no excess space exists to trap food or be esthetically displeasing. Papillary height is established by the level of the bone, the biologic width, and the form of the gingival embrasure. Changes in the shape of the embrasure can have an impact on the height and form of the papilla. The tip of the papilla behaves differently than the free gingival margin on the facial aspect of the tooth. Whereas the free gingival margin averages 3 mm above the underlying facial bone, the tip of the papilla averages 4.5 to 5 mm above the interproximal bone (Fig. 75-27). This means that if the papilla is farther above the bone than the facial tissue but has the same biologic width, the interproximal area will have a 1.0 to 1.5 mm deeper sulcus than is found on the facial. In 1982, Van-der-Veldon published results of a study in which he completely removed healthy papillae to the bone level and found that it routinely regenerated 4 to 4.5 mm of total tissue above bone, with an average sulcus depth of 2 to 2.5 mm.[73] The height above bone that the papilla wants to maintain was indirectly confirmed by Tarnow, who studied the relationship of the papilla between the interproximal contact and the underlying bone. When the gingival level of the interproximal tooth contacts measured 5 mm or less to the alveolar bone, the papilla always filled the space. When the contact was 6 mm from bone, only 56% of the papillae could fill the space. Finally, when the contact was 7 mm from bone, only 37% of the papillae could fill the spaces. Knowing that there is an individual variability to the required biologic width, this information relative to the papilla is applied by locating the lowest point of the interproximal contact in relation

to the top of the epithelial attachment. The ideal contact should be 2 to 3 mm coronal to the attachment, which coincides with the depth of the average interproximal sulcus. As in assessing the facial tissues for margin location, this technique requires that the tissue is healthy to allow accurate probing. If the sulcus measures greater than 3 mm, there is some risk of papillary recession with restorative procedures.

The clinician is most frequently presented with a normal or shallow sulcus with a papilla that appears too short, rather than a tall papilla with a deep sulcus. Management of this situation is best approached by viewing the papilla as a balloon of a certain volume that sits on the attachment. This balloon of tissue has a form and height dictated by the gingival embrasure of the teeth. If the embrasure is too wide, the balloon flattens out and becomes blunted, with a shallow sulcus (Fig. 75-28). If the embrasure is the ideal width, the papilla has a pointed form and a sulcus of 2.5 to 3 mm and is healthy. If the embrasure is too narrow, the papilla may grow out to the facial and lingual, form a col, and become inflamed. This information is applied when evaluating an individual papilla with an open embrasure. The papilla in question is compared with the adjacent papillae. If they are all on the same level and the other areas do not have open embrasures, then the problem is one of gingival embrasure form. If however, the papilla in the area of concern is apical to the adjacent papillae, evaluate the interproximal bone levels. If the bone under that papilla is apical to the adjacent bone levels, the problem is due to bone loss. If the bone is at the same level, the open embrasure is due to the embrasure form of the teeth and not a periodontal problem with the papilla.

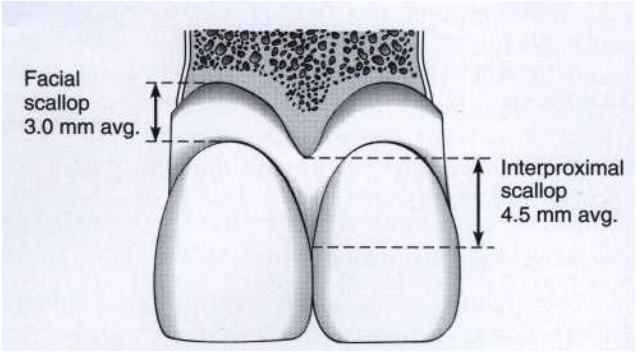

Fig. 75-27 A comparison of the behavior of the interproximal papilla relative to bone and the free gingival margin relative to bone in the average human. There is a 3-mm scallop from the facial bone to the interproximal bone. However, on average, a 4.5 to 5 mm gingival scallop exists between the facial tissue height and the interproximal papilla height. This extra scallop of 1.5 to 2 mm of gingiva compared with bone is the result of the extra soft tissue height above the attachment interproximally.

Restorative Correction of Open Gingival Embrasures

There are two causes of open gingival embrasures. Either the papilla is inadequate in height due to bone loss, or the interproximal contact is located too high coronally. If a high contact has been diagnosed as the cause of the problem, there are two potential reasons. If the root angulation of the teeth diverges, the interproximal contact is moved coronally, resulting in the open embrasure. Chapter 53 discusses correction of this problem. However, if

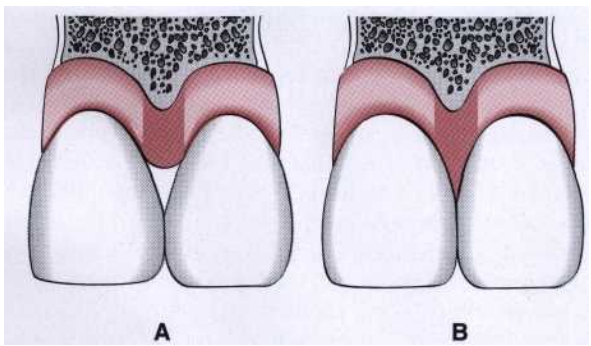

Fig. 75-28 The relationship between gingival embrasure volume and papillary form. A, The gingival embrasure of the teeth is excessively large due to a tapered tooth form. Because of the large embrasure form, the volume of tissue sitting on top of the attachment is not molded to the shape of a normal papilla but rather has a blunted form and a shallower sulcus. B, An ideal tooth form where the same volume of tissue sits on top of the attachment as in A. But because of the more closed embrasure form from the teeth in B, the papilla completely fills the embrasure and has a deeper sulcus averaging 2.5 to 3 mm. Note that the ideal contact position is 3 mm coronal to the attachment.

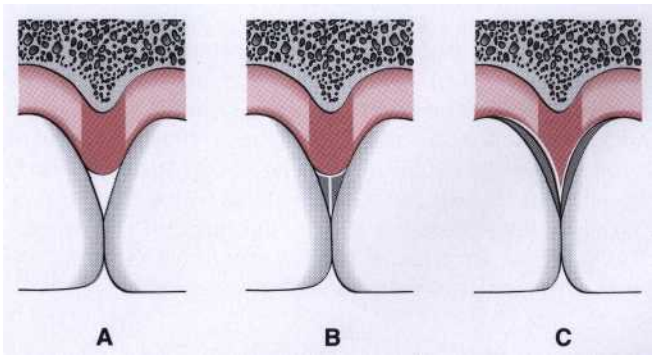

Fig. 75-29 Methods of altering gingival embrasure form. A, The typical open gingival embrasure due to excessively tapered tooth form. B, A common method employed by restorative dentists to correct the embrasure, whereby material is added supragingivally. This closes the embrasure by moving the contact to the tip of the papilla but results in overhangs that cannot be cleaned using dental floss. Removing these overhangs restoratively reopens the embrasure. C, The correct method of closing the gingival embrasure, whereby the margins of the restoration are carried 1 to 1.5 mm below the tip of the papilla. Note that this does not encroach on the attachment because the average interproximal sulcus probes 2.5 to 3 mm. This allows easy cleaning because of the convex profile. It also reshapes the papilla to a more pleasing profile esthetically.

the roots are parallel, the papilla form is normal, and an open embrasure exists, then the problem is probably related to tooth shape, specifically, an excessively tapered form. Restorative dentistry can correct this problem by moving the contact point to the tip of the papilla. To accomplish this, the margins of the restoration must be carried subgingivally 1 to 1.5 mm, and the emergence profile of the restoration is designed to move the contact point toward the papilla while blending the contour into the tooth below the tissue (Fig. 75-29). This can be accomplished easily with direct bonded restorations because the soft tissue can clearly be seen (Color Figs. 75-5 to 75-7). For indirect restorations, the desired restoration contours and embrasure form should be established in the provisional restorations, and the gingival tissues are allowed to adapt for 4 to 6 weeks before the tissue contour information is relayed to the laboratory to be used in the final restorations.

Management of Gingival Embrasure Form with Periodontal Recession

Management of the gingival embrasure form for patients who have experienced gingival recession varies depending on whether the treatment is either in the anterior or posterior regions of the mouth.[31] In esthetic areas, it is necessary to carry the interproximal contacts apically toward the papilla to eliminate the presence of large open embrasures. With multiple unit restorations, it also is possible to bake porcelain papillae directly on the restoration using tissue-colored ceramics. In the posterior areas where the interroot widths are significantly greater, it is often impossible to carry the proximal contacts to contact the tissue without creating large overhangs on the restorations. In these situations, the contact should be moved far enough apically to minimize any large food traps while still leaving an embrasure of a convenient size to be accessed with an interdental brush for hygiene. It should be noted that developing excessively long interproximal contacts, whether on anterior or posterior teeth, always creates rectangular, somewhat unesthetic tooth forms.

Pontic Design

Classically, four options should be considered in evaluating pontic design: sanitary, ridge-lap, modified ridge-lap, and ovate pontic designs (Fig. 75-30). Regardless of design, the pontic should provide an occlusal surface that stabilizes the opposing teeth, allows for normal mastication, and does not overload the abutment teeth. The restorative material for all four designs can be either glazed porcelain, polished gold, or polished resin. There is no difference in biologic response of the tissue from contact with the restoration, regardless of the material chosen, as long as it has a smooth surface finish.[26,54,64] The key differences between the four pontic designs relate to the esthetics and access for hygiene procedures. The primary method for cleaning the undersurface of pontics is to draw dental floss mesiodistally along the undersurface. The shape of this undersurface determines the ease with which plaque and food debris can be removed in the process. The sanitary and ovate pontics have convex undersurfaces that facilitate cleaning. The ridgelap and modified ridgelap designs have concave surfaces that are more difficult to access with dental floss. Although the sanitary pontic design provides the easiest access for hygiene procedures, it is rarely used due to its unesthetic form and a variable acceptance of the open contour by patients.

The ovate pontic is the ideal pontic form .[62] It is created by forming a receptor site in the edentulous ridge with either a diamond bur or electrosurgery. The site is shaped to create either a flat or concave contour so that when the pontic is created to adapt to the site, it will have a flat or convex outline. The depth of the receptor site is dependent on the esthetic requirements of the pontic. In highly esthetic areas such as the maxillary

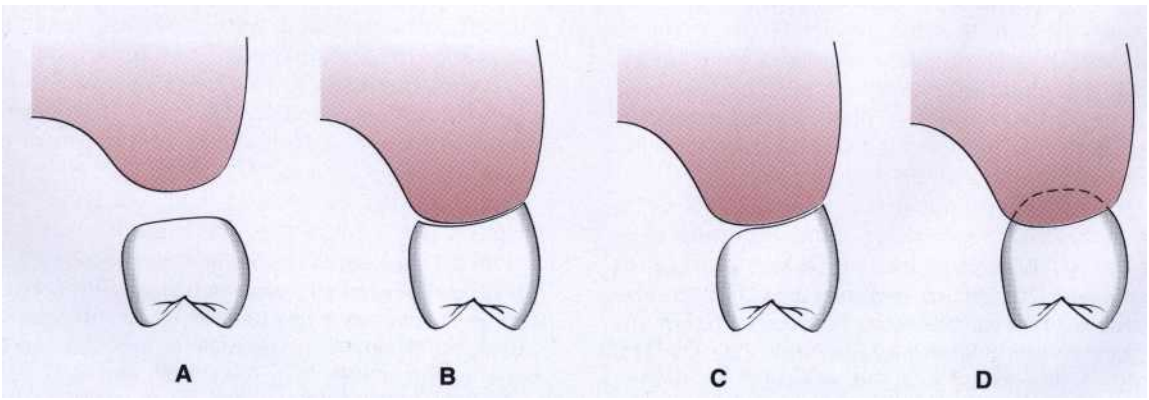

Fig. 75-30 Four options to designing the shape of a pontic. A, The sanitary pontic where the tissue surface of the pontic is 3 mm from the underlying ridge. B, The ridge lap pontic where the tissue surface of the pontic straddles the ridge much like a saddle. The entire tissue surface of the ridge lapped pontic is convex and very difficult to clean. C, The modified ridge lap pontic. The tissue surface on the facial is concave, following the ridge. However, the lingual saddle has been removed to allow access for oral hygiene. D, The ovate pontic. The pontic form fits into a receptor site within the ridge. This allows the tissue surface of the pontic to be convex and also optimizes esthetics.

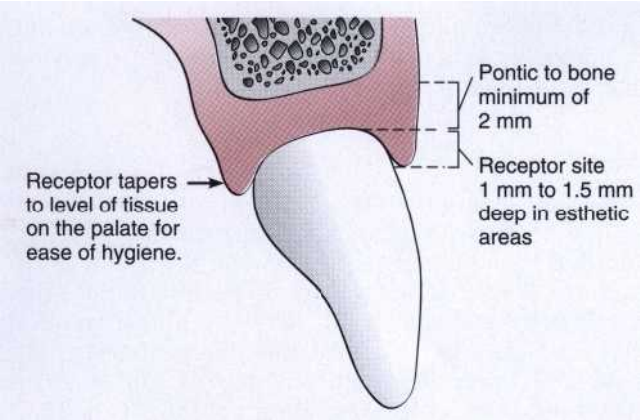

Fig. 75-31 The ideal shape and form of an ovate pontic in the esthetic area. The receptor site has been created 1 to 1.5 mm apical to the free gingival margin on the facial. This creates the illusion of the pontic erupting from the tissue. On the palatal, the pontic is tapered so that the receptor site is not extended below tissue. This allows for easier access for oral hygiene. Note that when the receptor site is created, the bone must be a minimum of 2 mm from the most apical portion of the pontic.

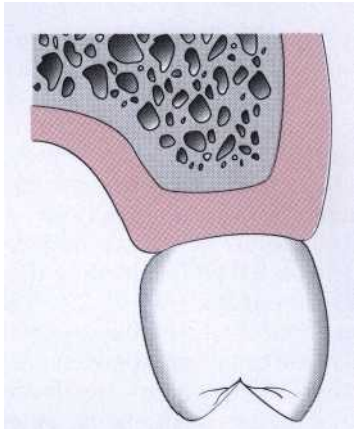

Fig. 75-32 An option for creating an ovate pontic receptor site in less esthetic areas of the mouth. Rather than creating the receptor site so that the pontic extends into the ridge, it is possible to create a flattened receptor site where the pontic sits flush with the ridge. This makes oral hygiene easier.

anterior region, it is necessary to create a receptor area that is 1 mm to 1.5 mm below the tissue on the facial aspect. This creates the appearance of a free gingival margin and produces optimum esthetics (Fig. 75-31). This site can then be tapered to the height of the palatal tissue to facilitate hygiene access from the palatal side. In the posterior areas, a deep receptor site can complicate hygiene access. In these situations, the ideal site has the facial portion of the pontic at the same level as the ridge, and then the site is created as a straight line to the lingual side of the pontic. This removes the convexity of the ridge and produces a flat, easily cleansable tissue surface on the pontic (Fig. 75-32).

When the ridge is being surgically modified, it is important to know the thickness of soft tissue above the bone. This measurement is obtained by probing to the bone through the anesthetized tissue. If the tissue is removed to less than 2 mm in thickness, significant rebound in ridge height may occur. If it is necessary to reduce the tissue height to less than 2 mm above the bone to create the desired pontic form, then some bone must be removed to achieve the desired result.

It is important when considering an ovate pontic to realize that certain soft tissue ridge parameters must exist to optimize the ovate pontic form. The ridge height needs to match the ideal height of the interproximal papillae where interproximal embrasures are planned, either between pontics or next to abutment teeth. The gingival margin height must also be at the ideal level or the pontic will appear too long. Finally, the ridge tissue must be facial to the ideal cervical facial form of the pontic so that the pontic can be made to emerge from the tissue. If any of these three areas are inadequate, some form of ridge augmentation is needed to produce a ridge on which an adequate receptor site can be created (Fig. 75-33). Any ridge augmentation procedures should be completed prior to or in conjunction with fabricating an ovate pontic. When constructing the final restorations, the contours of the developed ovate pontic receptor site can be conveyed to the laboratory by capturing a soft tissue impression 4 to 6 weeks after the site has been created.

The ovate pontic can serve another important periodontal function by maintaining the interdental papilla next to abutment teeth after extraction.[6a] When a tooth is removed, the gingival embrasure form is lost. The normal response of the papilla to this loss of embrasure form is to recede 1.5 to 2 mm, which corresponds to the additional soft tissue existing above bone on the interproximal compared with the facial. However, this recession can be prevented. By inserting the correct pontic form 2.5 mm into the extraction site on the day the tooth is removed, the gingival embrasure form and papilla can be maintained. At 4 weeks, the 2.5-mm extension can be reduced to a 1.0 to 1.5 mm extension to facilitate hygiene. This procedure can maintain the papilla next to the abutment teeth as long as the bone on the abutment tooth is at a normal level (Color Figs. 75-8 to 75-15).

The full-ridge lap pontic is an outdated design that straddles the convexity of the ridge buccolingually and creates an undersurface that is entirely concave and cannot be cleaned. It is not recommended for use in any situations. However, a modified ridge lap design can be an acceptable design if inadequate ridge exists to create an ovate pontic. With the modified ridge lap design, the pontic follows the convexity of the ridge on the facial but stops on the lingual crest of the ridge without extending down the lingual side of the ridge. Whereas the facial aspect of the undersurface has a concave shape, adequate access for oral hygiene is allowed by the more open lingual form.

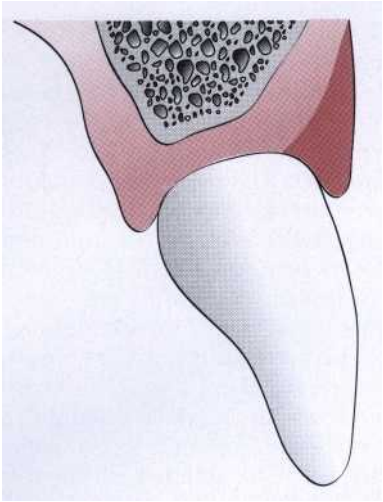

Fig. 75-33 Ridge considerations when an ovate pontic is desired. For an ovate pontic to be properly created, the soft tissue ridge must be labial to the desired cervical portion of the pontic. When the pontic is facial to the ridge, it is not possible to create what appears to be a free gingival margin correctly. The shaded area represents the necessary amount of tissue that would be augmented to produce an ideal ovate pontic in this particular site.

OCCLUSAL CONSIDERATIONS

The importance of occlusion and its role in dentistry has been decreasing significantly over the past 20 years. Occlusal trauma as a factor in periodontal disease and its role in orofacial pain has been deemphasized in numerous papers.[9,11,15,36,45,46,55,66,72] However, the role occlusion plays in restorative dentistry is becoming reemphasized. The increase in the utilization of dental implants and nonmetallic cosmetic restorations has resulted in an increased concern with force management. These restorations are more sensitive to occlusal trauma with subsequent structural failure than are traditional restorations on teeth. Consequently, for the restorative dentist wanting a high degree of predictability in their final result, understanding occlusion is critical. The clinician must know how to create an occlusion with the following guidelines as a goal:

1. There should be even simultaneous contacts on all teeth during centric closure. This distributes the force of closure over all the teeth instead of the few teeth that may touch first.
2. When the mandible moves from centric closure, some form of canine or anterior guidance is desirable, with no posterior tooth contacts. This combination of anterior guidance and posterior disclusion reduces the ability of the elevator muscles to contract and distributes the force of the movement onto the anterior teeth, which receive less force due to the class III lever system that is being applied in this situation. It has been shown that due to the class III lever action, the anterior teeth receive approximately one ninth the force of a second molar.[25,61]
3. The anterior guidance needs to be in harmony with the patient's neuromuscular envelope of function. Harmony of this relationship is demonstrated by a lack of fremitus and mobility on the anterior teeth, the ability of the patient to speak clearly and comfortably, and the patient's general sense of comfort with the overbite, overjet, and guidance created during chewing and when holding their head in an upright posture.
4. The occlusion should be created at a vertical dimension that is stable for the patient. It is generally accepted that the patient's existing vertical dimension is an equilibrium between the eruptive forces of their teeth and the repetitive contracted length of their elevator muscles. It has been demonstrated that vertical dimension can be altered with no sense of pain from muscles and joints. However, if this alteration lengthens the pterygomasseteric sling beyond its ability to adapt, the patient will not maintain the vertical change and will close the occlusal vertical dimension by intruding the teeth.[12,34,41-43]
5. When managing a pathologic occlusion or when restoring a complete occlusion, a repeatable condylar reference position is needed. *Centric relation,* defined as the most superior condylar position, provides such a starting point.[21] Centric relation has been shown to be reproducible over multiple appointments, allowing the clinician to create the occlusion indirectly on an articulator and return it to the same reference position in the mouth.[14,39,40,74] It is the only position that has been shown to shut off lateral pterygoid muscle contraction.[20] Because it is a border position, any mandibular movement will result in the condyle moving inferiorly. Therefore it is the only position from which an interference-free occlusion can be created.

To manage the occlusion as described here, the clinician must be able to make accurate casts, use a face-bow, and create centric relation records so that the information can be transferred to a suitable articulator. Although the details of these procedures are beyond the scope of this chapter, they are a routine part of any restorative treatment plan and must be mastered for the clinician to achieve predictable long-term restorative success.

SPECIAL CONSIDERATIONS

Restoration of Root-Resected Teeth

Although the availability of implant therapy has greatly reduced the frequency with which root-amputated teeth are saved, they are still a viable mode of treatment. Structural challenges are created in restoring these teeth because of the amount of tooth structure lost in the resection process (Fig. 75-34). Conservative tooth preparation maintains as much of the remaining tooth as possible, but the resulting supragingival or minimally prepared subgingival finish lines requires additional metal display in the final restoration. A cast post and core may be indicated to create an adequate foundation for the final restoration. Because the remaining roots are often very thin mesiodistally, it is difficult to cement prefabri-

cated posts and have adequate bulk to place a foundation core on the mesial and distal of the post. This problem is avoided with the one-piece cast post and core restoration.

Another area of concern when restoring these teeth is the development of appropriate contours for hygiene access. The primary concern is to avoid any excessively heavy convexities of contour that would prevent access (Figs. 75-35 and 75-36). Facially and lingually, the contours should be essentially a straight line from the margin coronally, whereas interproximally, the contour emerges from the margin as a straight line or is slightly convex as it slopes up to the contact point. The interproximal areas of root-amputated and -hemisected teeth often present with surface concavities on the root trunk, and these areas cannot be adequately cleaned with floss because it will bridge across the concavity. The gingival embrasure form created in the restoration must be fluted into these areas so that the surfaces can be accessed with an interdental brush.

Esthetics is usually not a major concern unless the tooth in question is a maxillary molar with a mesiobuccal root amputation and the patient has a broad smile. The solution is to create an artificial mesiobuccal root with normal crown contour coronal to it and a furcation made out of restorative material that is easily cleaned with an interdental brush.

Splinting

Splinting therapy may be applied with bonded external appliances, intracoronal appliances, or indirect cast restorations to connect multiple teeth together with the goal of improving tooth stability. Unstable teeth may be due to a lack of periodontal support from bone loss, a lack of support from tooth loss, or the need to splint abutment teeth to support pontics. Indications for splinting are mobility of teeth that is increasing or impairs patient comfort, migration of teeth, or prosthetics where multiple abutments are necessary. Before considering splinting, the etiology of the instability must be identified.' Excessive occlusal forces from parafunction or deflective tooth contacts are frequent causes of excessive mobility. Whenever the occlusion is the cause, occlusal therapy is always performed first. The mobility is then evaluated over time to determine whether it resolves before splinting is considered. In addition, any inflammation of the periodontal supporting apparatus must be controlled before making a decision on splinting because inflammation can produce mobility in the presence of normal occlusal forces and normal periodontal support. When the teeth are splinted, all the teeth in the splint share the occlusal load to some extent." The rigidity of the splint and the number of teeth used determines how the forces are distributed. The most common indication to splint mobile teeth is to improve patient comfort and provide better control of the occlusion if the anterior teeth are mobile. It is critical that adequate crown length on the teeth is being splinted so that the interproximal connectors do not impinge on the interdental papilla. Also, adequate space is needed between the connector and the papilla for access with dental floss anteriorly and an interproximal brush on posterior teeth.

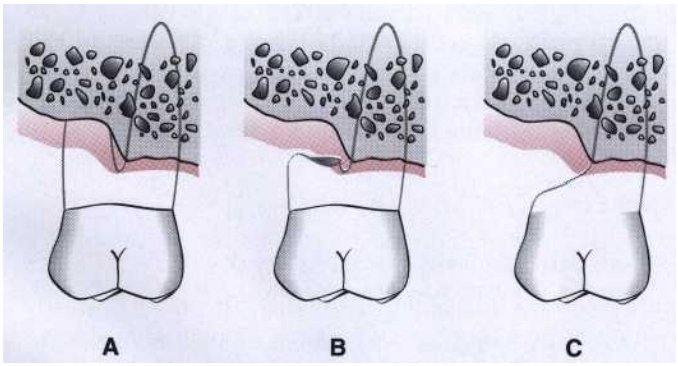

Fig. 75-34 A, A maxillary molar with a Class 3 furcation and bone loss surrounding the distal buccal root. B, The contour created when the distal buccal root is removed but the coronal contour has not yet been reshaped. Note the overhang, which can trap food and plaque and create gingival inflammation. C, The correct contour after the restoration or reshaping of the tooth. Note this illustration is only of the facial portion of the tooth. The palatal portion of the crown and the palatal root do not appear. Note how the contour has been altered to allow easy access for an interdental brush to the gingival tissue and the tooth in the area where the root was removed.

Anterior Esthetic Surgery

The importance of gingiva in relation to anterior esthetics has been well documented.[10,29,19,65] Various methods for altering gingival levels have been described, including gingivectomy, apically displaced flaps with osseous recontouring, and the use of orthodontics to position the gingival apically or coronally by intruding or extruding the teeth . Whenever an alteration in gingival levels is contemplated, the expected outcome must be communicated to the patient to determine whether the planned surgery is acceptable. Computer imaging can be used to provide the patient with a visual plan for the

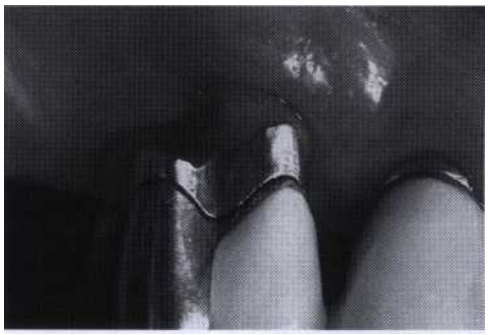

Fig. 75-35 A photograph taken 6 weeks after the removal of the distal buccal root on this maxillary first molar. Note the crown contour has not been altered yet and the presence of a large overhang that easily traps debris.

final esthetic result." However, the imaging process does not allow the dentist or patient to include the dynamics of lip movement in the evaluation of the proposed changes. Computer imaging provides enough information to accurately depict the final outcome when the planned surgery will alter the gingiva on one or two teeth while leaving the gingival levels of adjacent teeth in their existing position.

However, when the surgery will involve many or all of the anterior teeth and result in moving gingiva several millimeters, to the extent that a flap will be raised and bony levels altered, an additional guide is desirable before surgery. Constructing these guides directly on a stone cast is the easiest and least time-consuming method. Before constructing the guide, treatment planning is completed to determine the desired incisal edge position and gingival **level of the tissues.** This establishes the amount of tooth display at rest and at full smile. The information is transferred to a stone cast of the patient's teeth, and the desired shape of the gingival margins for each tooth is drawn on the cast. The existing incisal edge position of each tooth is used as a reference in establishing the desired gingival level. A composite or acrylic resin veneer is then constructed on the cast, extending gingivally to the desired tissue position. The veneer guide also can be extended incisally to the desired incisal edge position so that that information also can be included in the veneer. The veneer is trimmed, polished, and tried in the patient's mouth. When the patient approves the gingival levels established with the guide, the desired gingival correction can be completed using the veneer guide as a surgical template. In addition to locating the initial incisions at the correct level, the guide also can be employed after flap reflection to aid in the bony recontouring, ensuring adequate biologic width and sulcus depth at the new gingival position. The surgeon replaces the flap at closure to the gingival level established with the guide. Employing an esthetic template in this manner optimizes the predictability of the surgical therapy and establishes the ideal tissue framework to complete the esthetic restorations (Color Figs. 75-16 to 75-23).

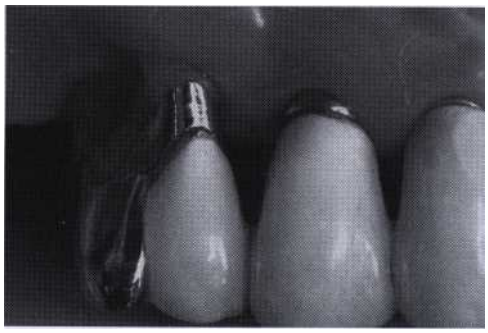

Fig. 75-36 The correct modification of the crown form seen in Fig. 75-35. The roof of the furcation of the remaining distal buccal root has been completely removed and the crown reformed to allow easy access to the remaining roots and soft tissue.

Periodontal Maintenance Phase

Henry H. Takei

The successful management of periodontal disease requires a positive program directed at maintaining and improving the results of treatment as well as preventing the development of new disease. The gradual microbial recolonization of tooth surfaces begins soon after plaque is eliminated; therefore the measures to stop recolonization also must be a constant effort on the part of the patient, following the professional instructions and guidance and including periodic professional care visits. This part also presents the overwhelming evidence that has been accumulated about the effectiveness of periodontal therapy.

Supportive Periodontal Treatment

- **Recurrence of Periodontal Disease**

CLASSIFICATION OF POSTTREATMENT PATIENTS
REFERRAL OF PATIENTS TO THE PERIODONTIST
TESTS FOR DISEASE ACTIVITY
MAINTENANCE FOR DENTAL IMPLANT PATIENTS

Preservation of the periodontal health of the treated patient requires as positive a program as that required for the elimination of periodontal disease. After Phase I therapy is completed, patients are placed on a schedule of periodic recall visits for maintenance care to prevent recurrence of the disease (Figs. 76-1 and 76-2).

Transfer of the patient from active treatment status to a maintenance program is a definitive step in total patient care that requires time and effort on the part of the dentist and staff. Patients must be made to understand the purpose of the maintenance program, and the dentist must emphasize that preservation of the teeth is dependent on it. Patients who are not maintained in a supervised recall program subsequent to active treatment show obvious signs of recurrent periodontitis (e.g., increased pocket depth, bone loss, and tooth loss). The more often patients present for recommended supportive periodontal treatment (SPT), the less likely they are to lose teeth. In fact, one study found that tooth loss is three times as common in treated patients who do not return for regular recall visits as in those who do[24]; another showed that patients with inadequate SPT after successful regenerative therapy have a 50-fold increase in risk of probing attachment loss as compared with those with regular recalls. Motivational techniques and reinforcement of the importance of the maintenance phase of treatment should be considered prior to performing definitive periodontal surgery.[1] Studies have shown that few patients display complete compliance with recommended maintenance schedules [1,34,36,60,62] (Fig. 76-3). *It is meaningless simply to inform patients that they are to return for periodic recall visits without clearly explaining the significance of these visits and describing what is expected of patients between visits.*

The maintenance phase of periodontal treatment starts immediately after the completion of Phase I therapy (see Figs. 76-1 and 76-2). While the patient is in the maintenance phase, the necessary surgical and restorative procedures are performed. This ensures that all areas of the mouth retain the degree of health attained after Phase I therapy.

RATIONALE FOR SUPPORTIVE PERIODONTAL TREATMENT

Studies have shown that even with appropriate periodontal therapy, some progression of disease is possible.[18,21,37,42,55] One likely explanation for the recurrence of periodontal disease is *incomplete subgingival plaque removal.*[58] If subgingival plaque is left behind during scaling, it regrows within the pocket. The regrowth of

Fig. 76-1 Incorrect sequence of periodontal treatment phases. Maintenance phase should be started immediately after the reevaluation of Phase I.

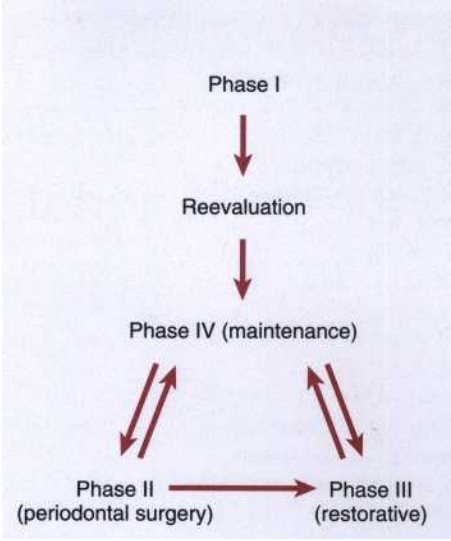

Fig. 76-2 Correct sequence of periodontal treatment phases.

subgingival plaque is a slow process compared with that of supragingival plaque. During this period (perhaps months), the subgingival plaque may not induce inflammatory reactions that can be discerned at the gingival margin. The clinical diagnosis may be further confused by the introduction of adequate supragingival plaque control because the inflammatory reactions caused by the plaque in the soft tissue wall of the pocket are not likely to be manifested clinically as gingivitis. Thus inadequate subgingival plaque control can lead to continued loss of attachment, even without the presence of clinical gingival inflammation.

Bacteria are present in the gingival tissues in chronic and aggressive periodontitis cases. [10,13,39,44] Eradication of intragingival microorganisms may be necessary for a stable periodontal result. Scaling, root planing, and even flap surgery may not eliminate intragingival bacteria in some areas.[16] These bacteria may recolonize the pocket and cause recurrent disease.

Bacteria associated with periodontitis can be transmitted between spouses and other family members. [56] Patients who appear to be successfully treated can become infected or reinfected with potential pathogens. This is especially likely in patients with remaining pockets.

Another possible explanation for the recurrence of periodontal disease is the microscopic nature of the dentogingival unit healing after periodontal treatment. Histologic studies have shown that after periodontal procedures, tissues usually do not heal by formation of new connective tissue attachment to root surfaces' [1,49,50] but result in a long junctional epithelium. It has been speculated that this type of dentogingival unit may be weaker and inflammation may rapidly separate the long functional epithelium from the tooth. Thus treated periodontal patients may be predisposed to recurrent pocket formation if maintenance care is not optimal.

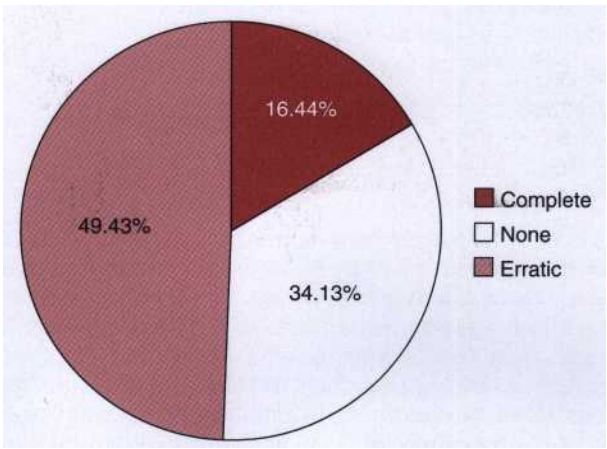

Fig. 76-3 Compliance with maintenance therapy in 961 patients studied for 1 to 8 years. (Adapted from Wilson TG Jr, Glover ME, Schoen J, et al: Compliance with maintenance therapy in a private periodontal practice.] Periodontol 1984; 55:468.)

Subgingival scaling alters the microflora of periodontal pockets. [35,41,41] In one study, a single session of scaling and root planing in patients with chronic periodontitis resulted in significant changes in subgingival microflora. Reported alterations included a decrease in the proportion of motile rods for 1 week, a marked elevation in the proportion of coccoid cells for 21 days, and a marked reduction in the proportion of spirochetes for 7 weeks.

Another study reported that subgingival bacteria had not returned to pretreatment proportions after 3 to 6 months.[47] However, the rate of return of the pretreatment microbial flora varied among patients. These findings indicate that mechanical debridement produces a relatively long-lasting effect on the microbial flora and that the different groups of microorganisms return to baseline values after varying time periods.

BOX 76-1

Maintenance Recall Procedures

Part I: Examination (approximate time: 17 minutes)[54]
- Medical history changes
- Oral pathologic examination
- Oral hygiene status
- Gingival changes
- Pocket depth changes
- Mobility changes
- Occlusal changes
- Dental caries
- Restorative and prosthetic status

Part II: Treatment (approximate time: 35 minutes)[54]
- Oral hygiene reinforcement
- Scaling
- Polishing
- Chemical Irrigation

Part III: Schedule next procedure (approximate time: 1 minute)[54]
- Schedule next recall visit
- Schedule further periodontal treatment
- Schedule or refer for restorative or prosthetic treatment

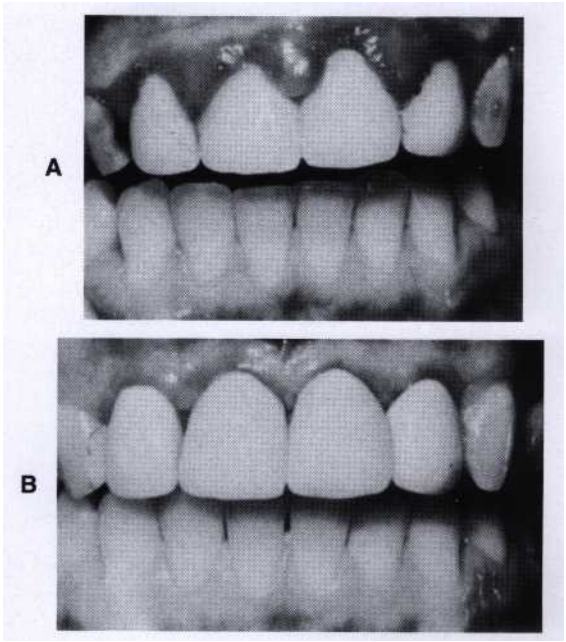

Fig. 76-4 A, Hyperplastic gingivitis related to crown margins and plaque accumulation in a 27-year-old woman. B, Four months after treatment, there is significant improvement. However, some inflammation around crown margins still exists, which cannot be resolved without replacing the crowns.

There is reason to believe that both the mechanical debridement performed by the therapist and the motivational environment provided by the appointment are necessary for good maintenance results. Patients tend to reduce their oral hygiene efforts between appointments.[4,62] Knowing that their hygiene will be evaluated causes them to perform better oral hygiene in anticipation of the appointment.

In one study, the proportion of spirochetes obtained in baseline samples of subgingival flora was highly correlated with clinical periodontal deterioration over a period of 1 year. However, subsequent reports in the same longitudinal study concluded that the arbitrary assignment of treated periodontitis patients to 3-month maintenance intervals appears to be as effective in preventing recurrences of periodontitis as assignment of recall intervals based on microscopic monitoring of the subgingival flora.[28,29] Microscopic monitoring was found not to be a reliable predictor of future periodontal destruction in patients on 3-month recall programs, presumably because of the alteration of subgingival flora produced by subgingival instrumentation.

In conclusion, there is a sound scientific basis for recall maintenance because subgingival scaling alters the pocket micro flora for variable but relatively long periods.

MAINTENANCE PROGRAM

Periodic recall visits form the foundation of a meaningful long-term prevention program. The interval between visits is initially set at 3 months but may be varied according to the patient's needs.

Periodontal care at each recall visit comprises three parts (Box *76-1).* The first part is concerned with examination and evaluation of the patient's current oral health. The second part includes the necessary maintenance treatment and oral hygiene reinforcement. The third part involves scheduling the patient for the next recall appointment, additional periodontal treatment, or restorative dental procedures. The time required for a recall visit for patients with multiple teeth in both arches is approximately 1 hour, which includes time for greeting the patient, setting up, and cleaning up.

Examination and Evaluation

The recall examination is similar to the initial evaluation of the patient discussed in Chapter 30. However, because the patient is not new to the office, the dentist primarily looks for changes that have occurred since the last evaluation. Analysis of the current oral hygiene status of the patient is essential. Updating of changes in the medical history and evaluation of restorations, caries, prostheses, occlusion, tooth mobility, gingival status, and periodontal pockets are important parts of the recall appointment. The oral mucosa should be carefully inspected for pathologic conditions (Figs. *76-4* to *76-9).*

Radiographic examination must be individualized depending on the initial severity of the case and the findings at the recall visit (Table *76-1).* These are compared with findings on previous radiographs to check the bone height and look for repair of osseous defects, signs of trauma from occlusion, periapical pathologic changes, and caries.

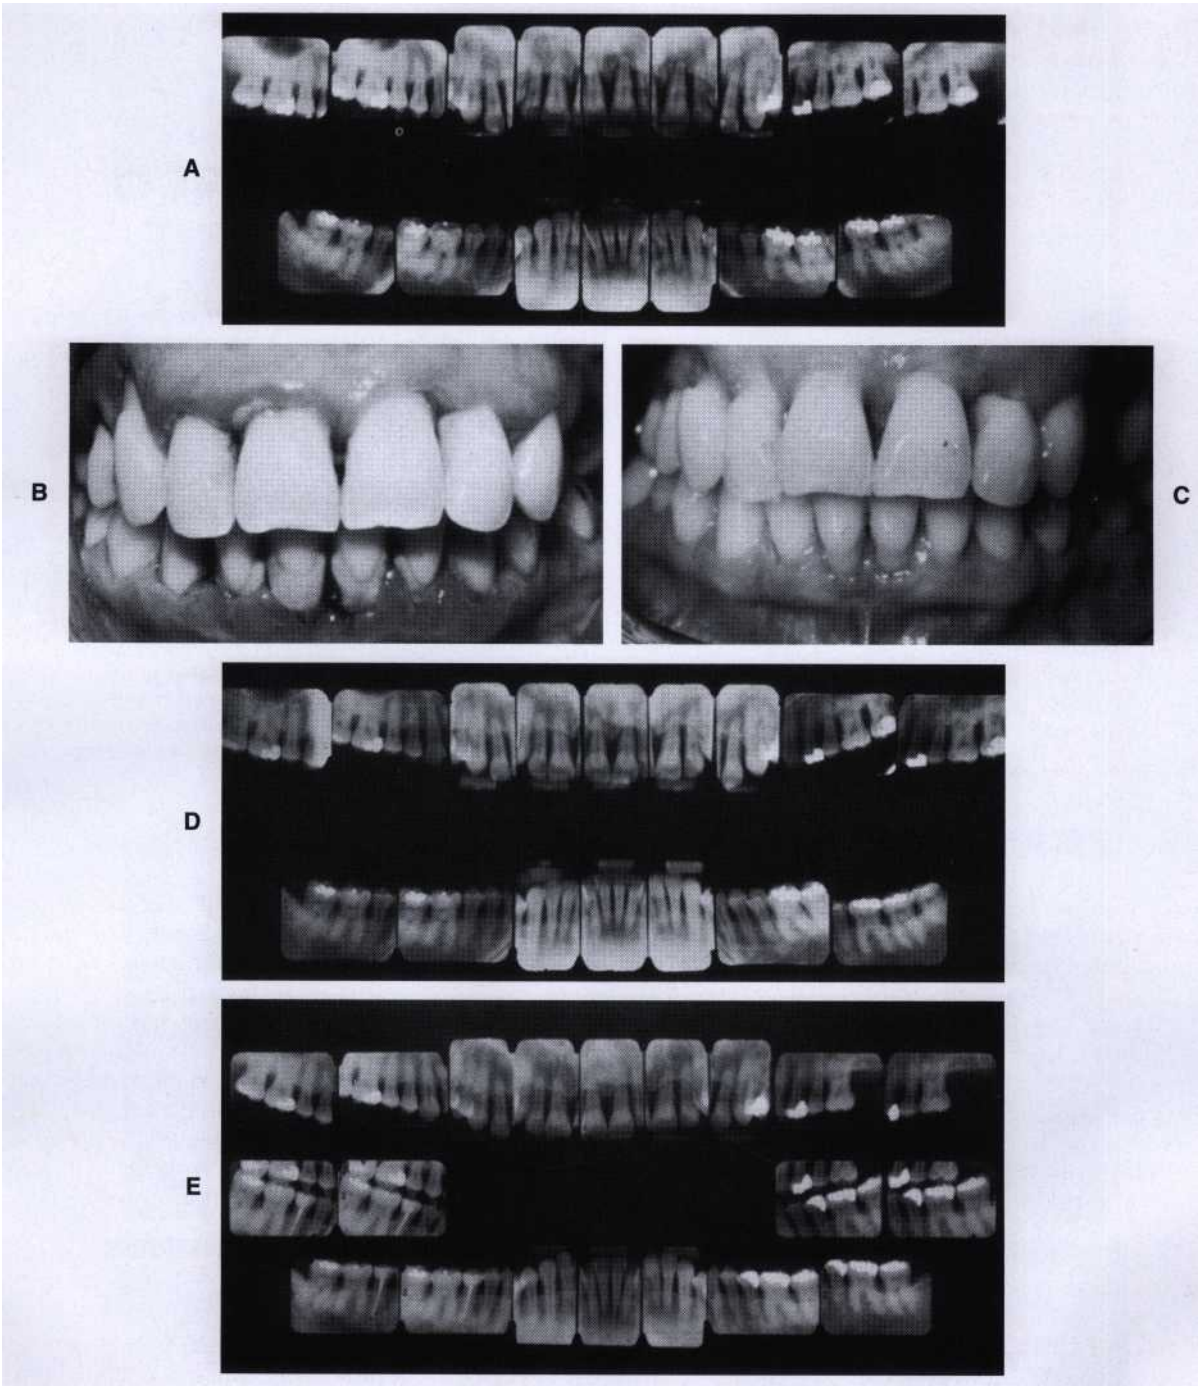

Fig. 76-5 A, The patient was 38 years old when these original radiographs were taken and was treated with a combination of surgical and nonsurgical therapy. This individual is a classic class C maintenance patient. B, Pretreatment photographs. Note the inflammation and heavy calculus deposits. C, Photograph taken 10 years after treatment. D, Radiographs taken 5 years after treatment. E, Radiographs taken 10 years after treatment. The radiographic appearance is as good as can be expected in such a severe case. Teeth #15 and #17 were extracted 8 years after treatment.

Checking of Plaque Control

To assess the effectiveness of their plaque control, patients should perform their hygiene regimen immediately before the recall appointment. Plaque control must be reviewed and corrected until the patient demonstrates the necessary proficiency, even if additional instruction sessions are required. Patients instructed in plaque control have less plaque and gingivitis than uninstructed patients,[4] and the amount of supragingival plaque affects the number of subgingival anaerobic organisms.[15,48]

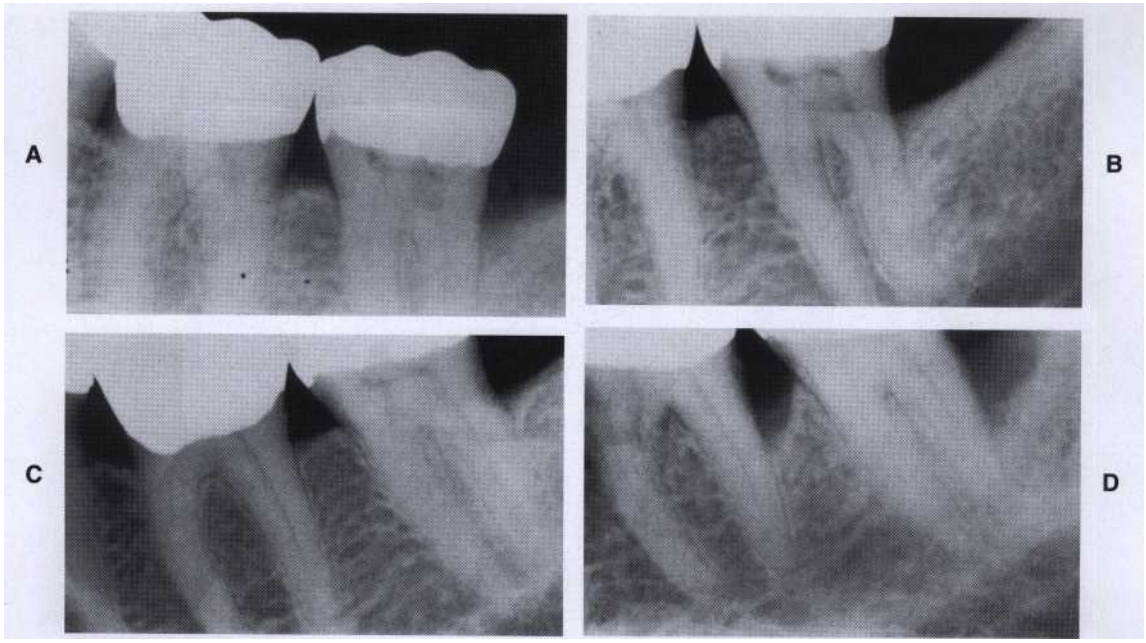

Fig. 76-6 This series of radiographs clearly shows the importance of maintenance therapy. A, Original radiograph of a 58-year-old man. Note the deep distal bone loss on tooth #18 and the moderate distal lesion of tooth #19. Surgical treatment that included osseous grafting was performed. B, Radiograph 14 months after surgical therapy. The patient had recall maintenance performed every 3 to 4 months. C, Appearance 3 1/2 years after surgery, with regular recalls every 3 to 4 months. D, Appearance after 2 years without recalls (7 years after surgery). Note the progression of the disease on the distal surfaces of teeth #18 and #19.

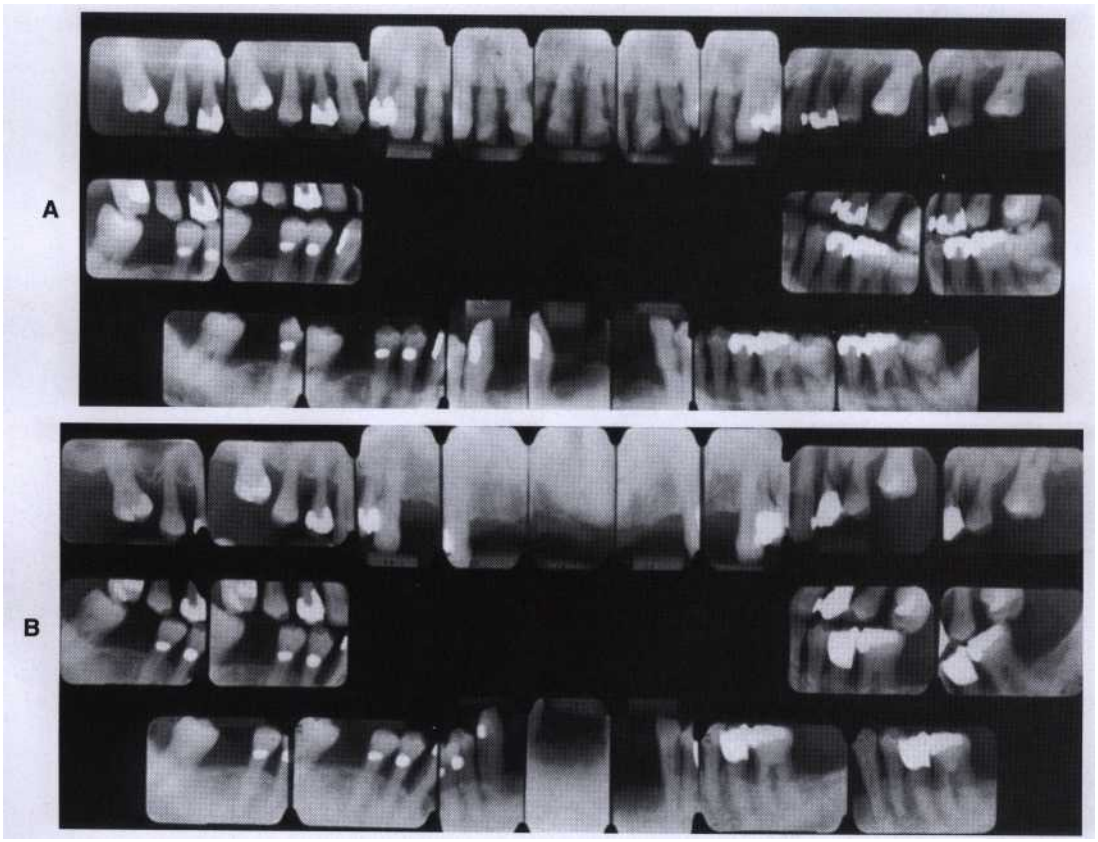

Fig. 76-7 Advanced cases sometimes do better than expected when the patient complies with maintenance therapy. A, Initial radiographs showing a very advanced case. The maxillary arch had extractions and nonsurgical treatment. A plastic treatment partial denture was placed and was expected to grow into a full denture within a few years. The mandibular arch was treated with periodontal surgery, and a permanent metal and plastic removable partial denture was placed. B, Radiographs taken 8 years later. The patient performed good oral **hygiene and had 3-month recalls.** Teeth #12 and #15 required extraction.

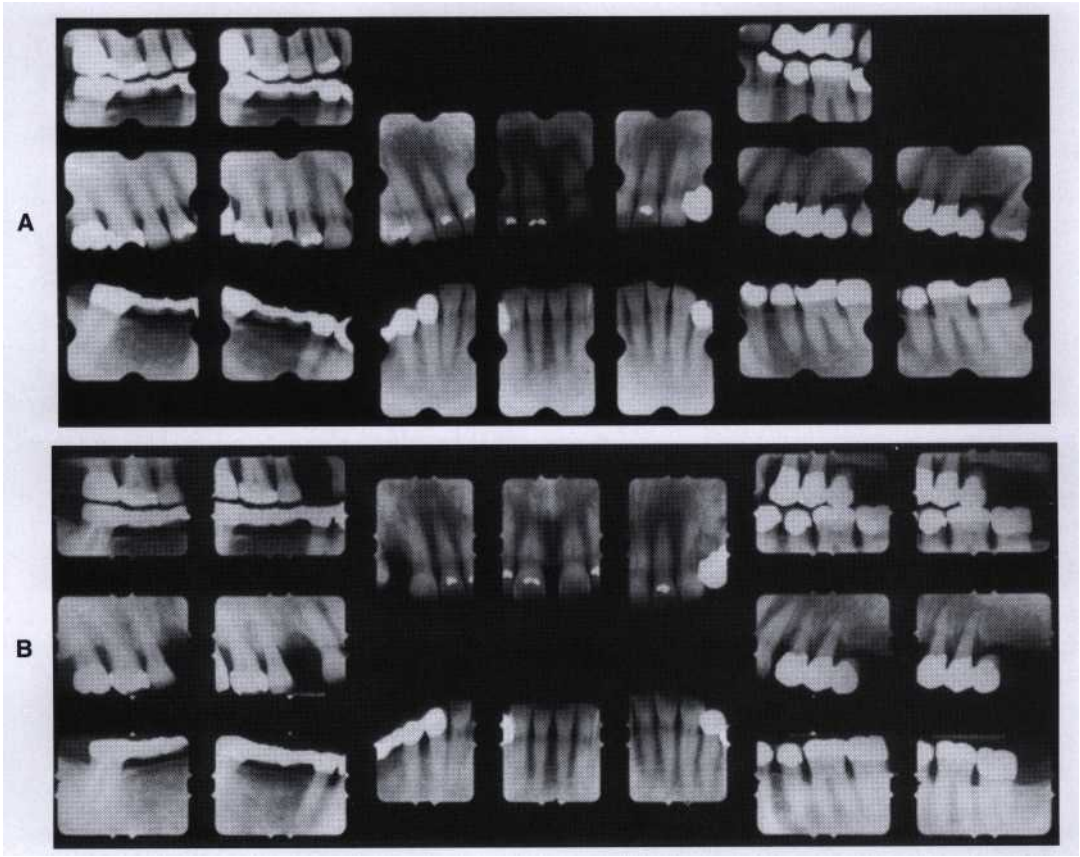

Fig. 76-8 A, Initial radiographs. The patient was advised to have localized areas of periodontal surgery and periodontal recall every 3 months. However, the patient did not comply and only had dental cleanings once or twice yearly. B, Radiographs 4 years later. Note the loss of teeth #5 and #15 and the increased bone loss of several premolars and molars.

Treatment

The required scaling and root planing are performed, followed by an oral prophylaxis (see Chapter 47). Care must be taken not to heavily instrument normal sites with shallow sulci (1 to 3 mm deep) because studies have shown that repeated subgingival scaling and root planing in initially normal periodontal sites result in significant loss of attachment. Irrigation with antimicrobial agents is performed in maintenance patients with remaining pockets .[25,31,45]

Recurrence of Periodontal Disease

Occasionally, lesions may recur. This often can be traced to inadequate plaque control on the part of the patient or failure to comply with recommended SPT schedules. It should be understood, however, that it is the dentist's responsibility to teach, motivate, and control the patient's oral hygiene technique, and the patient's failure is the dentist's failure. Surgery should not be undertaken unless the patient has shown proficiency and willingness to cooperate by adequately performing his or her part of therapy.

Other causes for recurrence are the following:

1. Inadequate or insufficient treatment that has failed to remove all the potential factors favoring plaque accumulation (see Fig. 76-4). Incomplete calculus removal in areas of difficult access is a common source of problems.
2. Inadequate restorations placed after the periodontal treatment was completed.
3. Failure of the patient to return for periodic checkups (see Fig. 76-6). This may be due to the patient's conscious or unconscious decision not to continue treatment or to the failure of the dentist and staff to emphasize the need for periodic examinations.
4. Presence of some systemic diseases that may affect host resistance to previously acceptable levels of plaque.

A failing case can be recognized by the following:

1. Recurring inflammation revealed by gingival changes and bleeding of the sulcus on probing.
2. Increasing depth of sulci, leading to the recurrence of pocket formation.
3. Gradual increases in bone loss as determined by radiographs.
4. Gradual increases in tooth mobility as ascertained by clinical examination.

Cases that do not respond to adequate therapy or recur for unknown reasons are referred to as *refractory periodontitis* (see Chapters 27 and 40).

TABLE 76-1

Radiographic Examination of SPT Recall Patients*[31,63,72]

Patient Condition	Type of Examination
Patients with clinical caries or high-risk factors for caries.	Posterior bitewing examination at 12- to 18-month intervals.
Patients with no clinical caries and no high-risk factors for caries.	Posterior bitewing examination at 24- to 36-month intervals.
Patients with periodontal disease not under good control.	Periapical and/or vertical bitewings of problem areas every 12 to 24 months; full-mouth series every 3 to 5 years.
Patients with history of periodontal treatment with disease under good control.	Bitewing examination every 24 to 36 months; full-mouth series every 5 years.
Patients with root form dental implants.	Periapical or vertical bitewings at 6, 12, and 36 months after prosthetic placement, then every 36 months unless clinical problems arise.
Transfer periodontal or implant maintenance patients.	Full-mouth series if a current set is not available. If a full-mouth series has been taken within 24 months, then radiographs of implants and periodontal problem areas should be taken.

* Radiographs should be taken when they are likely to affect diagnosis and patient treatment. The recommendations in this table are subject to clinical judgment and may not apply to every patient.

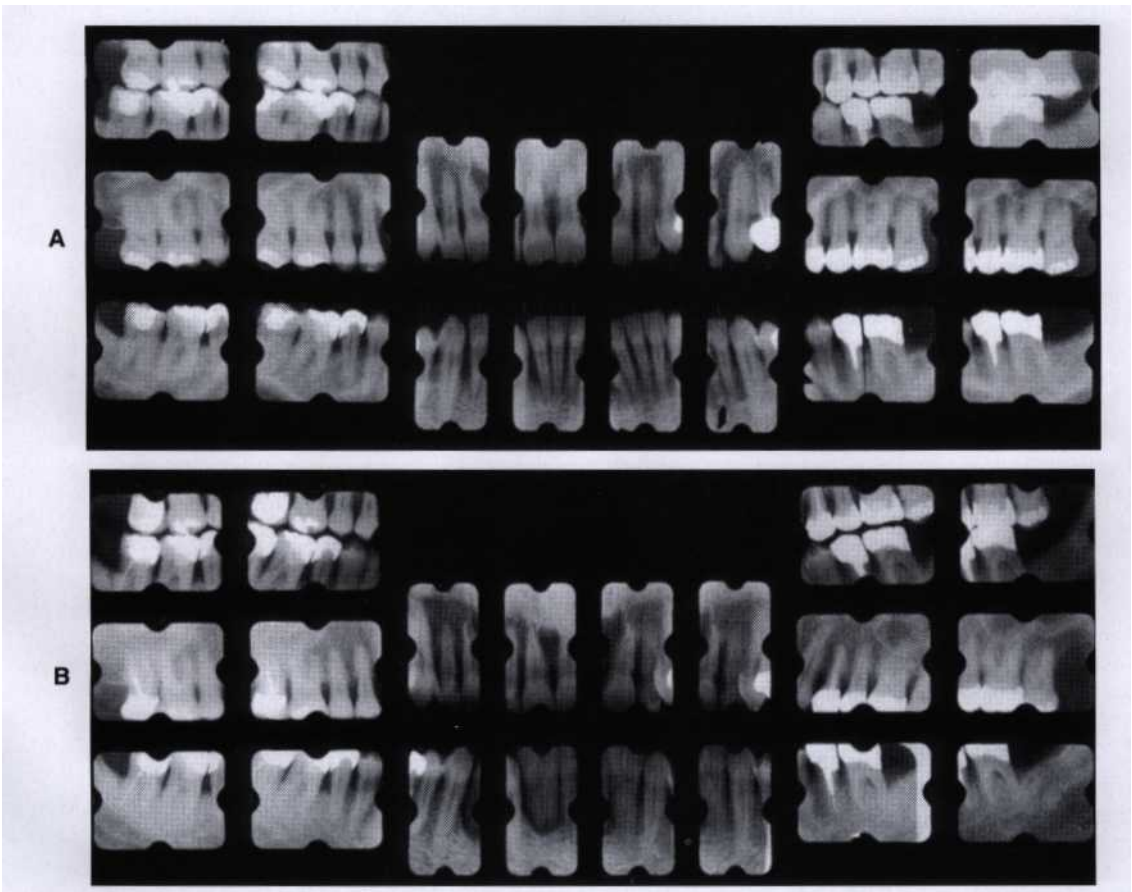

Fig. 76-9 A, Initial radiographs. The patient was advised to have localized areas of periodontal surgery and periodontal recall every 3 months. However, the patient did not comply and had no treatment other than emergency care and occasional dental cleanings. B, Radiographs 7 years later. Note the advanced bone loss and caries on many teeth.

TABLE 76-2

Symptoms and Causes of Recurrence of Disease

Symptom	Possible Causes
Increased mobility	Increased inflammation
	Poor oral hygiene
	Subgingival calculus
	Inadequate restorations
	Deteriorating or poorly designed prostheses
	Systemic disease modifying host response to plaque
Recession	Toothbrush abrasion
	Inadequate keratinized gingiva
	Frenum pull
	Orthodontic therapy
Increased mobility with no change in pocket depth and no radiographic change	Occlusal trauma due to lateral occlusal interference
	Bruxism
	High restoration
	Poorly designed or worn-out prosthesis
	Poor crown-to-root ratio
Increased pocket depth with no radiographic change	Poor oral hygiene
	Infrequent recall visits
	Subgingival calculus
	Poorly fitting partial denture
	Mesial inclination into edentulous space
	Failure of new attachment surgery
	Cracked teeth
	Grooves in teeth
	New periodontal disease
Increased pocket depth with increased radiographic bone loss	Poor oral hygiene
	Subgingival calculus
	Infrequent recall visits
	Inadequate or deteriorating restorations
	Poorly designed prostheses
	Inadequate surgery
	Systemic disease modifying host response to plaque
	Cracked teeth
	Grooves in teeth
	New periodontal disease

The decision to retreat a periodontal patient should not be made at the preventive maintenance appointment but should be postponed for 1 to 2 weeks." Often the mouth looks a great deal better at that time, owing to the resolution of edema and the resulting improved tone of the gingiva. A summary of the symptoms of recurrence of periodontal disease and their probable causes can be found in Table 76-2.

CLASSIFICATION OF POSTTREATMENT PATIENTS

The first year after periodontal therapy is important in terms of indoctrinating the patient in a recall pattern and reinforcing oral hygiene techniques. In addition, it may take several months to accurately evaluate the results of some periodontal surgical procedures. Consequently, some areas may have to be retreated because the results may not be optimal. Furthermore, the first-year patient often has etiologic factors that may have been overlooked and may be more amenable to treatment at this early stage. For these reasons, *the recall interval for first-year patients should not be longer than 3 months.*

The patients who are on a periodontal recall schedule are a varied group. Table 76-3 lists several categories of maintenance patients and a suggested recall interval for each. Patients can improve or relapse to a different classification with a reduction in or exacerbation of periodontal disease. When one dental arch is more involved than the other, the patient's periodontal disease is classified by the arch that is in worse condition.

In summary, maintenance care is a critical phase of therapy. *The long-term preservation of the dentition is closely associated with the frequency and quality of recall maintenance.*

TABLE 76-3

Recall Intervals for Various Classes of Recall Patients

Merin Classification	Characteristics	Recall Interval
First year	First-year patient-routing therapy and uneventful healing	3 months
	or First-year patient-difficult case with complicated prosthesis, furcation involvement, poor crown-to-root ratios, or questionable patient cooperation	1 to 2 months
Class A	Excellent results well maintained for 1 year or more Patient displays good oral hygiene, minimal calculus, no occlusal problems, no complicated prostheses, no remaining pockets, and no teeth with less than 50% of alveolar bone remaining	6 months to 1 year
Class B	Generally good results maintained reasonably well for 1 year or more, but patient displays some of the following factors: 1. Inconsistent or poor oral hygiene 2. Heavy calculus formation 3. Systemic disease that predisposes to periodontal breakdown 4. Some remaining pockets 5. Occlusal problems 6. Complicated prostheses 7. Ongoing orthodontic therapy 8. Recurrent dental caries 9. Some teeth with less than 50% of alveolar bone support 10. Smoking 11. Positive genetic test	3 to 4 months (decide on recall interval on the basis of the number and severity of negative factors)
Class C	Generally poor results following periodontal therapy and/or several negative factors from the following list: 1. Inconsistent or poor oral hygiene 2. Heavy calculus formation 3. Systemic disease that predisposes to periodontal breakdown 4. Remaining pockets 5. Occlusal problems 6. Complicated prostheses 7. Recurrent dental caries 8. Periodontal surgery indicated but not performed for medical, psychologic, or financial reasons 9. Many teeth with less than 50% of alveolar bone support 10. Condition too far advanced to be improved by periodontal surgery 11. Smoking 12. Positive genetic test 13. More than 20% of pockets bleed on probing	1 to 3 months (decide on recall interval on the basis of the number and severity of negative factors; consider retreating some areas or extracting the severely involved teeth)

REFERRAL OF PATIENTS TO THE PERIODONTIST

The majority of periodontal care belongs in the hands of the general dentist. This is because of the overwhelming number of patients with periodontal disease and the intimate relationship between periodontal disease and restorative dentistry.

For various reasons, an ever-greater number of periodontal maintenance patients are expected in future years. The number of caries per capita has dwindled since the mid-1970s by about 50%, and some evidence suggests that this decline will continue.[45] As more people retain their teeth throughout their lifetimes and the proportion of older people in the population increases,

more teeth will be at risk of periodontal disease. Hence the prevalence of patients requiring SPT is likely to increase in the future.

This expected increase in the number of periodontal patients will necessitate a greater understanding of periodontal problems and an increased level of expertise for the solution of such problems on the part of the general practitioner of dentistry. However, specialists always will be needed to treat particularly difficult cases, patients with systemic health problems, dental implant patients, and situations in which a complex prosthetic construction requires absolute assurance of reliable results.

The question remains where to draw the line between the cases to be treated in the general dental office and those to be referred to a specialist varies for different practitioners and patients. The diagnosis indicates the type of periodontal treatment required. If periodontal destruction necessitates surgery on the distal surfaces of second molars, extensive osseous surgery, or complex regenerative procedures, the patient is usually best treated by a specialist. On the other hand, patients who require localized gingivectomy or flap curettage usually can be treated by the general dentist.

It is immediately obvious that some patients should be referred to a specialist, whereas most patients clearly have problems that can be treated by a general dentist. However, for a third group of patients, it will be difficult to decide whether treatment by a specialist is required. Any patient who does not plainly belong in the second of these categories should be considered a candidate for referral to a specialist.

The decision to have the general practitioner treat a patient's periodontal problem should be guided by a consideration of the degree of risk that the patient will lose a tooth or teeth for periodontally related reasons.

The most important factors in the decision are the extent and *location of the periodontal deterioration.* Teeth with pockets of 5 mm or more, as measured from the cementoenamel junction, may have a prognosis of rapid decline. The location of the periodontal deterioration is also an important factor in determining the risk of tooth loss. Teeth with furcation lesions may be at risk even when more than 50% of bone support remains. Therefore cases in which strategically important teeth fall into these categories are usually best treated by specialists.

An important question remains: *Should the maintenance phase of therapy be performed by the general practitioner or the specialist?* This should be determined by the amount of periodontal deterioration present. Class A recall patients should be maintained by the general dentist, whereas Class C patients should be maintained by the specialist (see Table 76-3). Class B patients can alternate recall visits between the general practitioner and the specialist (Fig. 76-10). The suggested rule is that the *patient's disease should dictate whether the general practitioner or the specialist should perform the maintenance therapy*.

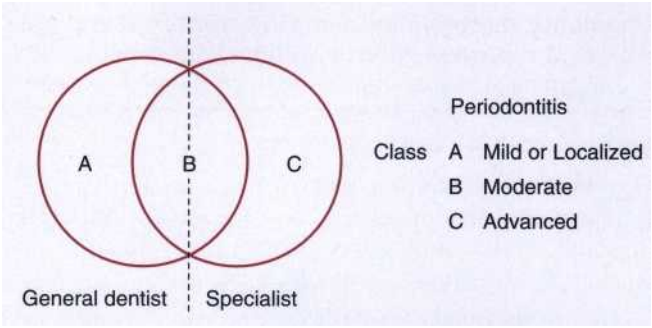

Fig. 76-10 Scheme for determining which practitioner should perform periodontal maintenance in patients with different degrees of periodontitis.

TESTS FOR DISEASE ACTIVITY

Periodontal patients, even though they have received effective periodontal therapy, are at risk of disease recurrence for the rest of their lives .[2,21] In addition, many pockets in furcation areas may not have been eliminated by surgery. At present, the best way of determining areas that are losing attachment uses a well-organized charting system[43,59]; some computerized systems offer the possibility of easy retrieval and comparison of past findings.

Comparison of sequential probing measurements gives the most accurate indication of rate of loss of attachment.[3] A number of other clinical and laboratory variables have been correlated with disease activity (see Chapter 34). At present, no accurate method of identifying disease activity exists, and clinicians rely on the information provided by combining probing, bleeding on probing, and sequential attachment measurements .[22,28,59] Patients whose disease is clearly refractory are candidates for bacterial culturing and antibiotic therapy in conjunction with additional mechanical therapy.

Tests will undoubtedly be developed in the future to help determine disease activity. The clinician must be able to interpret whether a test may be useful in determining disease activity and future loss of attachment.$ Tests should be adopted only when they are based on research that includes a critical analysis of the sensitivity, specificity, disease incidence, and predictive value of the proposed test.

MAINTENANCE FOR DENTAL IMPLANT PATIENTS

Patients with implants are susceptible to a form of bone loss called *periimplantitis,* and evidence suggests that such patients may be more prone to plaque-induced inflammation with bone loss than those with natural teeth[6,46,57] (see Chapter 73).

The overall periodontal condition in partially edentulous implant patients can influence the clinical condition around implants.' The microflora of implants in partially edentulous patients differs from that in edentulous patients. The implant microflora is similar to tooth microflora in the partially edentulous mouth. Periodontal and implant maintenance are linked because maintenance of a tooth microflora consistent with periodontal health is necessary to maintain implant microflora consistent with periimplant health. Because periimplantitis is difficult to treat,19 it is extremely important to treat

periodontal disease prior to implant placement and provide good supportive therapy with implant patients.

In general, procedures for maintenance of patients with implants are similar to those with natural teeth, with three differences:

1. Special instrumention that will not scratch the implants are used for calculus removal on the implants.
2. Acidic fluoride prophylactic agents are avoided.
3. Nonabrasive prophy pastes are used.

During the phase after uncovering the implants, patients must use ultrasoft brushes, chemotherapeutic rinses, tartar control pastes, irrigation devices, and yarn-like materials to keep the implants and natural teeth clean. Patients often are afraid to touch the implants but must be encouraged to keep the areas clean.

Special instruments should be used on the implants during recall appointments. 17,33 Metal hand instruments and ultrasonic and sonic tips should be avoided because they can alter the titanium surface. Only plastic instruments or specially designed gold-plated curettes should be used for calculus removal because the implant surfaces can be easily scratched. The rubber cup with flour of pumice, tin oxide, or special implant polishing pastes should be used on abutment surfaces with light, intermittent pressure. 32

Although daily use of topically applied antimicrobials is advised,33 acidic fluoride agents should not be used because they cause surface damage to titanium abutments. 4o

When prosthetics must be unscrewed and removed for maintenance, it is best done in the office responsible for placing the prosthetics. Each time the prosthetics are reattached, a slight change in the occlusion occurs. Time must be allowed for occlusal corrections.

CHAPTER

CHAPTER OUTLINE

PREVENTION AND TREATMENT OF GINGIVITIS
PREVENTION AND TREATMENT OF LOSS OF ATTACHMENT
Prevention of Loss of Attachment
Treatment of Loss of Attachment
TOOTH MORTALITY

The prevalence of periodontal disease, the high tooth mortality rate resulting from it, and the potential for multiple systemic health complications aggravated by chronic periodontitis raise an important question: Is periodontal treatment effective in preventing and controlling the chronic infection and progressive destruction of periodontal disease? Current concepts of evaluating health care require a scientific basis for treatment. This is referred to as evidence-based therapy. *Evidence is now overwhelming that periodontal therapy is effective in preventing periodontal disease, slowing the destruction of the periodontium, and reducing tooth loss.*

PREVENTION AND TREATMENT OF GINGIVITIS

For many years, the belief that good oral hygiene is necessary for the successful prevention and treatment of gingivitis has been widespread among periodontists. In addition, worldwide epidemiologic studies have confirmed a close relationship between the incidence of gingivitis and lack of oral hygiene.

Conclusive evidence on the relation of oral hygiene and gingivitis in healthy dental students was shown by Loe and co-workers. After 9 to 21 days without performing oral hygiene measures, experimental subjects with previously excellent oral hygiene and healthy gingiva developed heavy accumulations of plaque and generalized mild gingivitis. When oral hygiene techniques were reinstituted, the plaque in most areas disappeared in 1 or 2 days, and gingival inflammation in these areas disappeared approximately 1 week after the plaque was removed. Thus gingivitis is reversible and can be resolved by daily effective plaque removal.

A number of long-term studies have shown that gingival health can be maintained by a combination of effective oral hygiene maintenance and scaling procedures. [1,2,8,10,11,18,32,33]

A 3-year study was conducted on 1248 General Telephone workers in California to determine whether progression of gingival inflammation is retarded in an oral environment in which high levels of hygiene are maintained.[32,33] Experimental and control groups were computer matched on the basis of periodontal and oral hygiene status, past caries experience, age, and gender. During the study period, several procedures were instituted to ensure that the oral hygiene status of the experimental group was maintained at a high level. Subjects were given a series of frequent oral prophylaxis treatments combined with oral hygiene instruction. Subjects in the control group received no attention from the study team except for annual examinations. They were advised to continue their usual daily practices and accustomed visits for professional care. After 3 years, the

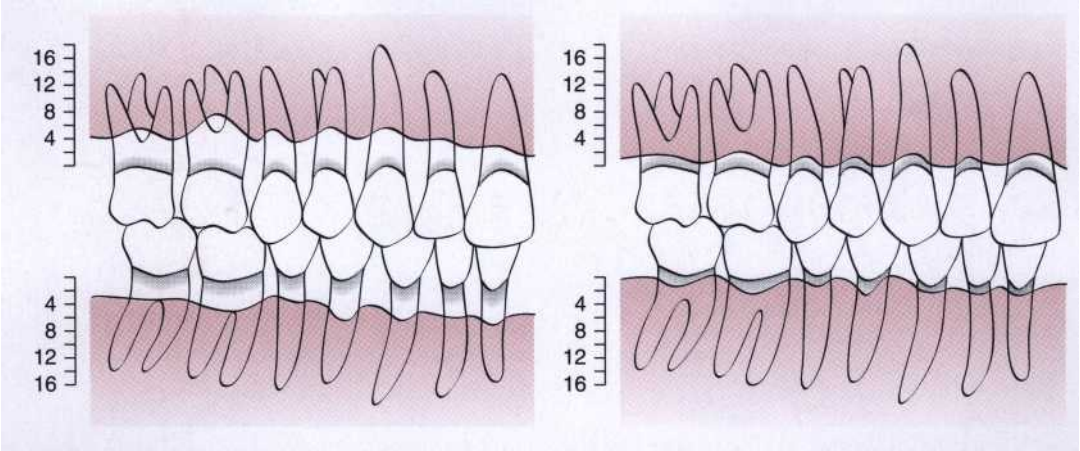

Fig. 77-1 Left Mean periodontal support of teeth of Sri Lankan tea laborers at approximately 40 years of age. *Right,* **Mean periodontal support of teeth of Norwegian academicians at approximately 40 years of age. increase in plaque and debris in the control group was four times as great as that in the experimental group. Similarly, gingivitis scores were much higher in control subjects than in the matching experimental group. Therefore *chronic marginal gingivitis can be controlled with good oral hygiene and dental prophylaxis.*

PREVENTION AND TREATMENT OF LOSS OF ATTACHMENT

Although periodontal therapy has been used for more than 100 years, it is only since the mid-1970s that a number of studies have been conducted to determine the effect of treatment on reducing the progressive loss of periodontal support for the natural dentition.

Prevention of Loss of Attachment

A longitudinal investigation to study the natural development and progression of periodontal disease was conducted by Loe and co-workers. 16 The first group, established in Oslo, Norway in 1969, consisted of 565 healthy male nondental students and academicians between 17 and 40 years of age. The principal reason for selecting Oslo as a study site was that this city had had a preschool, school, and postschool dental program offering systematic preventive, restorative, endodontic, orthodontic, and surgical therapy on an annual recall basis for all children and adolescents, complete with a documented attendance record, for the previous 40 years. Members of the study population had had maximum exposure to conventional dental care throughout their lives. A second group, established in Sri Lanka in 1970, consisted of 480 male tea laborers between 15 and 40 years of age. They were healthy and well built by local standards, and their nutritional condition was clinically fair. The workers had never been exposed to any programs relative to the prevention or treatment of dental diseases. Toothbrushing was unknown, and dental caries was virtually nonexistent.

The results of this study are quite interesting. The Norwegian group, as the members approached 40 years of age, had a mean individual loss of attachment of slightly above 1.5 mm, and the mean annual rate of attachment loss was 0.08 mm for interproximal surfaces and 0.10 mm for buccal surfaces. As the Sri Lankans approached 40 years of age, the mean individual loss of attachment was 4.50 mm, and the mean annual rate of progression of the lesion was 0.30 mm for interproximal surfaces and 0.20 mm for buccal surfaces. Fig. 77-1 shows a graphic interpretation of the difference between the two groups. This study suggests that without interference, periodontal lesions progress continually and at a relatively even pace.

Further analysis of the Sri Lankan laborers" showed that they were not all losing attachment at the same rate (Figs. 77-2 and 77-3). Virtually all gingival areas showed inflammation, but attachment loss varied tremendously. Based on interproximal loss of attachment and tooth mortality, three subpopulations were identified: individuals with rapid progression (RP) of periodontal disease (8%), individuals with moderate progression (MP) (81%), and individuals who exhibited no progression (NP) of periodontal disease beyond gingivitis (11%). At age 35, the mean loss of attachment in the RP group was 9 mm; in the MP group, 4 mm; and in the NP group, less than 1 mm. At the age of 45, the mean loss of attachment in the RP group was 13 mm and in the MP group, 7 mm. It is obvious that under natural conditions and in the absence of any therapy, 89% of the Sri Lankan laborers had severe periodontitis that progressed at much greater rates than in the Norwegian group.

In the previously discussed study of General Telephone workers in California, loss of attachment was measured clinically and alveolar bone loss was measured radiographically.29,30 After 3 years, the control group showed loss of attachment at a rate more than 32 times that of the matching experimental group during the same period (Fig. 77-4). In addition, subjects who received frequent oral prophylaxis and were instructed in

good oral hygiene practices showed less bone loss radiographically after 3 years than did control subjects. *It is clear that loss o f attachment can be reduced by good oral hygiene and frequent dental prophylaxis.*

Treatment of Loss of Attachment

A longitudinal study of patients with moderate to advanced periodontal disease conducted at the University of Michigan showed that the progression of periodontal disease can be stopped for a period of 3 years postoperatively regardless of the modality of treatment.[24-27] With long-term observations, the average loss of attachment was only 0.3 mm over 7 years.[24] These results indicated a more favorable prognosis for treatment of advanced periodontal lesions than previously assumed.

Another study was conducted in 75 patients with advanced periodontal disease to determine the effect of plaque control and surgical pocket elimination on the establishment and maintenance of periodontal health.13 This study showed that no further alveolar bone loss occurred during the 5-year observation period. The meticulous plaque control practiced by the patients in this study was considered a major factor in the excellent results produced. After 14 years, results for 61 of the initial 75 individuals were reported.[14] Repeated examinations demonstrated that treatment of advanced forms of periodontal disease resulted in clinically healthy periodontal conditions and that this state of health was maintained in most patients and sites during the 14-year period. A more detailed analysis of the data revealed, however, that a small number of sites in a few patients lost a substantial amount of attachment. Approximately 43 surfaces in 15 different patients were exposed to recurrent periodontal disease of significant magnitude. The frequency of sites that lost more than 2 mm of attachment during the 14 years of maintenance was *0.8%* to 0.1% per year.

Neither of these studies used a control group because failing to treat advanced periodontal patients cannot be justified for ethical reasons. However, in a study in private practice, an effort was made to find and evaluate patients with diagnosed moderate to advanced periodontitis who had not followed through with recommended periodontal therapy.[3] Thirty patients ranging in age from 25 to 71 years were evaluated after periods ranging from *18* to 115 months. All these untreated patients had progressive increases in pocket depth and radiographic evidence of progressive bone resorption.

In a study of the progression of periodontal disease in the absence of therapy, two different populations were monitored." One group of 64 Swedish adults with mild to moderate periodontal disease and one group of 36 American adults with advanced destructive disease were monitored but not treated for 6 years and 1 year, respectively. During the course of 6 years, 11.6% of all sites in the Swedish population *(1.9%* per year) showed attachment loss of greater than 2 mm, and the corresponding figure for the American population was 3.2% per year.

Thus the frequency of sites with disease progression was 20 to 30 times higher in untreated groups of patients than in the treated and well-maintained groups described in the preceding discussion.[13] *Thus treatment is effective in reducing loss o f attachment.*

TOOTH MORTALITY

The ultimate test for the effectiveness of periodontal treatment is whether the loss of teeth can be prevented. Enough studies from both private practice and research institutions are now available to document that loss of teeth is retarded or prevented by therapy.

The combined effect of subgingival scaling every 3 to 6 months and controlled oral hygiene was evaluated over a 5-year period in 1428 factory workers in Oslo." Tooth loss was significantly reduced in all patients. This study showed that frequent subgingival scalings reduce tooth loss even when oral hygiene is not good (Table 77-1).

The previously mentioned longitudinal study conducted at the University of Michigan included 104 patients with a total of 2604 teeth.[24-27] After 1 to 7 years of treatment, 53 teeth were lost for various reasons (Table 77-2). Approximately 32 teeth were lost during the first and second years after initiation of treatment. The remaining 21 teeth were lost in a random pattern over the next 6 years. Therefore the loss of teeth owing to advanced periodontal disease after treatment was minimal (1.15%).

Another study was undertaken to test the effect of periodontal therapy in cases of advanced disease.[13,14] The subjects were 75 patients who had lost 50% or more of their periodontal support (Fig. 77-5). Treatment consisted of oral hygiene measures, scaling procedures, extraction of untreatable teeth, periodontal surgery, and prosthetics if indicated. After completion of periodontal treatment, a 5-year period followed during which none of the patients showed any further loss of periodontal support. No teeth were extracted in the 5-year posttreatment period. It should be pointed out that the patients in this study were selected because of their capacity to meet high requirements of plaque control after repeated instruction in oral hygiene techniques. This fact does not detract from the validity of the study but tends to show the etiologic importance of bacterial plaque. The results indicate that periodontal surgery coupled with a detailed plaque control program not only temporarily cures the disease but also reduces further progression of periodontal breakdown, even in patients with severely reduced periodontal support. After 14 years, 61 of the original patients were still in the study." Recurrence of destructive periodontal disease in isolated sites of the dentition resulted in loss of a certain number of teeth during the observation period (Fig. 77-6). In the 6 to 10 years after active therapy, one tooth in each of three different patients was lost, and during the final observation period (11 to 14 years), three teeth in one patient, two teeth in each of three patients, and one tooth in each of four patients had to be extracted because of recurrent periodontal disease. In addition, three teeth in each of three different patients and one tooth in each of five patients were extracted owing to the development of extensive caries, periapical lesions, or other endodontic complications. During the entire course of the study, the total loss was 30 teeth (for all reasons) out of 1330 teeth. The tooth mortality rate was therefore 2.3%.

Several studies in private practice have attempted to measure frequency of tooth loss after periodontal therapy. In one study, 180 patients who had been treated for chronic destructive periodontal disease were evaluated.[28,29] The average age of the patients before treatment was 43.7 years. A total of 141 teeth were lost. From the beginning of treatment to the time of the survey, the majority of patients lost no teeth (Fig. 77-7). Three patients out of 180 (1.7%) lost 35 teeth, approximately

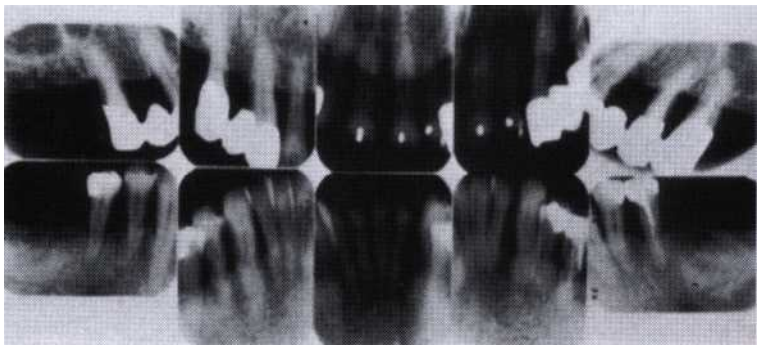

Fig. 77-5 Radiographs taken 5 years after typical periodontal treatment. Note the advanced bone loss, in spite of which teeth were retained in a healthy condition for the duration of the study. (From Lindhe J, Nyman S: The effect of plaque control and surgical pocket elimination on the establishment and maintenance of periodontal health. A longitudinal study of periodontal therapy in cases of advanced disease. J Clin Periodontol 1975; 2:67.)

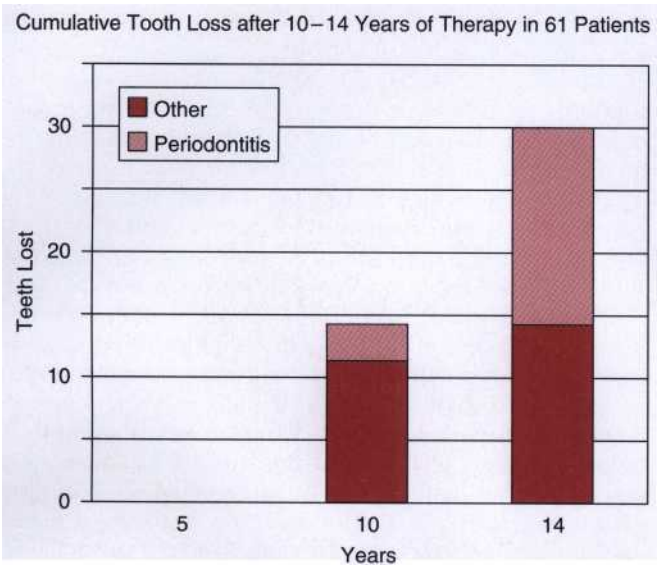

Fig. 77-6 Tooth loss in treated patients with very advanced periodontal disease. (Data from Lindhe J, Nyman S: Long-term maintenance of patients treated for advanced periodontal disease. J Clin Periodontol 1984; 11:504.)

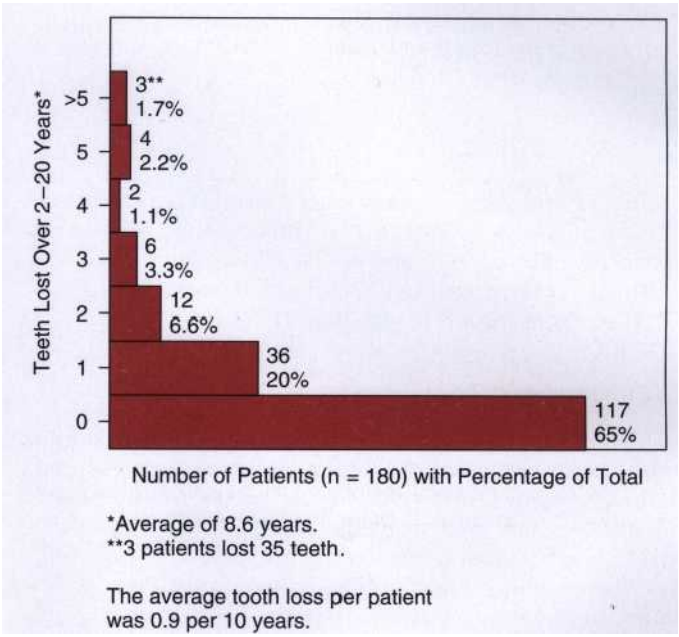

Fig. 77-7 Tooth mortality. (Adapted from Ross IF, Thompson RH, Galdi M: The results of treatment. A long term study of one hundred and eighty patients. Parodontologie 1971; 25:125.)

25% of the teeth lost. Twelve additional patients lost 46 teeth, or 32.6% of the teeth lost. Many patients in the study had advanced alveolar bone loss, including extensive furcation involvements. However, only a relatively small number (141) of the teeth were lost in the study group of 180 patients between the beginning of periodontal treatment and the time of the study.

The teeth were lost for several reasons including periodontal disease, caries, and other nonperiodontal causes.* The length of time after treatment varied from 2 to 20 years, with an average of 8.6 years. Of considerable significance is the large number of teeth (81 teeth, or 57.5%) lost by a few patients (15 patients, or 8.4%). Even when this group is considered with the remaining 165 patients, it may be seen that the periodontal care provided helped to retain most teeth, as the average tooth loss was slightly less than one tooth (0.9) over the 10 years after treatment.

In a follow-up study, the long-term results of periodontal therapy were evaluated after 15 to 34 years (average of 22.2 years).[4] The average tooth loss at this time was 1.6 teeth per 10 years. Patients were classified into three groups according to tooth loss. Approximately 62% had an average tooth loss of 0.45 per 10 years and were

* **U.S. Health Surveys conducted in the 1960s indicated that an average of 4.3 teeth were lost after age 35 in the general population.**[9]

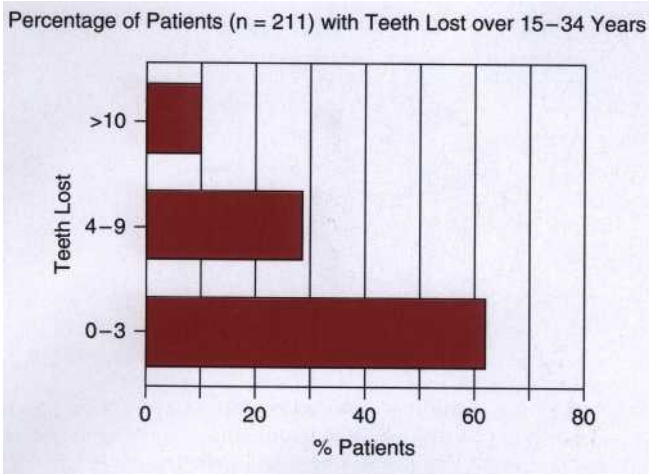

Fig. 77-8 Tooth mortality 15 to 34 years after initiation of therapy (average of 22.2 years). Average tooth loss is 1.6 teeth per 10 years. Compare with the same study population in Fig. 77-7. As the treated population ages, the rate of bone loss appears to increase. (Adapted from Goldman MJ, Ross IF, Goteiner D: Effect of periodontal therapy on patients maintained for 15 years or longer. J Periodontol 1986; 57:347.)

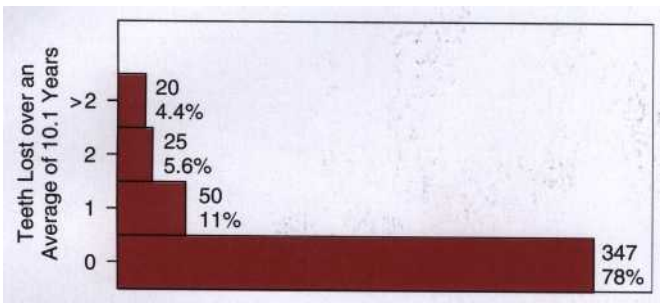

Fig. 77-9 Tooth mortality in 442 periodontal patients treated over 10 years. (Courtesy Dr. R. C. Oliver, Rio Verde, Ariz.)

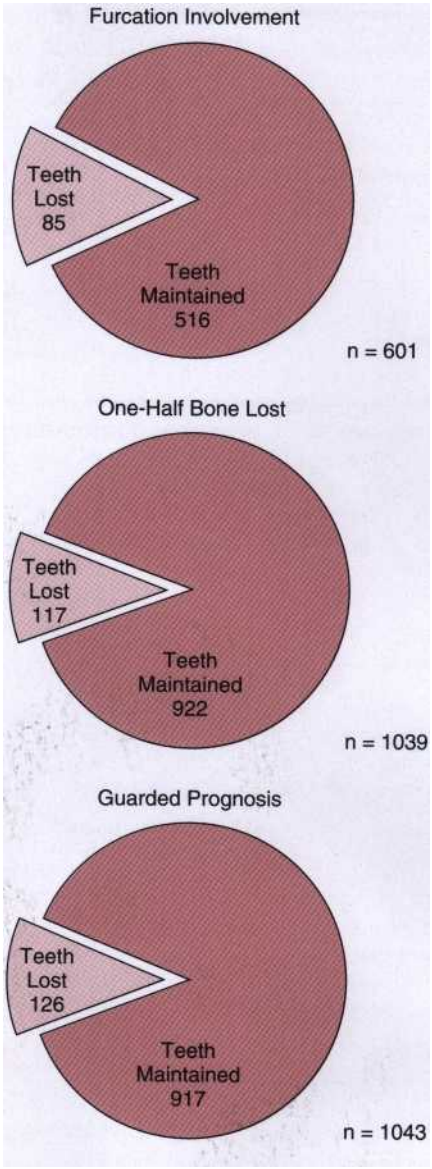

Fig. 77-10 Loss of teeth with advanced periodontal disease over 10 years. (Courtesy Dr. R. C. Oliver, Rio Verde, Ariz.)

considered "well maintained"; 28% lost an average of 2.6 teeth per 10 years and were considered "downhill"; and 10% lost an average of 6.4 teeth per 10 years and were considered "extreme downhill" (Fig. 77-8).

Another study included all patients in a practice who had been treated 5 or more years previously and had received regular preventive periodontal care since that time.[23] The 442 patients had an average of 10.1 years since treatment. Two thirds of the patients were older than 40 at the time of treatment. These patients had been seen every 4.6 months, on average, for their preventive periodontal care, which consisted of oral hygiene instruction and prophylaxis (Figs. 77-9 and 77-10).

The total tooth loss owing to periodontal disease was 178 of more than 11,000 teeth available for treatment. More important, 78% of the patients did not lose a single tooth after periodontal therapy, and 11% lost only one tooth. Considering that more than 600 teeth had furcation involvements at the time of the original treatment and that well over 1000 teeth had less than half of the alveolar bone support remaining, the tooth loss was low. During the same average 10-year period after periodontal therapy, only 45 teeth were lost through caries or pulpal involvement. Even more surprising are the statistics over an average 10-year period for teeth with a less-than-optimal prognosis. Only 85 (14%) of a total of 601 teeth with furcation involvement were lost, and 117 (11%) of 1039 teeth with half or less of the bone remaining were lost. Of the 1043 teeth listed as having a guarded prognosis for any reason by the clinician performing the initial examination, only 126 (12%) were lost over this 10-year average period. The average tooth mortality rate was 0.72 tooth lost per patient per 10 years.

In a third study in private practice, 600 patients were followed for between 15 and 53 years after periodontal therapy' (Table 77-3; Figs. 77-11 and 77-12). The majority (76.5%) had advanced periodontal disease at the start of treatment. There were 15,666 teeth present, for an

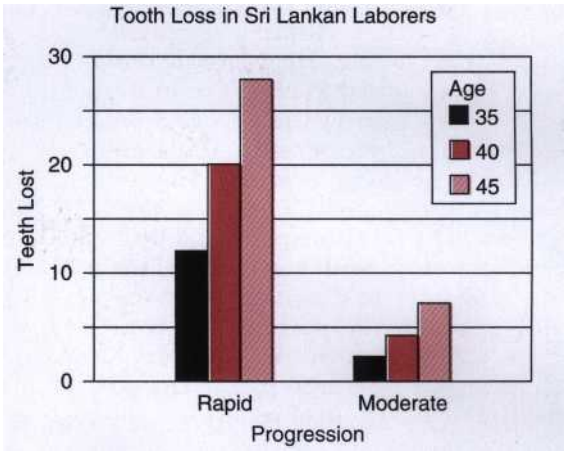

Fig. 77-13 Tooth loss in a population with untreated periodontal disease. (Data from L6e H, Anerud A, Boysen H, et al: Natural history of periodontal disease in man. J Clin Periodontol 1986; 13:431.)

average of 26 teeth per patient. During the follow-up period (average of 22 years), a total of 1312 teeth were lost owing to all causes. Of this number, 1110 were lost for periodontal reasons. The average tooth mortality rate per patient was 2.2 teeth; when this is converted to a 10-year rate, an average of one tooth was lost per 10 years in each patient. During this period of observation, 666 teeth with a questionable prognosis were lost out of a total of 2141. This means that 31% of the teeth with a questionable prognosis were lost over 22 years of treatment. A total of 1464 teeth with furcation involvement were treated, and 31.6% were lost during the period of study. Approximately 83% of the patients lost fewer than three teeth over the 22-year average treatment period and were classified as well maintained. The remaining 17 percent of the patients were divided into two groups: downhill (4 to 9 teeth lost) or extreme downhill (10 to 23 teeth lost). Thus 17% of the patients studied accounted for 69% of the teeth lost owing to periodontal causes. This study also showed that relatively few teeth are lost after periodontal therapy. In addition, relatively few of the teeth with guarded prognosis, including those with furcation involvement, are lost, and a small percentage of patients lose most of the teeth.

Two studies give insight into tooth mortality in untreated patients. The studies of L6e and co-workers in Sri Lankan laborers's showed that after the age of 35, an average of 5 and 16 teeth were lost per 10 years in the moderate progression and rapid progression groups, respectively (Fig. 77-13). In a previously discussed study in private practice ,3 an effort was made to find and evaluate patients with diagnosed moderate to advanced periodontitis who did not follow through with recommended periodontal therapy. Patients with untreated periodontal disease were losing teeth at a rate greater than 0.61 tooth per year (6.1 teeth per 10 years). A total of 83 teeth were lost in 30 patients, but the investigators excluded one patient who had lost 25 teeth. Including this patient would have increased the tooth loss in untreated patients to an even higher rate. When Tables 77-3 and 77-4 are compared, it is obvious that tooth mortality is much greater in untreated groups.

In summary, the prevalence of periodontal disease and the high tooth mortality rate resulting from the disease have raised the need for effective

(rapid progression)	

treatment. There is now strong evidence that periodontal disease can contribute to numerous health problems including pregnancy complications, heart disease, stroke, and diabetes.[21,22,30,31] Available treatment is effective in preventing the disease and stopping the progression of bone destruction after periodontitis is present. In addition, overwhelming evidence suggests that periodontal therapy greatly reduces tooth mortality. Every dental practitioner should be familiar with the philosophy and techniques of periodontal therapy. Failure to diagnose and treat periodontal disease or to make periodontal treatment available to patients causes unnecessary dental problems and tooth loss and places the patient at risk for systemic health problems.

RETRIEVAL OF SCIENTIFIC DATA ON THE WORLD WIDE WEB
CONCLUSIONS

Humans have an unquenchable thirst for knowledge. Since civilization began, communities have developed information networks using the best available technology. For millennia, this meant the conveyance of written, spoken, and graphic information directly by individuals specialized in the most effective transmission methods. Thus in 490 BCE the war news of Athenian victory at the battle of Marathon was carried by trained athletes to the Greek leaders. From this grew courier-based operations that used specialized methods to move packets of information across the planet. In the 19th century, horseback-based networks were connected to ship and railway-based systems in a complex mail network, which dramatically increased the number of people who could share communications.

The transmission problems were improved in each historical era, thus upgrading access, but there was also the problem of storage of information. Before the invention of printing with movable type in the 15th century, knowledge was written by individuals one copy at a time and kept solely in centralized information banks such as libraries, which were under strict controls by rulers, religious leaders, or other authoritarian groups. This resulted in two dramatic restrictions. First, only the privileged few whom were acceptable to the controlling elite, could read, and had geographic proximity could benefit. Secondly, the ruling elite controlled the nature of information and only allowed credence for that which was in support of their dogmas. This crippled scientific progress, and for centuries, false information survived. A good example of this is the perpetuation of false anatomic concepts. For centuries it was accepted that the human mandible was made up of two bones with a suture in the middle. This obvious mistake survived until Vesalius in the 16th century published his results of human dissection. He was ostracized by the ruling authorities of his time for using information gathered by observations from cadavers, even though his findings were true.

Networks became the keys to universal access when human-based methods were replaced by wire and cable connections. The use of telegraph to send Morse-encoded, binary-based information was an early example of a digital system of communications. However, analog systems using telephones, radio, and television gave immediate worldwide coverage that provided generalized sharing of knowledge but still with an overriding authority that could control content. The use of digital data together with decentralization and uncontrollable access to

The web addresses of host sites are often changed, and thus the sites listed in this chapter may not be current in the future.

multitudes of information sources make the Internet a truly revolutionary step in human development.

DEVELOPMENT OF THE INTERNET

At the end of the 20" century, this new era in communications has made management of information the primary focus of scientific, commercial, and personal interactions of society. The Internet and the World Wide Web have revolutionized information technology by providing universal global accessibility to scientific knowledge. No longer is it possible or necessary to restrict knowledge to an elite *cognoscenti* of intellectuals. No longer is geographic isolation or social restriction an insurmountable barrier to access to humanity's accumulated information base. Anyone with a simple digital processor and a connection to a telephone line or a network is immediately part of the World Wide Web. The full human resource is now able to participate and contribute to humanity's information base.

The prominence of information technology (IT) has come about by a combination of technologic progress and development of a conceptual model for unrestricted interaction between Internet users. An egalitarian ethos also drives this and has given access to the new methodologies to all wishing to use them. The electronic innovations are no more important than the conceptualized planning, which assured universal applicability to the networks that make up the information superhighway. It is a remarkable quality of the Internet that it has developed an administration that is decentralized, voluntary, and not under the direct control of agencies nor governments. This has resulted in enormous uncontrolled growth and complexity, which usually are not seen in human institutions. Networks that started as elite prerogatives of computer specialists working for the U.S. military gave rise to wider-ranging clusters of computers used by university-based scientists, which then grew to involve educators and commercial and industrial corporations, and then spread to all who desired connectivity with the advent of the personal computer.

The interconnectivity of computers was made possible by several innovative breakthroughs, but probably the most important was the use of packet switching as a means of conveying data. This utilization of digital data overcame the inadequacy of the circuit-switched telephone system. Packet switching involved the breaking down of data into datagrams, packages of information that contained the origin and forwarding electronic addresses of each packet. This meant that even if the first attempt at computer to computer linkage failed, the message could be resent by the original source. The first two computers to exchange host-to-host communications were those at the University of California, Los Angeles (UCLA) Network Measuring Center and the Augmentation of the Human Intellect project at Stanford University. This occurred in September 1968. Two more computers were connected later in 1968; one at the University of California, Santa Barbara involved in mathematics, and one at the University of Utah concerned with three-dimensional modeling. These formed the basis for a network called *ARPANET,* which was sponsored by the Advanced Research Projects Agency. The original ARPANET was designed to serve the needs of the military by providing a network of communications between computers that was decentralized and could maintain command and control of missiles and bombs after a nuclear attack, even if significant components of the system were destroyed or inoperable. The U.S. Department of Defense funded many military- and university-based research projects to develop this strategic connectivity, and its access was limited to those research contractors and employees. The next major achievement was the introduction of the first e-mail program in 1972. By this time, 23 host computers were included in the network. The ARPANET computers were all connected by special landlines capable of handling 50 kilobits of information per second. This was superseded in 1988 when the ARPANET was disbanded and T3 lines capable of 45 megabits per second were used for connectivity. By this time there were several networks and the number of host computers had grown to 56,000.

During the 1980s, the National Science Foundation started its own network named CSNET, which connected a selected group of computer scientists. At the same time, other U.S. government agencies such as NASA and the Department of Defense began their own computer-connected networks.

Eventually, the concept of an Internet composed of many independent and different networks allowed the initial ARPANET to be connected to a multitude of other networks, including those based on coaxial cable (ethernet) or radio and satellite links. These computer-to-computer systems were initially based on large complex research computers, and only later did simplifications of the electronic protocols allow the use of desktop computers such as the personal computer. Thus by 1985 an increasing number of people were using the Internet for electronic communication. By this time, this technology had spread from being the specialized domain of computer research scientists into involvement of a wide group of scientists, educators, and government agencies such as the National Science Foundation. Federal agencies shouldered the costs of research, development, and infrastructure development.

DEVELOPMENT OF THE WORLD WIDE WEB

Although the origins of the Internet began in the U.S., the wide-ranging facilitation was made possible by the development of the World Wide Web. This concept came to fruition in 1989, when Tim Berners-Lee developed a system to use hypertext to provide online access to specific pieces of information stored in large computers. This development of browser technology was founded by the Conseil European Pour La Recherche Nucleaire (CERN) in Switzerland, and they made the software available to the public.

Whereas the Internet is the system of host computers, routers, telephone lines, satellite, wireless, and cable connections accessed from a home computer, the *World Wide Web* refers to the abstract universe of information accessible on the Internet and is composed of data in documents, photographs, graphics, sounds, and videos.

TABLE 1

Development of the Internet

Year	Number of Host Computers
1968	4
1972	23
1983	213
1985	1961
1990	313,000
1995	6,642,000
2000	97, 758,400

TABLE 2

Number of Internet Users in December 2000: Top 10 Countries

Country	Number of Users (Millions)
United States	135.7
Japan	26.4
Germany	19.1
United Kingdom	17.9
China	15.8
Canada	15.2
South Korea	14.8
Italy	11.6
Brazil	10.6
France	9.0

CONNECTIVITY ON THE INTERNET

By the end of 2000, more than 99 million host computer sites were on the Internet. This number grew from the original 4 in 1968 to 213 in 1983 to 313,000 in 1990 (Appendix Table 1). These host sites generally have a server computer that can handle multitudes of requests at the same time. These requests for data are managed by processing similar requests just a few nanoseconds apart so that the end users get continuous seamless access. There are now 275.5 million users of the Internet. The U.S. and Canada make up almost half the users worldwide, with more than 50% of American homes having access to the Internet (Appendix Table 2). It is possible to view the growth of hosts and users of the Internet in real time at the site http://www.netsizer.com.

Connection to the Internet is made via an internet service provider (ISP), which has high-speed access to all the networks. These ISPs may be related to a university or combined with telephone companies or exist as stand-alone commercial entities.

The type of connection determines the speed of transmission of data to the individual user computer. A standard telephone wire and modem can give 56 kilobits per second. New technology using telephone lines to transmit digitalized data (digital subscriber line, or *DSL)* increases the speed of transmission over a range of 250 kilobits per second to as high as 7 megabits per second. DSL also allows simultaneous use of the wire for normal analog telephone conversations.

Coaxial cable connections currently used for cable television transmission have the capacity to carry up to 2 megabits per second; this is about 35 times faster than a 56k modem. Networks of fiber optic cables are currently being deployed in some cities to link homes as well as trunk lines connecting cities, countries, and continents. These give significant improvement over the widely used, telephone-wired 56k modem, with possible speeds of up to 5 gigabits.

The air transmission of digitalized data using either satellite or cellular phone networks allows downloads transmission speeds of 400 kilobits per second to 1 megabit per second.

These new, high-speed technologies are replacing the widely used telephone modem connections. The increased band width of data transmission results in more acceptable download times to the users' computers, thus increasing the utilization of complex data sets inherent in movies and complex graphics. This will result in wider use of different media by most host computer sites.

PERIODONTAL AND DENTAL APPLICATIONS

Computers are widely used in dentistry to manage clinical practices, and most dental offices in the U.S. now use computer-based programs for billing, account management, insurance claims, patient recall scheduling, and in some cases for patient appointments. General office accounting activities such as payroll, taxation, and retirement accounts may also be part of the computer-based practice management systems. However, the use of office computers by dentists for Internet activities is much less, and dentists are more likely to have an Internet connection at home than in the office. At present, the percentage of dentists with home-based connectivity is most likely higher than the national average of more than 50% of American homes.

As mentioned previously, the vast majority of domestic Internet connections are via telephone cables and use a standard modem. Consequently, most of the online material in periodontics is textual with photographs or simple graphics. Future advances in bandwidth using the whole spectrum of methodologies such as coaxial cable, fiber optics, and digital satellite systems will result in more sophisticated use of media in periodontal applications.

More than 86,000 dental host sites are available on the World Wide Web. These cover a wide range of topics and sponsors, but the most common sites are those developed by individual practitioners. These private practice sites are directed toward marketing each practice to prospective patients. As such they represent the individual dentist's or periodontist's view of his or her practice. Most commonly they contain biographic data of the practitioners, a description of the services offered, and

directives on how to find the office. Patient education material may also be included on the site as well as opportunities to use electronic mail to communicate with the dentist and staff. The production of these sites is either done by the periodontist using increasingly manageable software or produced by professional companies specializing in designing web pages for small businesses.

ONLINE DENTAL EDUCATION

Dental education has used the Internet for continuing education courses originating in universities, professional organizations, and private companies. Periodontics has always been prominent in these endeavors, and in 1999 periodontal online courses were the largest subject group in dentistry. Some of the earliest educational sites in periodontics were the site established at the University of Lund by Dr. Rolf Attstrom and associates (this site is now called *Periodontology from Sweden and Denmark* and comes from the Center for Oral Health Sciences at Malmo University and the School of Dentistry at Copenhagen at http://www.odont.ku.dklbasic periodontology/main.html) and the UCLA Periodontics Information Center supported by the Tarrson Endowed Chair in Periodontics at www.dent.ucla.edu/pic.

Commercial companies were also involved in the beginning offerings of online courses, with periodontal programs for dentists, dental hygienists, and periodontists. Colgate offers access to its publication Oral Care *Report* and continuing education credit can be obtained by answering questions. This is offered in conjunction with the Harvard School of Dental Medicine. The home pages can be found at http://www.colgate.com/Pro/index.html. Continuing education courses are available on such commercial sites as Procter & Gamble, which offers courses for dentists, dental hygienists, dental assistants, and office managers at http://www.dentaicare.com.

Most of these online continuing educational courses are available free for preview, but it is usually necessary to pay a fee if the health professional wishes to receive documentation of course completion. To verify an individual's mastery of the subject material, many courses have a postcourse examination that is taken online. Completion of this test allows participants to receive credit for satisfactory completion of the course. This may be used to satisfy continuing educational requirements for maintenance of state dental licenses in the U.S. or to be recognized by professional organizations such as the British Royal College of Surgeons.

Payment of tuition for these Internet courses is handled online using the students' credit cards. Security of these transactions is protected by commercial services, which process the credit card data with state-of-the-art security encryption that is almost impossible to intercept and translate. The initial consumer reticence to offer credit card data to online businesses essentially has been overcome by general acceptance that online financial transactions are more secure than direct, store-based, credit card purchases.

Since the inception of the UCLA Periodontics Information Center in 1996, many dentists have used this site for continuing education. Between 100 and 250 users come to this site each day (Appendix Box 1). There they get involved in a wide variety of courses ranging from periodontal examination procedures to management of patients with hypertension. This site has worldwide use, with 60% of the viewers coming from outside the U.S. People from many large and small countries are frequent users, including from those countries with relatively high access to the Internet such as Canada, Germany, Japan, Brazil, Australia, and the United Kingdom, and participants from other countries where Internet services are not widely used, such as India, Vietnam, Russia, Egypt, and Peru. It is a remarkable example of global access that so many widely placed practitioners can experience periodontal education from just one source. In any given month, the domains of more than 60 countries use this Internet periodontal site.

BOX 1

Typical Daily Log for Use of UCLA Periodontics Information Website

Number of individual users: 221
Average number of pages viewed per user: 4.4
Data transferred in kilobytes: 28,978

University-based dental education is now beginning to use Internet-based courses to supplement the conventional teaching programs of the dental curriculum. Many universities including UCLA now require entering students to purchase a laptop computer and have access to the Internet. This gives students the ability to review course material outside of the classroom and individualize their educational experience. Computer-based laboratory and clinical teaching, with students using their laptop computers connected to Internet outlets in the laboratory or clinical cubicle, expands the educational opportunities by allowing each student to select specific topics and spend as much time as they wish to master the content. At UCLA, significant university funds have been spent to give all schools and departments Internet access via high-speed landlines and to wire clinics and the preclinical laboratories for personalized access.

In the immediate future, dental schools and others will be more universally involved in teledentistry, with site-to-site connections by either satellite or coaxial and fiber optic cables. This permits conferencing across continents with both voice and visual connectivity so that lectures, laboratory clinical demonstrations, and patient-centered learning can be shared. Dental schools are already using these links. Recently, a teleconference between the faculties of the UCLA School of Dentistry, the University of California, San Francisco School of Dentistry, and a government agency in Washington, D.C. was able to facilitate the development of a joint research grant proposal.

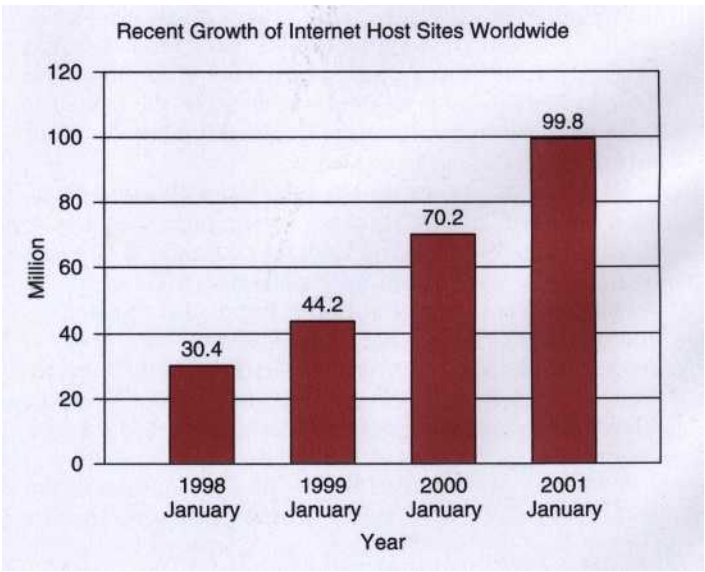
In 2000, at least 68 dental schools had home pages. These dental schools' web sites provide information on curricula, faculty, and enrollment requirements to

prospective students. At UCLA it is possible to apply for postdoctoral educational programs in periodontics via the Internet. At present, more than one third of completed applications arrive electronically. This results in quicker receipt of enrollment data and allows for the immediate request of any additional material.

PROFESSIONAL ORGANIZATIONS ON THE INTERNET

Periodontal professional organizations throughout the world have a presence on the World Wide Web. The American Academy of Periodontology has developed a broad spectrum of information available at http://www.12erio.org. Visitors to this site can access information on periodontal disease and treatment in segments designed for patient education. Pages also are devoted to members, with courses, practice administration information, a buyer's guide with direct links to dental companies and manufacturers, classified advertisements and bulletin boards, educational and career opportunities, and links to the journal of Periodontology and the American Board of Periodontology.

The European Federation of Periodontology, at www.efp.net/organizations.htmll gives information on meetings, with online registration for Europerio available. This site also gives educational guidelines and curricula for periodontal programs for training specialists, dentists, and hygienists. Current news is also listed with a link to the *journal of Clinical Periodontology*. Periodontal societies of various European countries also list their addresses and officers on this site.



Several European countries have their periodontal societies with web sites, e.g., the British Society of Periodontology at www.derweb.ac.uk/bsp/, the Irish Society of Periodontology at http://homepages.iob.re/-perio/index.htmi the Belgium Society of Periodontology at http://users.swing.beNDB/sbp-bvp1, the Swiss Society of Periodontology at http://users.swing.be/FDB/sbp-bvp, and the Nederlandse Vereniginy voor Paradontologie at http://www.nvvp.org. These all give lists of members and officers, patient-oriented information, and schedules of meetings and current news in periodontics. Similar sites have been established in other geographic regions such as the Sociedad de Periodoncia de Chile at http://www.free cl/spoch/spch.regalem.htm#h.

RETRIEVAL OF SCIENTIFIC DATA ON THE WORLD WIDE WEB

Access to scientific journal articles is also an important part of online services in the field of periodontics. Some individual journals offer Internet access to complete articles to subscribers. In some cases, this is included in the regular subscription. In other cases, an additional payment is required and a separate online subscription is yet another method of utilization. Some examples are the *journal of Periodontology* accessed through the American Academy of Periodontology site at http://www.perio.org or directly at http://www.perio.org/journal.html. The *journal of Clinical Periodontology* can be accessed via the European Federation of Periodontology or directly at http://www.efp.net/jcp.htm1. Information on the *journal of Periodontal Research is* reached at http://www.munksgaard.dk/. The *International Journal of Oral and Maxillofacial Implants* has a site at http://www.quint.pub.com.

The U.S. National Library of Medicine has a free service to medical and dental literature via Medline. This gives users the ability to search by author, topic, and journal and to download abstracts of selected articles (www.ncbi.nim.nih.gov/PubMed). Essentially all of the important periodontal, dental, and medical journals are viewable at the National Library of Medicine site. More than 11 million citations are stored in their servers' database, which also gives online access to participating online journals. Another web site at the National Library of Medicine is called Grateful Med (http://igm.nlm.nih.gov), which includes Medline as well as many other databases. Some examples are Chem ID, with a file of 344,000 chemical compounds of interest to health scientists; DIRLINE, with 16,000 records of health and biomedical information on courses associated with health care organizations; CATLINE, a database of 786,000 monographs and manuscripts going back to the 15th century; BIOETHICSLINE, with 53,000 entries concerned with ethics; and two sites devoted to information on AIDS, AIDSLINE and AIDSTRIALS. POPLINE has data on family planning, SPACELINE has data from NASA, and TOXLINE has toxicologic data. This Grateful Med site is the most comprehensive portal to health-related scientific data.

The pace of growth of information technology ensures that networks will spread wider and wider in the coming years. At present, 160,000 new connections to the Internet are made everyday, and the number of host sites continues to show dramatic growth (Appendix Fig. 1). This has important implications for periodontics. New proven procedures will be used by more clinicians in much shorter time periods than previously. The race to solve the problems of treatment prevention and control of human periodontal disease now has a much more optimistic time for the finish line.

CONCLUSIONS

It is obvious that these scientific search sites offer everyone an enormous opportunity to retrieve the whole range of information relevant to periodontics. The Internet and World Wide Web provide the means for a complete understanding of current knowledge in our field.

In the immediate future, more nonspecialist dentists will become skilled in periodontal therapy, and these skills will be improved by continuing educational programs using the World Wide Web and national and international teleconferencing and teleclinics. Patient data will be digitalized and shared by network connectivity. Patients who desire to understand their own periodontal conditions will become sophisticated consumers, searching for the most accessible and acceptable clinical expertise. Universities and professional and commercial organizations will become more dependent on distance learning and less oriented toward traditional, geographic-based education. Periodontics and all scientific-based specialties will grow at a rate not previously seen nor anticipated. The hope for a cure for periodontal disease and other human maladies is much closer to fruition because of the acceleration of scientific knowledge bought about by dedicated intellectualism and a commitment to information technology.
